## DEDICATION

---

To my husband, Joshua, and my parents, Sara and Jose, for their endless love and support; my mentors James and Milap for igniting and molding my passion for pediatrics and teaching; and finally to my sons, Joshua and Jude, ... for reminding me every day what really matters in life.

*S. Benavides*

I dedicate this work to my students and fellows, patients and caregivers, colleagues and collaborators, mentors and friends, and family in the United States and India for their inspiration, affection, and support.

*M. Nabata*

## PREFACE

---

The pediatric population is distinct from the adult population. The uniqueness of neonates, infants, children, and adolescents is beyond the physical and developmental distinctions. Consequently, drugs behave differently in this population. Medications may not be absorbed, distributed, metabolized, or eliminated in the same manner as in adults, and the pharmacokinetics may vary across the age continuum from birth to adolescence. Furthermore, medications may have altered pharmacodynamics in children compared with adults, causing increased or decreased efficacy or safety—about which much is still unknown.

As pediatric clinicians, we are faced each day with challenges in selecting the appropriate pharmacotherapy for children and adolescents. Yet until now, there has been no resource to guide the aspiring pediatric pharmacist in selecting the best pharmacotherapeutic approach. In this book, we focused on common pediatric illnesses and conditions and sought content experts to create chapters geared toward a pharmacy student, a PGY1 resident, an early practitioner, or an adult practitioner occasionally caring for a pediatric patient. The contributors to this book strove to offer essential knowledge of each topic, together with a detailed description of pharmacotherapeutic options. As educators, we

understand the need to provide a concise, easy-to-understand, yet thorough resource that allows the reader to glean the most salient points. This book was written, reviewed, and edited by leading clinicians and educators. It presents an overview of disease pathophysiology, clinical features, clear goals for therapy, and insightful treatment considerations based on primary literature, clinical guidelines, and extensive clinical experience.

Our vision in creating this book was to assist the student, resident, and relatively new practitioner in learning about the unique intricacies of the pediatric patient and pediatric pharmacotherapies. For students using this textbook in a pediatric elective or advanced pharmacy practice experience, we hope it will spark their interest in pursuing practice in this dynamic and rewarding specialty. For the PGY1 resident gaining experience in a pediatric rotation, we hope it will be used as an initial point of reference to understand an approach to treating patients. Those early in their careers, or only occasionally caring for pediatric patients in any setting, will perhaps be inspired to learn more about the use of medications in children. Our overarching intent was to empower the book's readers to positively affect the care of the pediatric population.

## ACKNOWLEDGMENTS

---

The editors would like to thank the dedicated editorial board members for sharing our vision for this book and contributing in many ways, including selection of content, author and reviewer identification, and writing, reviewing, and editing chapters. Each of the editorial board members brought a unique talent and complementary expertise to this project, which resulted in this comprehensive resource for students and young practitioners.

We would like to acknowledge the time and work invested by the authors, particularly for their diligence to the revisions that came from the reviewers, editorial board members, editors, and the medical editor. We appreciate the time given by each of the experts who reviewed chapters to ensure that the most current and relevant issues were clearly presented by the authors. We know the time devoted to complete these tasks was usually taken away from other activities, responsibilities, and family, and we are grateful for the sacrifices.

The realization of this book would not have been possible without the guidance and organization of the project manager, Janel Mosley. She single-handedly managed the communication between the editorial board members, authors, and reviewers. Janel's devotion to the success of the project and her unwaveringly positive outlook were priceless. Thank you, Janel.

Thank you also to Kimma Sheldon, the medical editor, for the attention to detail in the copyediting process and also to Jen DeYoe, the desktop publisher, for designing the cover and layout of the book. Janel, Kimma, and Jen committed countless hours behind the scenes editing and reviewing each individual chapter, which the editors appreciate.

Numerous students assisted the editors in reviewing and providing feedback on the chapters. Although we could not have captured the names of all the students who contributed to the book, their insight and feedback were valued.

The mission of the American College of Clinical Pharmacy (ACCP) is "to improve human health by extending the frontiers of clinical pharmacy." The College has been instrumental in promoting clinical pharmacy through research, practice, and education. Throughout the creation of this book, we stayed true to the vision of ACCP in creating a text to teach pharmacy students, residents, and new practitioners about the uniqueness of pharmacotherapy in pediatric patients. We are grateful to ACCP for their enthusiastic support of this project.

Finally, thanks to all the practitioners who care for children on a daily basis and to those who contribute to the literature through original research, review articles, and case reports. Without these clinical experiences and publications, our vision would have never been accomplished.

# CHAPTER 1

## INTRODUCTION TO PEDIATRICS

*Hanna Phan, Pharm.D., BCPS; and  
Milap C. Nahata, Pharm.D., FCCP*

### LEARNING OBJECTIVES

1. Define the different age groups and corresponding developmental milestones in pediatric patients.
2. Describe differences in vital signs and laboratory normal values based on age.
3. Describe fundamental differences between pediatric and adult patients regarding drug therapy, including availability of treatment options, clinical data, and administration challenges.
4. Define off-label medication use and its implications in pediatric drug therapy.
5. Apply general pharmacotherapeutic concepts and pediatric-specific factors toward providing care and education to patients and families.

### LIST OF ABBREVIATIONS

AAP	American Academy of Pediatrics
BMI	Body mass index
CDC	Centers for Disease Control and Prevention
GFR	Glomerular filtration rate
PD	Pharmacodynamics
PK	Pharmacokinetics
WHO	World Health Organization

### THE ROLE OF A PEDIATRIC PHARMACIST

Pediatric patients are not simply “smaller adults”; they make up their own population with a need for specialized patient care (Reference 1). Pediatric pharmacy practice focuses on the provision of safe and effective drug therapy in infants, children, and adolescents. As such, the American Society of Health-System Pharmacists (ASHP) recognizes the specialized nature of pediatric pharmacy practice through its statement regarding pediatric pharmaceutical services and its accreditation of specialized postgraduate training programs in pediatric pharmacy practice (References 2–4). The Pediatric Pharmacy Advocacy Group (PPAG) composed a response in support of the ASHP statement. Also noteworthy are the PPAG position statements regarding pediatric pharmacy practice, including the role of pediatric pharmacists in personalized medicine and clinical

pharmacogenomics (References 3, 5, 6). The American College of Clinical Pharmacy (ACCP) also supports pediatric pharmacy practice through the Pediatric Practice Research Network and contributions such as the opinion paper about pediatric pharmacy education and training (Reference 7). Drug selection and use, monitoring of effectiveness and toxicity, prevention of medication errors, patient/caregiver education, and contributions to knowledge through research are among the responsibilities of pharmacists when caring for pediatric patients (Reference 8). Likewise, other professional organizations support the role of pharmacists in pediatric patient care. The American Academy of Pediatrics (AAP) acknowledges the importance of interdisciplinary teams in pediatric patient care. In fact, the AAP recommends that prescribers use pharmacist consultation, when available, including the integration of clinical pharmacists in patient care rounds and activities that involve reviewing medication use procedures and orders (Reference 9).

Pharmacists who care for pediatric patients should possess knowledge regarding disease states and drug therapy as well as the skills to apply this knowledge to practice. Pediatric practice includes a wide range of patient ages, with conditions varying from lower respiratory tract infection to trauma. Chronic disease states include lifelong or long-term diseases, such as type 1 diabetes mellitus, asthma, or congenital heart disease. This introductory chapter provides a broad discussion of pediatric drug therapy considerations, whereas subsequent chapters further discuss specific pediatric illnesses and their treatment strategies.

### CLASSIFICATION OF PEDIATRIC PATIENTS

Pediatric patients are a specialized patient population. Their ages are expressed in days, weeks, months, or years. General classification is often age-dependent. Neonates are the patients from birth to younger than 28 days (4 weeks) of life when born full term, whereas infants are those 28 days to younger than 12 months. Children are often defined as 1–12 years of age. Adolescents can vary in definition, but they are most often recognized as age 13–17 years. Some government agencies combine adolescents with young adults who are up to 24 years of age (References 1, 10–12). Additional classifications are based on other factors such as birth weight and gestational age. For example, “low birth weight” is defined as having a birth weight between 1500 and less than 2500 g, and

“premature” is defined as being born before 37 weeks of gestational age (see Introduction to Neonatology chapter) (Reference 10). An appreciation of the classification of pediatric patients is important in guiding medication selection because some medications are contraindicated for patients of certain ages. Medication dosing can also be affected by such classifications because dosing may depend on organ function (e.g., kidney or liver) development, which progresses with age. For example, neonates and infants lack the ability to metabolize alcohol by alcohol dehydrogenase, whereas adults have this ability. Thus, the use of elixir formulations should be avoided whenever possible in infants (Reference 13).

## UNIQUENESS OF PEDIATRIC PHARMACOTHERAPY

Pediatric patients are unique because of their differences in regards to pharmacokinetics and pharmacodynamics (PK/PD), psychosocial influences on drug therapy selection, and treatment options from their adult counterparts. Developmental changes in PK/PD affect drug therapy selection and dosage requirements in the pediatric age continuum, from birth to 18 years (see Pediatric Pharmacokinetics chapter). Pediatric clinicians must also consider factors that affect caregiver medication administration hesitance. These include cultural beliefs, socioeconomic status, and psychosocial differences among age groups (e.g., child vs. adolescent). Pediatric patients also require special consideration when using specific drug formulations. For example, because children younger than 6 years are generally unable to swallow solid dosage forms, oral liquids are preferred for this younger age group.

Off-label use occurs often because of the limited availability of U.S. Food and Drug Administration (FDA)-approved indications for this patient population. From 67% to 96% of outpatient prescriptions and about 79% of inpatient admissions involve off-label medication use in the United States (References 14, 15). With limited evidence-based data (e.g., randomized controlled trials) available for many needed medications, selection and dosing of pediatric drugs is a considerable obstacle for health care professionals. Pharmacists who specialize in pediatrics are an important and integral part of the patient care team, both in the outpatient and inpatient care settings, because they are equipped with skills to evaluate drug information and possess specialized knowledge about developmental PK/PD (Reference 7).

## EPIDEMIOLOGY OF THE PEDIATRIC POPULATION

The pediatric population accounts for almost one-third of the U.S. population, as well as those of other nations such as Canada (References 16, 17). Although chronic illnesses primarily occur in adult patients, patients

younger than 17 years also face many chronic conditions, with more than 10 million suffering from asthma and 5 million from attention deficit-hyperactivity disorder in the United States (Reference 18). Although long-term or chronic medication use is often associated with adults, especially the elderly, more than 14% of children (9.5 million) in the United States take a prescription medication chronically for at least 3 months during a year (Reference 18).

Infants, children, and adolescents compose a considerable proportion of the patients in a variety of health care settings, including community pharmacies, clinics, emergency departments, and hospitals. With almost 26 million ambulatory care visits in a 10-year period (1997–2007) among 0–24 year olds compared with about 14 million among those 65 years and older, this younger patient population uses a considerable number of outpatient health care resources (Reference 19). Overall, hospitalization rates of pediatric patients younger than 15 years (about 358 per 10,000 population in 2007) are often lower compared with adults 45–64 years of age (about 1100 per 10,000 population in 2007) (Reference 20). However, greater than 20 million emergency department visits occurred among pediatric patients younger than 15 years, compared with 24 million visits among adults who were 45–64 years of age in 2007. These data emphasize a continued need for pediatric-specific care, especially drug therapy (Reference 21).

## GROWTH AND DEVELOPMENT

Infants and children are often monitored for growth and development. Markers of physical growth include weight, length or height, head circumference, weight-for-length, and body mass index (BMI). These markers are age- and sex-dependent; therefore, the use of correct tools for measuring pertinent parameters on the basis of these factors is important for proper nutritional status and the physical growth assessment of pediatric patients. For children younger than 2 years, the World Health Organization (WHO) growth charts are recommended to assess these parameters (Figure 1). Since breastfeeding is the recommended standard for infants by the Centers for Disease Control and Prevention (CDC), the WHO growth charts reflect growth based on this feeding approach. The WHO growth patterns represent infants who were predominantly breastfed for at least 4 months duration and continue to breastfeed at 12 months of age. The CDC growth charts are recommended when assessing children 2 years and older (Figure 2) (Reference 22). Growth charts provide a graphic representation of a child’s growth with respect to the general pediatric population among six countries including the United States. To use these charts, a patient’s parameters (e.g., age and BMI) should be plotted

**Birth to 24 months: Girls**

2 to 20 years: Boys  
Body mass index-for-age percentiles

NAME \_\_\_\_\_  
RECORD # \_\_\_\_\_

Figure 2. Example of CDC growth chart: boys (age 2–20 years), body mass index-for-age percentiles, 2000 (Reference 22).

BMI = body mass index.  
 Reproduced from Centers for Disease Control Growth Charts ([www.cdc.gov/growthcharts](http://www.cdc.gov/growthcharts)) developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion, May 30, 2000 (modified October 16, 2000).

on each axis, finding the cross-coordinate between the two parameters. This point should correlate with a percentile (e.g., 10th percentile) (Reference 22). Nutrition status is often assessed on the basis of growth percentiles (e.g., BMI) (see Parenteral and Enteral Nutrition and Pediatric Obesity chapters). Also noteworthy is the gradual development of organ (e.g., kidney and liver) function and drug distribution space (e.g., total body water) affecting the PK/PD of drugs administered to the patients (see Pediatric Pharmacokinetics chapter).

Motor and cognitive milestones are also important in child development. Motor development milestones involve the ability to perform an activity such as sitting straight or taking first steps. Motor skills can be divided into two classifications. Gross motor skills are often considered large movements; smaller movements often associated with appendages or mouths are considered fine motor skills. Both skill types are monitored closely, especially during the first 2 years of life. Examples of gross motor skills include holding the head steady upright, sitting upright on one's own, beginning to walk, beginning to run, and beginning to jump at 3, 6, 12, 18, and 24 months of life, respectively. Fine motor skills also develop in tandem with grasping toys, transferring objects from hand to hand, grasping with fingers, stacking building blocks, and the ability to hold eating utensils at the same time intervals (References 23–25). These markers of normal physical development from birth to adulthood can affect medication administration. For example, the ability to grasp and hold objects is needed in manipulating and self-administering dosage forms such as metered dose inhalers.

The Piaget stages are often used to describe cognitive development. These stages (sensorimotor, preoperational, concrete operations, and formal operations) span the ages from birth to 18 years and indicate the progression of comprehending language and knowledge (see Communicating with Children, Adolescents, and Their Caregivers chapter) (Reference 26). Cognitive development is of importance in medication administration and education about medications and techniques. Comprehension of language and knowledge can affect one's understanding of medication administration instructions and the importance of treatment. A poor understanding of why and how to take medications can result in both poor medication adherence and poor patient outcomes. Assessments of growth, motor, and cognitive developmental milestones are recommended during each pediatric preventive care visit, also known as “a well-check visit,” to detect developmental delay as early as possible (Reference 25).

### **DIFFERENCES IN PEDIATRIC PATIENT DATA—VITAL SIGNS, LABORATORY VALUES, AND CALCULATIONS**

Assessment of vital signs, as in adult medicine, is imperative in the evaluation of pediatric patients. Changes in vital signs can be indicative of efficacy and safety in drug

therapy. For example, respiratory rate and heart rate can be used as markers of efficacy and adverse reactions from the use of albuterol, respectively. Normal values for heart rate, respiratory rate, blood pressure, and body temperature are different from adult values because of physiologic differences. Pain scores are also an important marker for assessing a pediatric patient and should be considered “vital” in their care. Pain is perceived by patients of all ages, including newborns. Therefore, pain assessment should be part of the routine assessments of pediatric patients. Laboratory values of infants and children also differ from those of their adult counterparts because of physiologic differences, and they should be evaluated appropriately. Different equations are also used to assess pediatric patient data (e.g., creatinine clearance).

### **Vital Signs**

Normal ranges for heart rate and respiratory rate are age-dependent. Blood pressure ranges are not only reliant on age, but also on sex and height percentile (see Pediatric Hypertension chapter). It is important to be familiar with normal ranges and individualized patient data in order to optimize the monitoring of patient outcomes on drug therapy. Reference ranges for heart and respiratory rates can vary by resource and are not necessarily evidence based (Reference 27). The American Heart Association has a set of ranges for heart and respiratory rates as part of the Pediatric Advanced Life Support guidelines. For patients from birth up to 3 months of age, the normal heart rate is between 85 beats/minute and 205 beats/minute, and the heart rate range decreases to 100–190 beats/minute at 2 years of age. The heart rate of children ranges from 80 beats/minute to 140 beats/minute at 2–10 years of age and is closer to that of adults at 60–100 beats/minute among patients older than 10 years. Respiratory rate is similar to heart rate in its downward trend with increasing age, with ranges of 30–60 breaths/minute for infants, 24–40 for children up to 3 years of age, and 22–34 for children around 3–5 years of age. For school-aged children up to about 12 years of age, respiratory rate is between 18–30 breaths/minute and, around adolescence, approaches adult values at 12–16 breaths/minute (Reference 28).

The AAP guidelines provide blood pressure reference ranges for assessment on the basis of age, sex, and height for children 1 year or older. In general, systolic blood pressure at the 50th percentile can range from 80 to 98 mm Hg, 91 to 106 mm Hg, and 99 to 122 mm Hg, and diastolic pressure can range from 34 to 56 mm Hg, 53 to 63 mm Hg, and 59–70 mm Hg at age ranges 1–5, 6–11, and 12–17 years, respectively. For specific ranges based on height percentile, sex, and age, one should refer to the Report on Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents (Reference 29). Overall, heart and respiratory rates decrease with age, and blood pressure increases with age.

Body temperature can be determined rectally, orally, axillary, and tympanically. Rectal temperature measurement is recommended by the AAP for children younger than 4 years. For older children, oral measurement can be used. Axillary measurement can be used for patients as young as 3 months, although it is thought to be less accurate than oral and rectal measurements. Tympanic measurement is considered potentially less accurate because of cerumen accumulation (References 30, 31). Some institutions use temporal artery thermometry, which is most accurate in patients older than 3 months (Reference 32). In general, the difference in body temperature between rectal, oral, and axillary temperatures, from highest to lowest, is about 0.6°C (1°F).

Fever is a normal physiologic response involving the hypothalamic reaction to pyrogens, and its presence should not be cause for immediate drug therapy treatment in otherwise healthy pediatric patients unless it is accompanied by discomfort. In patients at increased risk of severe infection, the threshold for action is considerably lower, and fever should be evaluated further. In general, with a mean normal temperature considered a reading of 37°C (98.6°F), a low-grade fever is considered a body temperature ranging from 37.8°C to 39°C (100°F–102°F). A high fever, temperature greater than 40°C (104°F), may have greater risk of heat-related adverse outcomes. Antipyretics such as acetaminophen may be given for body temperatures greater than 38.3°C (101°F), measured by any route, if the individual presents with discomfort (Reference 33). The definition of fever can vary depending on the route of measurement and patient age. For example, a rectal temperature of 38°C (100.4°F) in a neonate is considered a fever. In infants up to 3 months of age, the threshold for the definition of fever is higher, up to 38.2°C (100.7°F) (Reference 34). The vital signs for premature and term infants or neonates are discussed in the Introduction to Neonatology chapter.

It is also important to assess pain in pediatric patients. Difficulties in pain assessment are most common among patients with a limited ability to have direct communication, such as neonates or infants and young children. Some older pediatric patients (e.g., critically ill individuals) may be unable to verbally express pain symptoms. In such instances, indicators of pain include physiologic markers, like increased respiratory and/or heart rate and oxygen desaturations, as well as changes in behavior (e.g., grimacing or high-pitched crying). Standardized assessment scales such as the Neonatal Infant Pain Scale (NIPS) and the Face, Legs, Activity, Cry Consolability (FLACC) scale use these physiologic or behavioral indicators for neonates or infants and children up to 4 years of age, respectively (References 35, 36). The Wong-Baker FACES scale, with graphic facial expressions, is often used in children older than

4 years (Reference 37). A visual analog scale, or a numeric pain scale, can be used in older children (e.g., 10 years old) who can verbalize and comprehend number values. Additional information regarding the assessment and treatment of pain can be found in the Pain Management chapter.

### Laboratory Values

Normal laboratory values in infants and children can differ from those seen in adults. Physiologic differences account for variation in normal ranges by age and are noted throughout the book in reference to the disease states discussed. With the advances in software technology, laboratories now often report abnormal values with adjacent normal ranges based on the age of pediatric patients. Standard pediatric handbooks or references such as *The Harriet Lane Handbook* or the *Pediatric & Neonatal Dosage Handbook* also serve as resources for normal laboratory values for pediatric patients (References 38, 39).

### Calculations

In addition to differences in normal vital signs and laboratory value ranges, calculations used to assess pediatric patients differ from those used for adult patients. Body surface area, BMI, and ideal body weight calculations are sometimes used in the dosing of certain medications and in assessing nutritional status (Table 1) (References 40–44). Creatinine clearance is used to assess a patient's renal function and is applied in dosing when renal dysfunction is present or the patient is taking a potentially nephrotoxic drug. The Schwartz equation is used to calculate estimated creatinine clearance in pediatric patients, including low-birth-weight infants and patients up to 21 years of age (Reference 44). The Cockcroft-Gault and Jelliffe equations have been studied and validated in normal adult populations but should not be applied when evaluating pediatric patients (References 45, 46). Although there is a common approach to estimating glomerular filtration rate (GFR) in pediatric patients, the Schwartz equation has limitations. For instance, the Schwartz equation can potentially overestimate GFR, especially in moderate to severe renal insufficiency, because serum creatinine is a crude marker of GFR (References 47, 48). Thus, alternative methods based on additional factors such as cystatin C or blood urea nitrogen have been proposed to estimate GFR in children with renal insufficiency such as chronic kidney disease (Reference 49). Most of the equations listed (Table 1) apply to infants, children, and adolescents; however, their application is limited in the neonatal population. Assessment methods for neonates and premature infants can be found in the Introduction to Neonatology chapter.

## CHALLENGES OF MEDICATION ADHERENCE

Medication adherence, defined as the “extent to which patients take (or in the care of younger pediatric patients, are given) medications as prescribed,” is a challenge for all patient populations; pediatric patients are no exception to this continued health care issue (Reference 50). Although chronic illnesses, such as asthma and diabetes mellitus, are often associated with a high potential for poor adherence, short antibiotic treatment courses for conditions such as acute otitis media are also worth investigating (Reference 50). Consequences of nonadherence include delayed or absent clinical improvement, worsening of illness, and unnecessary therapy modifications that can lead to adverse clinical outcomes. Medication adherence is often difficult to document in ambulatory care practice environments. Approaches to measuring medication adherence include self-report, clinician’s impression, dose count (e.g., pills or inhaler counter), refill verification, and monitoring of serum drug concentrations when appropriate (References 51, 52). Devices such as electronic monitors have been used in research settings. However, these are not commonplace in clinic settings and are cost-prohibitive for routine use at this time (Reference 53).

Nonadherence, often considered adhering to a prescribed therapy less than 80% of the time, is multifaceted in nature. Moreover, identifying approaches to improve adherence is challenging. Reasons for poor adherence include forgetting the time to administer doses, experiencing difficulty with caregiver’s and/or patient’s personal beliefs, encountering socioeconomic limitations, experiencing adverse drug effects, and having unpleasant or inconvenient medication formulation or schedules, as well as child psychological factors, such as peer acceptance among adolescents. In general, younger children (e.g., younger than 5 years) have greater medication adherence to the treatment of chronic illnesses such as asthma (Reference 52). This is because of caregiver responsibility and action in administering necessary medication in most cases. However, it should not be assumed that all caregivers adhere to prescribed treatment regimens. Caregiver education is imperative with every medication dispensed for a child.

Poor medication adherence is seen in all age groups, from infancy to adolescence. For infants and younger children, the caregiver is the primary individual responsible for administering medications. A reason for poor adherence in this subpopulation is apprehension regarding medication adverse effects. An example is

**Table 1.** Common Equations Used for Calculations in Pediatric Patients (References 40–44, 64)

Calculation	Equation										
Body surface area (BSA) <sup>a</sup>	$BSA (m^2) = \text{sqrt} [(height \times weight) \div 3600]$										
Body mass index (BMI) <sup>a</sup>	$BMI = weight \div height \div height \times 10,000$

<sup>a</sup>With height in centimeters, weight in kilograms.

nonadherence to inhaled corticosteroid therapy for asthma because of the fear of growth suppression. Other reasons for nonadherence in this younger population can include the caregiver's inability and unavailability to administer the drugs in a timely manner. Some caregivers may become overwhelmed by their many responsibilities, or confusion may occur regarding who among a child's caregivers is responsible for dosing, resulting in missed doses and poor adherence (Reference 54).

Inappropriate measurements of a medication dose can also affect medication adherence. For example, if a caregiver uses a measuring device to administer a liquid medication that results in larger doses (e.g., a large kitchen spoon), adverse drug effects as well as early therapy discontinuation may ensue. Conversely, if caregivers use a device that provides a smaller amount of medication (e.g., a small dining teaspoon), subtherapeutic dosing and poor patient outcomes with respect to efficacy may ensue. Thus, caregivers should be provided with and educated about proper measuring devices such as oral syringes. Some caregivers may also miss doses because of resistance from the child. As a child gets older and enters early adolescence, responsibility for medication administration moves from the caregiver to the child or adolescent. Approaches to improve medication adherence should address the transition from childhood to adolescence, which involves factors such as peer pressure, perceived invisibility, and potential for oppositional or rebellious behavior (Reference 55).

Different approaches have been suggested to improve medication adherence. Behavioral and educational approaches have received the most emphasis in studies regarding chronic diseases such as pediatric asthma and diabetes mellitus (References 56, 57). Caregiver education regarding medications should be reinforced at several points of health care visits because it is important to enhance the caregiver's understanding of the importance and benefit of completing treatment and the risk of adverse effects. Ease of administration, including palatable dosage forms and the need for less frequent dosing, can help caregivers keep to a treatment schedule. Poor palatability of medication, specifically liquid medications, can negatively affect medication adherence. Despite the lack of extensive research data, clinician and parental experiences have shown the importance of palatability as a target to improve adherence (Reference 52, 54). The use of a reward system and positive reinforcement may aid in decreasing resistance by young children during treatment periods. Empowering older children and adolescents positively with knowledge about their disease may improve self-management of drug therapy and medication adherence (Reference 55).

## OFF-LABEL MEDICATION USE IN PEDIATRIC PATIENTS

Off-label medication use is defined as the use of a medication outside its FDA-approved labeled indication(s). Labeled indication includes the age group in which a medication is used, the disease or illness it treats, and the route of administration. Currently, more than 75% of the drugs approved for use in adults lack dosing, efficacy, and safety data pertaining to pediatric patients (Reference 15). Off-label use is legal and well accepted as long as it is based on appropriate clinical judgment. However, limitations to off-label medication use exist, including the potential for denied insurance provider coverage of the medication. Other limitations to off-label medication use are possible medical liability due to serious adverse effects, limited experience for treatment of a condition or specific age group (e.g., neonates), and limited available formulations for use in young populations. Thus, a strong need remains for additional clinical trials to determine the appropriateness of selecting and dosing medications in the pediatric population.

Regulatory changes have been made to decrease the off-label use of drugs in the pediatric population. The Pediatric Rule, issued in 1994, permitted manufacturers to label drugs for pediatric use on the basis of extrapolated efficacy data and additional PK/PD data specific to the pediatric population when disease and therapy response were considered similar to those of their adult counterparts (Reference 58). Unfortunately, this resulted in only a few well-conducted studies regarding infants and children because of the difficulties involved in predicting dose-response from adult data. The FDA Modernization Act (FDAMA) followed in 1997, offering a financial incentive of 6 months' extended market exclusivity for performing pediatric studies (Reference 59). Because of the FDAMA, additional drugs were assigned pediatric labeling. However, efficacy data were still lacking. In 2002, an incentive-based Best Pharmaceuticals for Children Act (BPCA) was implemented, extending the FDAMA and offering a 6-month extension of patent exclusivity to encourage industry to conduct pediatric studies for branded products labeled only for adults (Reference 60). The Pediatric Research Equity Act (PREA) of 2003 also provided potential requirements for the pediatric assessment of drug applications submitted to the FDA for approval in adults. This assessment includes the potential use and evaluation of risk versus benefit in pediatric patients (Reference 58). The FDA pediatric decision tree, a process whereby agents are evaluated for pediatric study regarding PK/PD, efficacy, and safety, is depicted in Figure 3 (Reference 61). For rare diseases with

an occurrence of 200,000 people or less in the United States, such as inborn errors of metabolism, the Orphan Drug Act provides support in the development of needed treatment (Reference 62).

The BPCA has been effective primarily for the blockbuster drugs to receive 6-month patent exclusivity. Thus, the concern remains when extrapolating adult data to treat pediatric patients for many branded products with a limited market and for generic drugs with no incentives. Extrapolation is challenging because this approach is not always accurate when determining safe and effective pediatric dosing. A wide range of evidence in pediatric drug therapy through the identification of well-designed, appropriate biomedical literature is needed to provide optimal, evidence-based care to the pediatric population. The use of available guidelines, such as those commissioned by the National Asthma Education and Prevention Program and National Heart, Lung and Blood Institute for asthma (Reference 63), is recommended, though their individualized application to specific patients is necessary in patient care.

Because of limited pediatric-specific guidelines for much of drug therapy, use of primary literature is crucial in providing evidence-based care to infants, children, and adolescents. Although randomized, placebo-controlled trials are considered the “gold standard” of primary literature, much of the available literature consists of retrospective cohort studies of the pediatric population. Careful evaluation of these data should guide the applicability of the results in clinical practice. Evaluation of literature includes appropriateness of study design, generalizability to the population at hand, and appreciation for statistical and clinical significance of findings. Furthermore, the use of case reports and case series can provide some data regarding unknown effects of newer drug therapy. However, given the small patient populations in these reports, clinicians should assess the appropriateness of applying them to their own patient(s).

A dilemma with newer adult drug therapy options is that there is no exact, recommended approach to dosing such agents in pediatric patients, especially because the agents have no pediatric indication. Although adult dosing often involves a standard dose for most

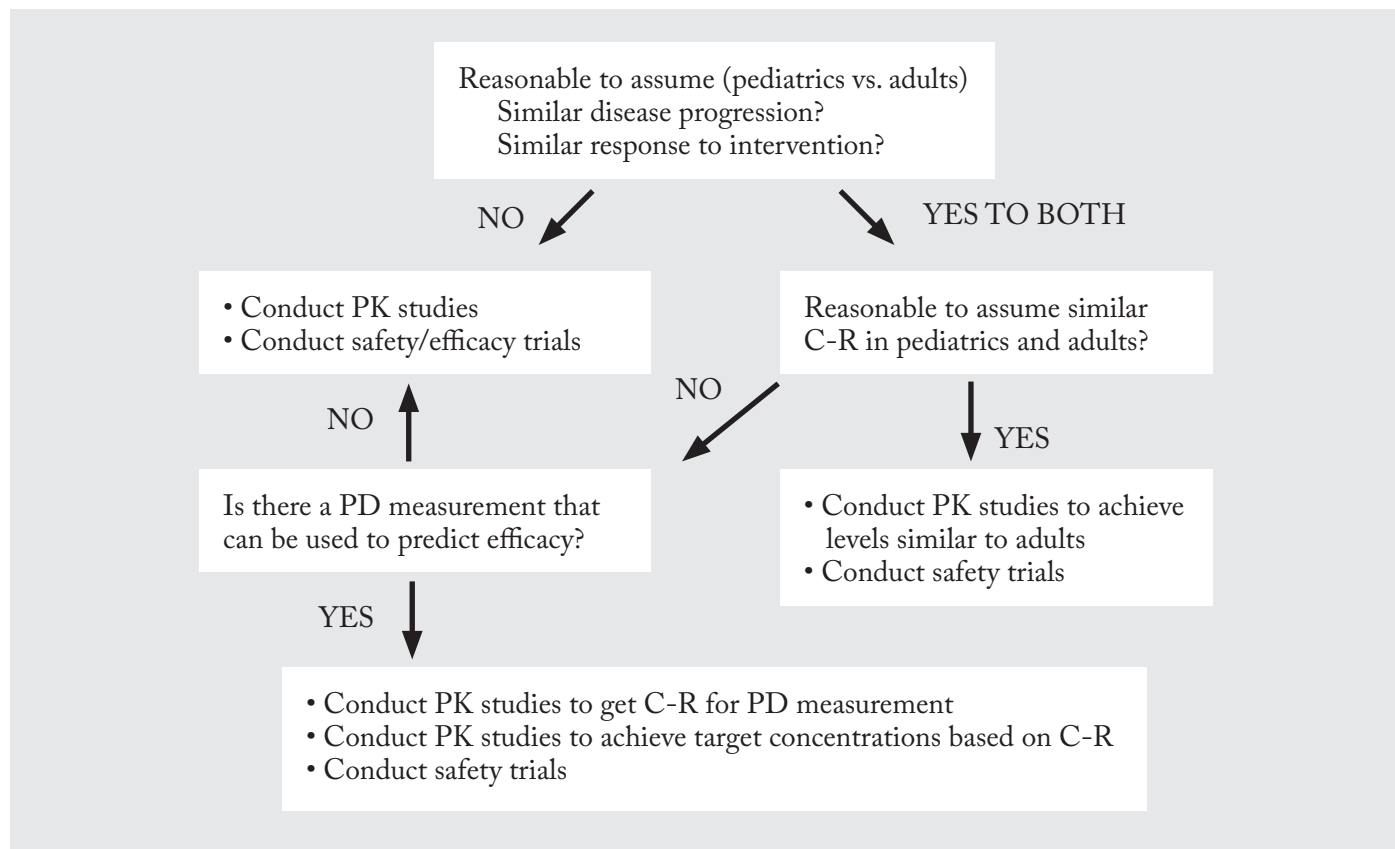

Figure 3. The FDA pediatric decision tree (Reference 61).

C-R = concentration response; PD = pharmacodynamic; PK = pharmacokinetic.

Available at [www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm072109.pdf](http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm072109.pdf). Accessed May 9, 2012.

of the population regardless of age and weight (e.g., omeprazole 20 mg orally daily), pediatric dosing is often weight-dependent (e.g., omeprazole 1 mg/kg orally daily). Pediatric dosages may also be based on age (e.g., neonate vs. child). Rounding of doses is a dilemma not often seen in the care of adults. In pediatric patients, doses of wide-therapeutic index medications (e.g., antibiotics) can be rounded for ease of measurement. Some institutions round doses by 10% to 20%, depending on the risks associated with a given medication.

In the past, approaches to dosing included Fried's Rule, Clark's Rule, or Young's Rule to estimate dosing when pediatric-specific data were not available. However, these equations differentiated a child from an adult by one factor of difference such as age in months or years or weight in pounds. This approach oversimplifies the known complex differences between the pediatric and adult populations. As a result, these approaches can over- or underestimate dosing in pediatric patients. Thus, these methods are no longer recommended for estimating off-label dosing in pediatric patients. If there is no alternative therapy—or if there are limited or no pediatric data for dosing but evidence to support the safety of the drug in pediatric patients—some clinicians may elect to dose on the basis of the body surface area ratio if the child is of normal height and weight for age (Table 1) (Reference 64). However, of note, this method is not a well-studied approach to off-label medication dosing, and caution should be used when considering this option. A potential exists for unaccounted differences in PK/PD between pediatric and adult patients when using this dose-estimating approach, resulting in differences in efficacy and safety. Thus, clinical judgment should be applied when considering off-label medication use and dosing in instances of limited pediatric data.

## MEDICATION SAFETY

Medication errors are preventable events that result from human or system flaws (Reference 9). Pediatric patients are at increased risk of medication errors, with an error rate of 15% of pediatric medication orders compared with 5% of adult medication orders (Reference 9). Prescribing and transcription errors account for many of the medication errors in U.S. neonatal and pediatric intensive care units at 50% of all errors. Because pediatric doses are often calculated (e.g., milligram per kilogram), the risk of calculation error is high. Accuracy and consistency in the units of measurement used are important in preventing calculation and prescribing errors. Decimal errors, such as trailing zeros (e.g., 5.0 mg) and missing leading zeros (e.g., .5 mg), also result in 10-fold or greater errors.

Calculation inaccuracies can lead not only to prescribed dose error, but they can also cause error when medications are compounded into intravenous solutions or oral suspensions. One should also be cautious of potential dispensing errors when the incorrect strength of a medication is selected. Calculation errors can be reduced through computer physician order entry, which can provide automated medication-dosing calculators and mandatory prescription order fields (Reference 65). The use of an alert-based decision support system can potentially prevent several errors; however, it also has the potential to cause “alert fatigue” because of too many unnecessary alerts, which can lead a clinician to bypass warnings for incorrect medication orders. Barcode technology has also helped reduce the incorrect selection and administration of medications (Reference 66). Medication administration error rates have also decreased with the use of technologies such as smart pumps for parenteral medications in daily care (Reference 67). Despite technological advances, however, a potential for human or system error remains during the process of preparing, dispensing, and administering medications. Thus, medication error prevention is a multifaceted task involving the active participation of the health care team as well as the patient and caregiver. Communication between all parties and continued efforts to improve medication use practice are essential in the provision of safe patient care (see Medication Safety chapter).

## FUNDAMENTALS OF PEDIATRIC PATIENT CARE

Application of pediatric-specific knowledge and clinical skills is vital to the successful care of infants, children, and adolescents. Within each subpopulation, it is imperative to recognize differences because of patient-specific factors (e.g., age, disease, culture) and adapt approaches to suit each individual to provide optimal patient care. The following “checklists” are clinical pearls to keep in mind when caring for patients within each age subpopulation in pediatrics.

### Infants and Young Children

- For neonates and premature infants, please refer to the Introduction to Neonatology chapter.
- Educate the caregiver about the purpose, effectiveness, and potential adverse effects of the medication.
- For children younger than 3 years, review birth history and history of illness, including hospitalizations; review medical record for assessment of cognitive and motor skills development.
- Note body weight, height, and head circumference (for infants), and assess growth percentiles (e.g., by using the WHO or CDC growth chart).

- For infants, evaluate weight-based dosing regularly, especially for medications used in chronic illnesses that require dose adjustments with growth (e.g., weight gain).
- Elixir formulations should be avoided because of alcohol content, especially in neonates and young infants, or when chronic use or larger volumes are indicated.
- Be aware of the palatability of medications—if an oral liquid formulation tastes bad, investigate whether an alternative exists in a solid dosage form that is safe to administer as either a crushed tablet or an opened capsule, putting the contents in a palatable vehicle. An example of a poor-tasting oral solution is clindamycin; if a dose fits a capsule size, some clinicians elect opening the capsule in soft food (e.g., applesauce) versus administering the liquid oral formulation.
- Do not crush or modify extended- or sustained-release solid dosage forms.
- Use appropriate measuring devices (e.g., oral syringe) with oral liquid formulations.
- Be aware of potential medication contraindications because of age (e.g., ceftriaxone use in premature neonates due to potential to displace bilirubin from albumin and increase risk for kernicterus).
- Often, children around 6 years of age can swallow a tablet or capsule, but this should not be assumed for all children. Ask the patient and caregiver whether liquid or solid dosage forms are preferred.
- Use correct age, weight (in kilograms), and height.
- Consider social factors such as patient or caregiver health beliefs and culture.
- Correctly use units of measurement such as dose (e.g., milligram vs. gram) and body weight (e.g., kilogram vs. pound).
- Calculate and verify doses by body weight (e.g., actual, ideal, adjusted) as appropriate.
- Evaluate current conditions and determine optimal drug therapy for such conditions.
- Consider comorbidities.
- Evaluate appropriateness of current drug therapy including complementary and alternative medications, supplements, and over-the-counter drugs.
- Assess medication adherence.
- Be careful about inappropriate abbreviations and notations such as trailing zeros (e.g., 1.0 mg) and missing leading zeros (e.g., .1 mg).
- Evaluate for potential adverse drug effects (i.e., ask open-ended questions of patients and/or caregivers).
- Evaluate for drug–drug and drug–food interactions.
- Round doses to measurable amounts. Dose rounding by 10% to the closest measurable dose is common practice. Dose rounding should be avoided in narrow therapeutic index medications (e.g., digoxin).
- Develop a drug therapy monitoring plan with identification and assessment of parameters for efficacy or safety.
- Reconcile medications and dosage regimens at each patient encounter.
- Provide patient and caregiver education. This is not a one-time activity; rather, it should be reinforced at several points of care (e.g., hospital, clinic, pharmacy)—repetition is beneficial!

### Older Children and Adolescents

- Educate patients and caregivers about the purpose, effectiveness, and potential adverse effects of the medication.
- Consider issues that are more mature or adult in nature affecting health including alcohol, tobacco, illicit drug use, sexual activity, and psychosocial concerns.
- Adolescence is often considered a “nadir” of medication adherence; thus, education and age-appropriate approaches to improve adherence should be initiated.
- Be aware of the need for increasing independence, including medication administration.
- Involve the patient as an active participant in overall care.

### Overall Drug Therapy Assessment

The following are examples of general items that should be considered and assessed as part of selecting, using, and monitoring drug therapy for all pediatric patients (References 2, 3, 5, 7):

### Patient and Caregiver Education

Patient and caregiver education is fundamental to the care of pediatric patients. Drug therapy can be daunting to some caregivers, especially to new parents or caregivers of patients with a new disease diagnosis. Clinicians should be considerate of their approach when communicating with patients and caregivers including health literacy, culture or beliefs, socioeconomic status, and family structure/dynamic. Information that patients and caregivers should be privy to includes:

- Reason(s) for medication use
- Dose measurement (with appropriate device)
- Medication storage
- Potential adverse drug effects
- Therapy duration

- If therapy is chronic and requires laboratory monitoring, discuss what these tests are, why they are used for monitoring efficacy or safety, and how frequently they would be done.
- Expected therapy outcomes

Educational points should be specific regarding the type of drug therapy to be included in the regimen. For example, specialized information is needed when discussing aerosolized or nebulized medication and use of a nebulizer device. An important educational point in this case is administration technique in the use of a metered dose inhaler with or without a spacer. Other medication administration techniques that patient and caregivers may not be as familiar with are the proper administration of otic drops, ophthalmic drops or ointments, and nasal sprays. Additional information is provided in the Communicating with Children, Adolescents, and Their Caregivers chapter. Patient and caregiver education should be provided in all patient care settings in both inpatient and outpatient environments. Reinforcement of essential points is critical in optimizing medication adherence and safety. Continuity of care should include clear communication between inpatient and outpatient clinic settings. This bridge of care involving health care providers as well as patients and their families is necessary in providing optimal patient care. Pharmacists can bridge the gaps by encouraging patients and their families to ask questions and by providing information

about current medications. For example, pharmacists can provide a means for patients and their families to maintain medication lists (written or electronic), thereby empowering them to participate in their health care.

### THE PRESENT AND FUTURE OF PEDIATRIC PHARMACY PRACTICE

Pediatric patients are seen in all health care settings, including community pharmacies, clinics, physician offices, community hospitals, and large academic, tertiary institutions. A fundamental understanding of the needs of this special population is essential for the provision of patient care by pharmacists. Although pharmacists in the community setting often lack specialty training in pediatric practice, all pharmacy practitioners should have an appreciation of general concepts in pediatrics, such as approaches to dosing (e.g., milligram per kilogram), unique pharmacokinetics, and drug administration needs, as well as the ability to identify potential drug-related problems (e.g., contraindicated medications for certain age groups).

Pediatric pharmacy practice is a growing specialty area of pharmacy practice, serving future generations of patients with a mission focused on patient advocacy and provision of safe and effective drug therapy through professional responsibility, education, and research. This area of practice will continue to grow with its expansions in the professional pharmacy school curriculum and continued education training in pediatric postgraduate residencies and fellowships. Practice opportunities

in pediatric pharmacy have expanded beyond the pharmacy counter, with an increasing number of pharmacists working as part of interdisciplinary teams in the care of infants, children, and adolescents, from intensive care units to specialist clinics such as cystic fibrosis centers nationwide. Opportunities exist to advance pediatric practice for present and future generations of pharmacists, including expanding the role of pharmacists in areas such as pediatric immunizations, chronic care management, and continuity of care between inpatient and outpatient care. Pharmacists must also initiate and participate in pediatric pharmacotherapy research to advance health care and the profession. Examples of pharmacist-driven innovations include increasing the understanding of approaches to drug therapy management, discovering new therapeutic approaches, and developing behavioral interventions to optimize medication adherence. This partnership of advanced practice and scholarship is what the pharmacy profession must promote to make unique contributions to the body of knowledge in pediatrics and provide quality patient care.

#### ADDITIONAL GENERAL PEDIATRIC RESOURCES

Additional information regarding pediatric patient care, including medication dosing, extemporaneous compounding, and an overview of general pediatric diseases, can be found in various resources from the Internet to print books (Box 1) (References 38, 39, 68–73). With the growth in information technology, many drug-dosing references are also available by smartphone or tablet computers. Clinicians caring for pediatric patients should have access to at least one pediatric-dosing reference and one reference on general pediatric disease pathophysiology and treatment options.

# CHAPTER 2

## PEDIATRIC PHARMACOKINETICS

*Jacob T. Brown, Pharm.D.;*  
*and Susan M. Abdel-Rahman, Pharm.D.*

### ABBREVIATIONS IN THIS CHAPTER

AAG	$\alpha$ -1-acid glycoprotein
AUC	Area under the curve
CYP	Cytochrome P450
DRP	Digoxin reduction product
GFR	Glomerular filtration rate
GST	Glutathione <i>S</i> -transferase
MIC	Minimum inhibitory concentration
P-gp	P-glycoprotein
SULT	Sulfotransferase
UGT	UDP-glucuronosyltransferase
$V_d$	Volume of distribution

### INTRODUCTION

The safe and effective use of medications is guided by an understanding of the relationship between dose, exposure, and response. For special populations, including children, much of this knowledge is nonexistent (Reference 1). Despite regulatory initiatives designed to increase the conduct of clinical trials that would enhance our knowledge of pediatric pharmacokinetics, the number of sponsored drug trials conducted in children remains limited (References 2–5). As a result, the drug label tends to offer few data that can be used to guide pediatric pharmacotherapy (Reference 6).

Fortunately, many of the factors that influence dose-exposure relationships are obvious and predictable from recognized patterns of developmental physiology (Reference 7). By contrast, the ontogeny of some physiologic processes is well characterized, but its impact on drug disposition is not readily apparent because of limited historical data that correlate physiology and disposition (i.e., relatively few drugs are susceptible to the biologic process in question). The physiologic factors that drive the disposition of other drugs are not yet defined, and for these drugs, the impact of development will go unappreciated without the conduct of pediatric pharmacokinetic studies (Reference 7).

The sections that follow discuss pediatric drug disposition in the context of existing knowledge on developmental anatomy and physiology. The impact of disease on the disposition of drugs in children is left to other chapters in this textbook. Where human data

are lacking, data on the ontogeny of drug disposition pathways in animals are introduced. Attention is drawn to the areas of pediatric pharmacokinetics in which the impact of growth and development remains unknown.

### ABSORPTION

Drugs administered by any extravascular route (e.g., oral, sublingual, buccal, intramuscular, percutaneous, rectal) encounter physical, chemical, and mechanical barriers to absorption, irrespective of a patient's age. Of importance, the fundamental mechanisms by which drugs overcome these barriers do not change with age, but the rate and extent to which these processes occur are altered because of normal growth and development.

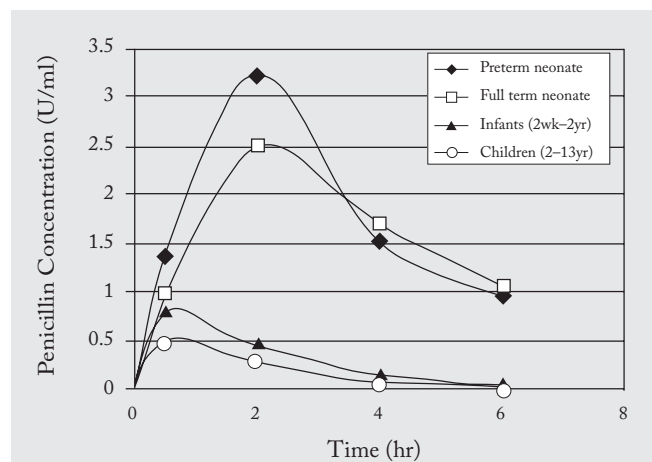

### Peroral Administration

Oral administration is the most common route for drug delivery. Although several chemical and physical factors influence the bioavailability of drugs administered by mouth, one of the most overlooked barriers to oral drug administration resides with the ability to get the drug past the oropharynx. Children will reject medications on the basis of color, taste, texture, and temperature, rendering even the most potent of medicines useless. Taste and smell both play a significant role in the acceptability of oral medications, and clear ontogenic patterns are attributed to gustatory and olfactory development. The ability to perceive sweet tastes appears to be present at birth, with evidence to suggest that the perception of sweet can be detected in utero (e.g., increased fetal swallowing is observed when sweetened solutions are injected into the amniotic sac) (Reference 8). The ability to detect bitter, salty, and sour flavors appears to develop by 2 years of age, whereas the response to trigeminal stimuli (e.g., texture, temperature, piquancy) develops within the first 1–2 years of life. Of note, the affective response to odor does not fully mature until about 5–7 years of age (Reference 8). Consequently, the common formulation strategy of trying to mask an aversive taste with a pleasant odor may not be effective in the young child (Reference 6).

Beyond the oropharynx, several ontogenic processes can influence the bioavailability of orally administered drugs. Children experience a period of relative achlorhydria shortly after birth, despite increased concentrations of circulating gastrin (References 9–11). This failure to

produce adult levels of gastric acid is believed to result from a decrease in receptor responsiveness to gastrin, leading to a higher gastric pH early in life. Discussions of pH are inevitably accompanied by a reference to the Henderson-Hasselbalch equation and the ionized/unionized ratio; however, the stomach is not the primary absorptive site for most orally administered drugs. As such, the consequence of increased pH in the young infant is less applicable to the degree of ionization and more relevant to the chemical stability of the drug being administered. For example, many of the  $\beta$ -lactam and macrolide antibiotics are acid labile, and in adults, a significant fraction of the delivered dose can be broken down before entering the intestine (if an acid-resistant formulation is not employed). By contrast, these same drugs are relatively protected in the stomach of a young infant. As a result, more intact drug will reach the intestine and be available for absorption. Figure 1 illustrates the impact of gastric pH on the absorption profile of penicillin administered at comparable weight-based doses to newborns, infants, and children. As predicted, given our knowledge of developmental gastric physiology, pre- and full-term neonates achieve concentrations 5–6 times higher compared with those observed in infants and children (Reference 12).

For drugs formulated in lipid-based vehicles or lipophilic drugs that require solubilization by bile acids, maturation of biliary function can play a key role in absorption. Postprandial sampling of two major bile salts in the circulation of newborns and young infants reveals that their concentrations exceed those observed in adults. However, the corresponding concentrations within the intestinal lumen are lower through the first 6 months of life. This finding is likely the result of immature bile salt transport into the biliary canaliculus

**Figure 1.** Plasma concentration vs. time profiles for penicillin in neonates, infants, and children after oral administration of a single 10,000-units/lb dose.

(References 13, 14). As a result, the extent of fat absorption is lowest early in the neonatal period (References 15–17). The clinical relevance of this finding can be illustrated by pharmacokinetic studies of the antipicornaviral agent pleconaril, which is formulated in a vehicle of medium-chain triglycerides. Dose escalation in adults shows a proportional increase in total body exposure (Reference 18), whereas a 50% increase in dose delivered to neonates produces no change in either maximum plasma concentration ( $C_{max}$ ) or area under the curve (AUC) (Reference 19). The capacity-limited absorption observed in the pleconaril studies and in similar studies of a lipid-based chloramphenicol formulation (Reference 20) supports the assertion that knowledge of developmental physiology can guide our understanding of age-dependent changes in dose-exposure relationships. Of note, both intrinsic (i.e., physiology) and extrinsic (i.e., formulation) factors were involved in determining the disposition profiles of these anti-infectives such that the magnitude of their combined influence might not have been predicted without carefully constructed and executed pharmacokinetic studies.

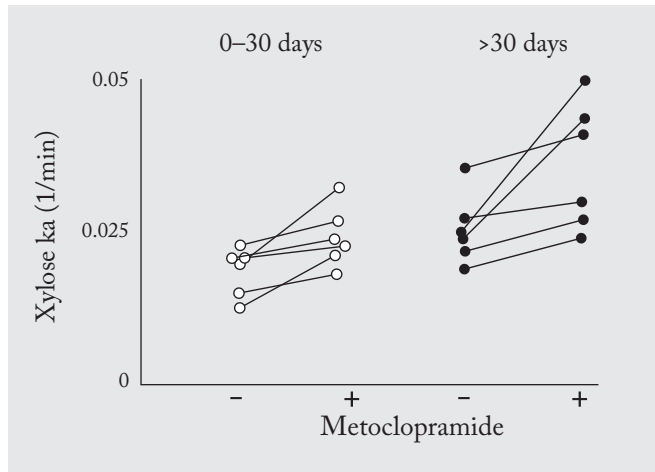

Irrespective of a drug's physiochemical properties, the rate of gastric emptying influences the rate at which the drug is presented to the primary absorptive site (i.e., the small intestine). Gastric-emptying rates increase dramatically during the first week of life (Reference 21); however, several other factors influence this in the newborn period, including prematurity, gastroesophageal reflux disease, respiratory disease, congenital heart disease, and the caloric density of feeds. By extension, intestinal motility also controls the rate at which medications are distributed along the primary absorptive site. The frequency and amplitude of intestinal contractions are reduced in the newborn and young infant, contributing to irregular peristaltic activity shortly after birth (Reference 22). Although highly variable, most children usually attain adult motility patterns by 6–8 months of life (Reference 23). The impact of altered motility on drug absorption will depend, in large part, on the disintegration and dissolution characteristics of the drug molecule and the formulation in which it is administered. The combined effect of both reduced gastric emptying and poorly coordinated intestinal contractility is nicely illustrated by the pharmacokinetic profiles for cisapride. The time to achieve maximal plasma concentrations ( $T_{max}$ ) averages 5.0 hours in children 28–36 weeks postconception, 4.3 hours in children 36–42 weeks postconception, and 2.2 hours in children 42–54 weeks postconception compared with 1.8 hours in adults (Reference 24).

Even when pharmacologic intervention is employed to enhance gastric emptying and intestinal motility, the maximal attainable absorption rate is limited by age.

Neonates younger than 30 days and infants older than 30 days respond to the prokinetic metoclopramide with an increase in the absorption rate of a concomitantly administered sugar (Figure 2) (Reference 23). However, neonates do not attain the same absolute absorption rate as observed in young infants, suggesting that other developmental factors restrict absorption in the young infant. This has led many pediatric clinicians to attribute reduced absorption rates in young infants to diminished intestinal surface area, yet considered in the context of an infant's primary function (i.e., to assimilate nutrients and grow), a reduction in intestinal surface area would seem counterintuitive. In fact, a careful examination of anatomic and anthropometric data reveals that intestinal villi mature by 20 weeks of gestation and that overall intestinal length, as a percentage of adult values, exceeds other measures including total body length, body weight, and body surface area (Figure 3) (Reference 25). These data refute the assertion of decreased intestinal surface area, leaving no clear explanation for delayed absorption in the young infant. We hypothesize that differences in absorption rate are partially attributed to differences in splanchnic blood flow. Preprandial blood flow velocity increases by 30% to 40% during the first few weeks of life (References 26–28), which may influence the concentration gradient across the intestinal mucosa.

The intestinal lining of the gastrointestinal tract is also an active site of drug biotransformation. Both phase I and phase II enzymes (described in greater detail under Metabolism) are found at varying levels along the gastrointestinal tract. Unfortunately, few studies have examined intestinal enzyme expression as a function of age. Early work examined the activity of several intestinal enzymes from biopsies taken at the duodenojejunal flexure. Among these were epoxide hydrolase, glutathione peroxidase, and aryl hydrocarbon hydroxylase, now referred to as cytochrome P450 (CYP) 1A1 (CYP1A1). Of the three enzymes examined, only CYP1A1 appeared to show some level of developmental dependence, with activity increasing with increasing age (Reference 29). The expression and activity of CYP3A has also been examined in pediatric duodenal biopsies. Neither protein nor activity was detected to any appreciable extent in the fetus; however, a steady increase in both expression and activity was observed from the neonatal period through preadolescence (Reference 30). For orally administered medications that are inactivated by CYP1A1 or CYP3A, reduced presystemic clearance in younger children would be expected.

The phase II enzyme glutathione *S*-transferase (GST) can also be found in the enterocytes of the small intestine. The glutathione-conjugating capacity of distal duodenal biopsies on the antineoplastic busulfan appears to be highest in children younger than 5 years compared with children older than 8 years and

**Figure 2.** Absorption rate constant of xylose in neonates (younger than 30 days) and young infants (older than 30 days) with and without concurrently administered metoclopramide. Adapted with permission from Reference 23: Heimann G. Enteral absorption and bioavailability in children in relation to age. *Eur J Clin Pharmacol* 1980;18:43–50.

**Figure 3.** Intestinal length, total body length, body surface area, and body weight with age as a percentage of adult values.

adolescents (Reference 31). Of note, the age-dependent activity observed *in vitro* parallels the changes in the apparent oral clearance of busulfan *in vivo*, implying that younger children may require higher doses of drugs whose primary route of clearance is by glutathione conjugation. Other phase II enzymes (e.g., UDP-glucuronosyltransferases [UGTs]) are expressed along the intestinal tract at levels comparable to or in excess of those found in the liver; however, no attempts have been made to examine the influence of ontogeny on their expression and/or activity (Reference 32).

We would be remiss not to mention the role of normal intestinal flora on the inactivation (by metabolism) and reactivation (by deconjugation) of orally administered medications, though relevant to only a few drugs.

Anaerobic intestinal bacteria that predominate in the intestines of adults mediate digoxin inactivation to digoxin reduction products (DRPs). Recovery of DRPs in the urine of patients receiving digoxin increases steadily from birth through adulthood, with the biggest increase occurring near the time of weaning. This increase in urinary DRPs coincides with an increase in DRP-positive cultures that can be recovered from the stool (Reference 33). Of importance, the predominant bacterial organisms observed in the intestinal tract differ substantially within and between pediatric populations, depending on age and the constitution of feeds (Reference 34). As such, predicting the impact of age on the activity of intestinal microflora is unrealistic.

Finally, intestinal transporters play a considerable role in facilitating or restricting the uptake of many orally administered drugs. Unfortunately, most of the data on the ontogeny of intestinal transporters are from the study of nutrient and ion uptake in animal models. For some transport substrates (e.g., lactose-derived sugars that use the apically situated sodium-glucose cotransporter 1 [SGLT1] and basolaterally situated glucose transporter 2 [GLUT2]), maximal translocation can be observed shortly after birth (Reference 35). For others like iron (absorbed by the divalent metal transporter 1 [DMT1]), the capacity for absorption increases linearly during infancy, attaining adult capacity in early childhood (Figure 4) (References 36, 37). Although limited, data on the ontogeny of drug transporters in children are being acquired directly and indirectly. Studies examining the expression of P-glycoprotein (P-gp) suggest that this transporter is present within the intestine as early as 1 month of age and that it is continuously expressed through adulthood (Reference 38). Other studies allow us to acquire this information indirectly. Pharmacokinetic investigations of the H<sub>2</sub>-receptor antagonist nizatidine reveal very little of an age effect when the drug's terminal elimination rate constant is examined. By contrast, apparent oral clearance shows appreciable age-dependent changes, providing support for the developmentally dependent expression of one or more transporters for which the drug may be a substrate (Reference 39). Of note, dietary constituents and phytochemicals can alter the activity of several intestinal transporters, including those found in apple juice (Reference 40). Thus, the potential for drug-nutrient interactions will depend largely on the age-dependent level of expression for the transporters in question.

## Extraoral Administration

Although used less commonly as a means of drug delivery, extraoral formulations also encounter developmental barriers that influence the rate and extent to which the drugs they contain enter the body. Rectal administration is an efficient means of drug delivery and is often used in children for whom oral administration is not an option or has proven difficult. However, both formulation and developmental physiology must be considered when employing the rectal route. The number of high-amplitude pulsatile contractions (defined as an amplitude of 80 mm Hg or greater, lasting at least 10 seconds, and propagating at least 30 cm) of the lower gastrointestinal tract is more common in infants than in older children and adults (Reference 41). Although the impact on drug absorption from rectal solutions or fast-melt suppositories may not be significantly affected, suppositories that deliver their contents over hours will very likely be expelled before liberating the entire drug dose.

The impact of altered lower gastrointestinal motility on drug absorption is illustrated by the age-related differences observed in erythromycin concentrations between neonates and children. When administered intravenously, the differences in AUC between neonates, infants, and children are negligible. However, when equivalent weight-based doses are delivered by suppository, bioavailability is markedly lower in neonates (28%) than in infants (36%) and children (54%) (Reference 42). Similarly, acetaminophen delivered rectally at comparable weight-based doses reveals reduced absorption in full-term neonates compared with children and adults. However, preterm neonates show enhanced absorption, likely the result of differences in both motility and metabolism (References 43–45).

**Figure 4.** Enteral iron absorption as a percentage of the dose administered. Adapted with permission from Reference 37: Gladtko E, Rind H. Iron therapy during childhood. *Ger Med Mon* 1966;11:43 8–42.

Percutaneous drug application is rarely exploited for systemic drug delivery in pediatrics. Nonetheless, topical drug administration can be accompanied by significant systemic exposure in children. Children demonstrate a markedly larger surface area per unit of mass than do adults (Figure 3), a greater degree of hydration to their skin (as measured by capacitance, conductance, and transepidermal water loss), and higher rates of perfusion, all of which contribute to enhanced drug permeability (References 46, 47). In addition, premature infants show a thinner stratum corneum than do older children and adults, further facilitating the enhanced translocation of drugs. Although the epidermal and dermal layers can be thinner in full-term newborns and young infants, the primary percutaneous barrier constituted by the uppermost layers of the skin are fully mature in the full-term newborn and even in the preterm newborn by 2 weeks of life (Reference 48). All of these findings, in concert, contribute to an increased risk of systemic toxicity (and, in some cases, death) in infants and children after topical exposure to a variety of chemicals ranging from the therapeutically active (antihistamines, steroids, silver sulfadiazine) to the seemingly inert (talcum powder, laundry detergent) (Reference 49).

Intramuscular absorption represents the final extraroral route of drug delivery that will be reviewed. It is often suggested that absorption after intramuscular administration is erratic in children. For many drugs, however, intramuscular injection can be a very efficient route of drug delivery. Apart from the variability contributed by formulation, capillary density is one of the primary intrinsic drivers of drug absorption when medications are administered by intramuscular injection. Partly because of an increase in metabolic demand, young infants show a 25% increase in skeletal muscle capillary density compared with older children and a 56% increase compared with adults (Reference 50). This increase in capillary density results in greater intramuscular bioavailability for many drugs, including the aminoglycoside and  $\beta$ -lactam antibiotics (Figure 5) (References 51, 52).

## DISTRIBUTION

A drug's volume of distribution ( $V_d$ ) reflects the size of a compartment necessary to account for the total amount of drug administered, presuming that the drug is present throughout the body at the same concentration as observed in the plasma. Of importance, this theoretical "compartment" does not always correspond to a true physiologic space, and it can be difficult to discern into which tissues a drug distributes without quantitative tissue studies. As a result, the impact of development on drug distribution is not apparent for all drugs; however, this knowledge is available for some drugs that share selected physiochemical characteristics.

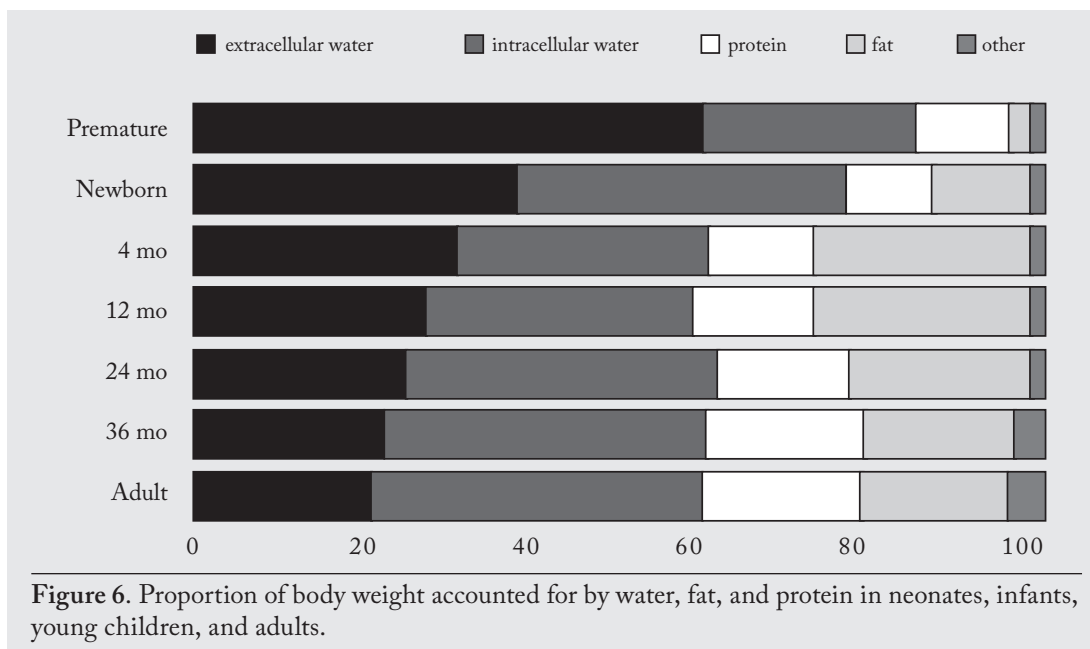

**Figure 5.** Maximal cephalothin plasma concentrations observed in neonates, infants, and young children after intramuscular administration of a 12.5-mg/kg injection.

At birth, humans exhibit larger fractions of total body water than at any other point in their life. Around 80% of a pre- or full-term newborn's body weight is composed of water, a fraction that gradually decreases throughout the first 4 months of life (Figure 6) (Reference 53). Even the fat stores in these youngest children consist of a higher proportion of water and a lower proportion of lipid compared with the fat of mature adults. Consequently, hydrophilic drugs that restrict their distribution to body water stores show larger apparent distribution volumes and lower plasma concentrations in neonates and young infants.

The clinical impact of expanded body water stores is well illustrated by several classes of antibiotics. The aminoglycosides distribute into a  $V_d$  that approximates extracellular fluid. Given their higher extracellular fluid stores, young children experience considerably lower peak gentamicin concentrations after the administration of equivalent weight-based doses. Compared with infants, young children have peak concentrations that are almost 33% greater and almost 50% greater in older children (Reference 54). When their reduced renal clearance is accounted for in the selection of a dosing interval, infants will eventually achieve gentamicin concentrations comparable to those observed in adults. However, the delay can have deleterious clinical consequences for this concentration-dependent drug (References 55, 56). Attaining high peak plasma concentrations early in therapy affords rapid bacterial killing while minimizing the risk of adaptive resistance (References 57, 58).

Linezolid, an oxazolidinone antibiotic, provides a similar example for drugs that distribute into a volume approximating total body water. Based on age-dependent changes in total body water stores, linezolid displays higher  $V_d$  values in the neonatal population ( $0.83 \pm 0.18$  L/kg) and correspondingly lower maximal plasma

concentrations ( $12.5 \pm 3.5$  mg/L) after a comparable weight-based dose compared with children ( $0.71 \pm 0.18$  L/kg,  $17.0 \pm 5.2$  mg/L) and adults ( $0.63 \pm 0.13$  L/kg,  $19.7 \pm 4.9$  mg/L). When coupled with the more rapid rate of clearance observed in infants, the clinical implications for this time-dependent antibiotic become apparent. If linezolid were administered with the same weight-adjusted dose and dosing frequency across all age groups, infants would be predicted to spend just 20% to 35% of the dosing interval above the minimum inhibitory concentration (MIC) for susceptible organisms. By comparison, it is predicted that children and adults would spend 35% to 70% and 70% to 100%, respectively, of the dosing interval above the MIC (Reference 59).

In contrast to body water stores, body fat stores are limited in the premature and newborn infant. Considerable increases in body fat stores are seen between 24 and 36 months of life, when the percentage of body fat approaches that of adult values (Figure 6). Although this may seem to suggest that highly lipophilic drugs will exhibit smaller distribution volumes in infants and young children, these drugs, in fact, associate with lipids and other cellular components such that marked distinctions in  $V_d$  with age are not as readily apparent.

Another factor that influences drug distribution is the amount of free drug available to translocate from the circulation into peripheral tissue sites. The free fraction of drug is determined, in part, by the binding affinity of the drug for circulating proteins, the concentration of circulating proteins, and the presence of endogenous circulating ligands that have the ability to displace drugs from their protein binding sites (e.g., bilirubin, free fatty acids) (References 60–62). Several physiologic differences in the neonate and young infant predispose

them to increases in the free fraction of drugs, among which are the reduction in circulating plasma proteins (e.g., albumin,  $\alpha$ -1-acid glycoprotein [AAG]) (Reference 63). In addition, a proportion of the circulating albumin in newborns is constituted by fetal albumin, for which many drugs appear to have a lower binding affinity. Consequently, neonates and young infants (typically younger than 6 months) experience higher unbound fractions of drugs than do older children and adults.

Thiopental, a short-acting barbiturate used primarily for sedation, binds mainly to albumin. Because neonates display higher circulating bilirubin levels and lower albumin stores, they experience a lower percentage of protein binding of thiopental (73.2%) compared with adults (84.4%), resulting in higher free fractions (Reference 64). Sufentanil, a derivative of the opioid analgesic fentanyl, offers a similar example of drugs bound to AAG. Because of reductions in AAG, the free fraction of sufentanil is significantly increased in neonatal (19.5%) and infant (11.5%) populations compared with children (8.1%) and adults (7.8%) (Reference 65).

The clinical impact of developmental differences in protein binding depends in large part on the drug under consideration. For a drug like phenytoin, with its high degree of protein binding and narrow therapeutic index, small changes in protein binding can result in dramatic increases in the drug's free fraction and a corresponding increase in the risk of toxicity. A reduction from 99% protein binding (1% free) to 98% protein binding (2% free) effectively doubles the free fraction of the drug. By contrast, a reduction in ampicillin binding from 22% in adults to 10% in neonates results in a modest (15%) increase in free fraction and a negligible alteration in risk profile (Reference 66).

Finally, growing attention has been paid of late to the many transport proteins that facilitate the vectorial transport of endogenous compounds (e.g., steroids, peptides, nucleotides, electrolytes) as well as a wide range of xenobiotics within the body. The normal biologic substrates of these transporters support somatic development and maintain homeostasis in the growing child. Within different tissues, they are used to different extents at different times throughout development. As such, adaptive mechanisms likely contribute to variability in the tissue-specific expression, quantitative expression, affinity, and turnover rate of transporter proteins during human maturation. Unfortunately, only scant data describe a change in the tissue-specific expression of transport proteins with age. A single study examining P-gp expression in postmortem brain tissue from neonates born between 23 and 42 weeks' gestation suggests that by late gestation, the pattern of P-gp localization is similar to that of adults; however, the quantitative abundance is significantly reduced (Reference 67). By contrast, animal studies have suggested that changes in blood flow and pore density account for differences in central nervous system drug penetration with age; however, the relevance of these findings to humans is unclear.

## METABOLISM

The human liver is responsible for an array of synthetic, metabolic, and homeostatic functions in addition to its prominent role in the removal of toxins and other foreign substrates from the blood. Although hepatic detoxification pathways likely arose to deal with endogenous ligands and exogenous chemicals or toxins found in nature (e.g., phytochemicals), these pathways serve a dual role as major routes of clearance for an array of medications to which we are exposed. Those classified as phase I enzymes covalently modify drugs (by oxidation, reduction, hydrolysis) to increase their polarity, whereas phase II enzymes act to conjugate endogenously synthesized polar functional groups to the parent drug or any of its phase I metabolites. Of note, several phase I and phase II enzymes are located in tissues other than the liver (e.g., kidney, lung, adipose, intestine, skin); however, these extrahepatic sites (with the exception of the intestine) are of limited quantitative importance, and the discussion that follows will be restricted to the liver.

In the context of interindividual variation in drug metabolism, a review of the literature reveals that far more emphasis is placed on genetic polymorphisms than ontogeny. Scientific investigations that followed the tragedy of chloramphenicol and the "grey baby syndrome" were among the first to reveal the contribution of development to drug biotransformation (Reference

68), and respectable efforts have been made to describe the ontogeny of various hepatic drug metabolism pathways. However, the vast majority of publications focus on the consequence of sequence variations on enzyme activity. Given that genetically encoded variations in the structure or function of drug-metabolizing enzymes remain constant with age, we will not spend time reviewing their significance. However, we would be remiss not to point out the potential relevance (or lack thereof) of polymorphisms in the context of ontogeny. Sequence variations that encode for an enzyme with low or no function have no bearing on the disposition of a substrate if the developmental signal to "turn on" and express the protein has yet to be received. Thus, the ontogenic profiles described below inform more than simply age-dependent changes in the rate and extent of drug biotransformation; they inform whether and to what extent the potential for drug-drug, drug-food, drug-environment, and drug-gene interactions may be experienced.

### Phase I Metabolism

The primary drug-metabolizing enzymes responsible for carrying out phase I reactions are the CYPs. The relative contribution of CYPs to medication therapy are the CYP3A family, followed closely by CYP2D6, the CYP2C family, CYP2E1, and finally CYP1A2.

CYP3A4 is estimated to be involved in the metabolism of more than 50% of available medications, including benzodiazepines, calcium channel blockers, and HMG-CoA reductase inhibitors. Humans experience a CYP3A isoform switch shortly after birth, transitioning from the expression of CYP3A7 (responsible for the 16 $\alpha$ -hydroxylation of dehydroepiandrosterone) to CYP3A4 (responsible for the 17 $\alpha$ -hydroxylation of testosterone). Levels of CYP3A4 increase steadily throughout infancy, maturing to adult levels by 1 year of age (References 69, 70). Consistent with this observation, the clearance of sildenafil, a phosphodiesterase inhibitor metabolized primarily by CYP3A4, rapidly increases within the first 10 days of life, correlating with an increase in the expression of CYP3A4 (Reference 71). Similarly, the terminal half-life of cisapride, a prokinetic agent also primarily metabolized by CYP3A4, is significantly longer in preterm infants younger than 36 weeks' gestational age (11.7 hours) compared with term infants older than 36 weeks' gestational age (7.7 hours), infants older than 42 weeks (4.8 hours), and adults (4.1 hours) (References 24, 72).

The CYP2D6 enzyme is estimated to contribute to the metabolism of 25% of the drugs on the market, including  $\beta$ -blockers, antidepressants, and antipsychotics. The CYP2D6 enzyme is highly polymorphic, with significant interindividual differences observed within and between populations. A study examining CYP2D6

activity from birth through year 1 of life revealed that activity comparable to that of adults can be detected by 2 weeks of age and confirmed that the impact of inheritance on interindividual CYP2D6 variability is of greater significance than development (Reference 73).

Distinct developmental profiles are seen between the two primary isoforms of the CYP2C family. In vitro quantitation of immunoreactive protein from hepatic tissue reveals that CYP2C9 expression appears to be rather invariant with postnatal age, whereas the expression of CYP2C19 appears to increase during the first 6 months of life (Reference 74). Of interest, clinical pharmacokinetic data suggest that the terminal half-life of phenytoin (a primary substrate for CYP2C9) drops from an average of 20 hours at birth to 8 hours by 2 weeks of life (References 75, 76). By contrast, the proton pump inhibitor omeprazole (a substrate for CYP2C19) shows higher rates of clearance in young infants and correspondingly faster half-lives normalizing during the first 5 years of life (References 77–81). Both examples highlight the challenge that can arise when attempting to predict in vivo disposition on the basis of in vitro protein or transcript expression data.

The CYP2E1 enzyme is involved in the metabolism of various anesthetics, including enflurane, halothane, and isoflurane. Transcript, protein, and activity levels are all negligible during prenatal life, with a gradual increase in expression and activity observed throughout childhood. Levels with 80% of adult values are attained after the first year of life (References 82, 83).

The CYP1A2 enzyme metabolizes various substrates, including theophylline, caffeine, clozapine, haloperidol, and duloxetine. Activity levels of CYP1A2 are absent throughout fetal development and extremely low in the neonatal population (4% to 5% of adult levels). A steady increase is observed thereafter, with infants 1–3 months of age showing 10% to 15% of adult levels, infants 3–12 months of age exhibiting 20% to 25% of adult activity, and children 1–9 years of age displaying 50% to 55% of the activity of an adult (Reference 84). Of note, dietary factors can also influence the rate of CYP1A2 metabolism. Examining changes in the disposition of caffeine with age reveals that breast-fed infants are slower to decrease their caffeine half-life compared with infants who are formula fed (References 85, 86).

### Phase II Metabolism

Phase II reactions entail the conjugation of drug molecules with endogenously synthesized functional groups (e.g., glucuronic acid, glutathione, glycine, sulfate). These reactions further increase the polarity of intermediate metabolites, making the compound more water-soluble and thereby enhancing its excretion. Several major gene families have been identified that are

involved in phase II reactions, including *N*-acetyltransferases (NATs), UGTs, GSTs, and sulfotransferases (SULTs). Analogous to the CYP families, these gene families also have individual isoforms displaying their own ontogenic profile.

The UGTs are among the most well-characterized phase II gene families. UGT1A1 is involved in the metabolism of acetaminophen, ibuprofen, and warfarin among other medications. UGT1A1 activity is shown to be absent in fetal liver, followed by the immediate acquisition of activity shortly after birth and reaching adult levels between 3 and 6 months of life (Reference 87). By contrast, UGT1A9 (substrates include ethinyl estradiol, ibuprofen, and acetaminophen) transcript expression is about 44% that of adult values by 6 months of life and is still only 64% by 2 years of age (Reference 88). UGT2B7, in combination with the UGTs1A, is responsible for the glucuronidation of morphine. Pharmacokinetic data from which morphine clearance is derived suggest that clearance (and by extension UGT2B7 activity) is lowest in premature neonates, increasing exponentially during the first year of life to activity levels that exceed those of adults (Reference 89).

The SULTs play a role in steroid hormone biosynthesis, catecholamine metabolism, and thyroid hormone homeostasis. SULT1A1 is present in the fetal liver, and the levels of expression appear consistent from birth through adolescence. By contrast, SULT2A1 activity levels increase substantially within the first 3 months of life and achieve activity comparable to that of adults after 3 months of age (Reference 90). Finally, both GSTA1 and GSTA2 are present in the prenatal liver; however, adult values are not achieved until 1–2 years of life (Reference 91).

Despite the wide array of developmental profiles observed for the phase I and phase II drug-metabolizing enzymes, neonates and young infants are not always disadvantaged when it comes to clearing xenobiotics. The element of redundancy built into human detoxification pathways means that many drugs undergo biotransformation by multiple enzymes. For some drugs, compensatory mechanisms ensure that the overall clearance rate does not change with age. For other drugs, the contribution of minor pathways, although important, may be less efficient, resulting in delayed drug clearance until maturation of the primary pathway occurs. Acetaminophen offers a great example of the latter scenario. The major routes of metabolism are UGT1A6 and SULT1A1. Sulfate conjugates account for most acetaminophen metabolites recovered in newborns, with a shift in ratio observed with increasing age (Figure 7) (Reference 92). However, infants still exhibit longer overall half-lives than do young children and adolescents (Reference 93). Ultimately, the impact of ontogenic changes in drug metabolism on drug disposition

and action will depend on the nature of the chemical moiety (active drug vs. prodrug), its therapeutic index, and the number of pathways for which the drug serves as a substrate.

## ELIMINATION

Although the body uses many organs to facilitate the removal of xenobiotics and endobiotics, the kidneys remain a major organ of elimination for many drugs and/or their metabolites. Both active and passive processes work in concert to clear endogenous and foreign substrates while maintaining normal fluid and electrolyte homeostasis. Of note, the kidney serves as a prototypic organ for which the completion of organogenesis does not signal structural and functional maturation of the organ. Nephrogenesis is complete by 36 weeks' gestation, yet maturation continues through childhood, as reflected by changes in the anatomic dimensions of the organ. Macroscopically, kidney length more than doubles from birth to 12 years of age. Kidney weight exhibits a comparable linear increase during this same time. Microscopically, the diameter of the average glomerulus in a newborn is about 1/3 that of an adult, and the average proximal tubule is about 1/10 the length of that in an adult (Reference 94). The radius of the small pores in the glomerulus increases by more than 25% during the first 3 months of life (from 19.6 to 25 Å), whereas the ratio of large pores to small pores shifts in favor of the former. Neonates also experience an increase in vascular resistance and reduced renal blood flow, with fractional cardiac output to the kidney increasing almost 4-fold during the first year of life (Reference 95).

Because of these and other changes, renal function in children differs quantitatively from that of adults, with both passive and active processes showing clear developmental profiles (Figure 8). Glomerular filtration rate (GFR) increases abruptly after birth, more than doubling in the first 2 weeks of life and increasing uninterrupted

**Figure 7.** Percentage of an acetaminophen dose recovered as glucuronide or sulfate conjugates in newborns, children, and adults.

until growth is complete. However, when examined with respect to body surface area, adult filtration capacity is achieved in the first 1–2 years of life (References 95, 96). Of note, GFR is significantly decreased in the premature newborn, and postnatal acquisition of functional filtration capacity follows a different trajectory in these children (Figure 9) (Reference 97). Analogous to GFR, concentrating capacity in newborns is significantly diminished at birth, increasing from less than 600 mOsm/kg of water to greater than 900 mOsm/kg of water during the first month of life and ultimately to 1200 mOsm/kg of water when growth is complete (Reference 97).

Based on these observations, gestational and post-conceptual age, in addition to comorbid disease processes and coadministered drugs, should be considered

**Figure 8.** Changes in glomerular filtration (solid circles, solid line) rate and para-aminohippurate clearance (open circles, dashed line) as a function of age.

**Figure 9.** Postnatal acquisition of functional renal filtration capacity as a function of gestational age.

**Table 1. Clinically Relevant Renal Drug Transporters**

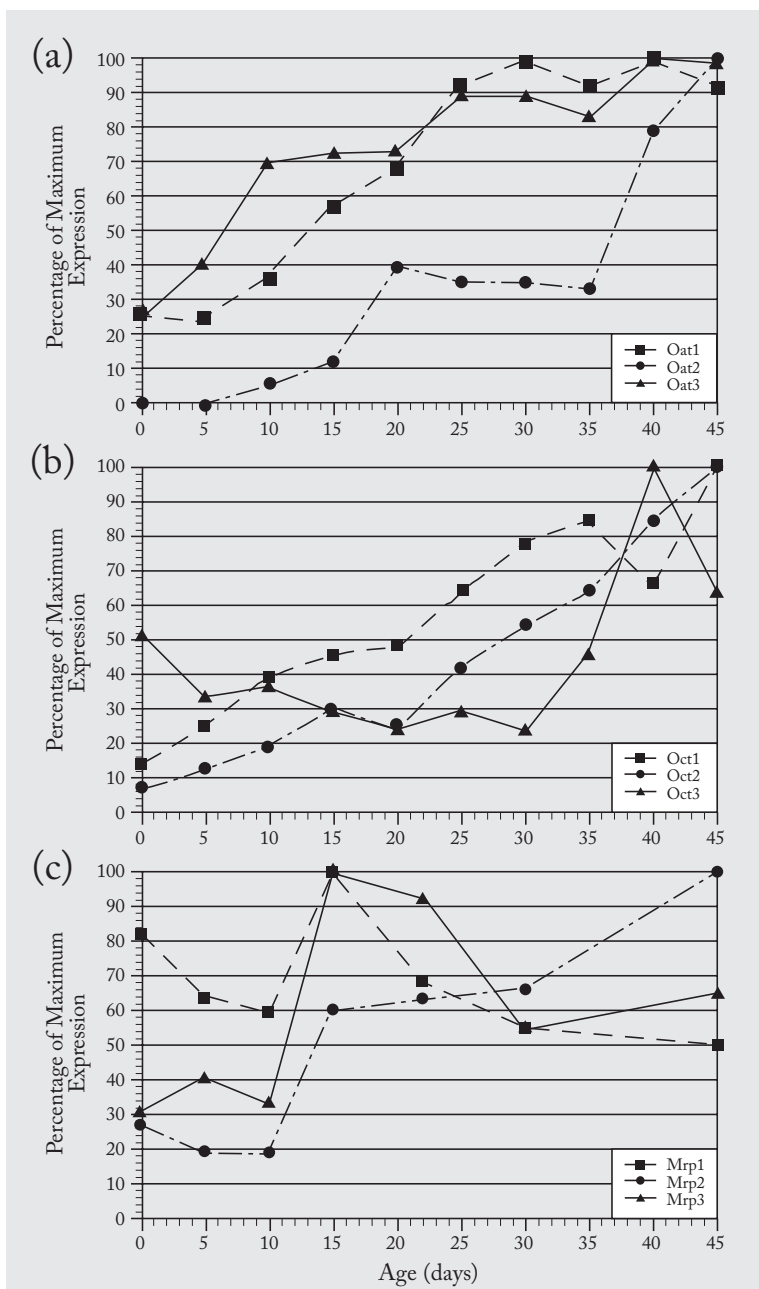

Common Name	Gene	Substrates	Inhibitors
SLC21A3	<i>OATP-A</i>	Chlorambucil, fexofenadine, ouabain, rocuronium	Dexamethasone, erythromycin, lovastatin, naloxone, naltrindole, quinidine, verapamil
SLC21A9	<i>OATP-B</i>	Benzylpenicillin	
SLC21A11	<i>OATP-D</i>	Benzylpenicillin	
SLC21A12	<i>OATP-E</i>	Benzylpenicillin	
OCT1	<i>SLC22A1</i>	Acyclovir, ganciclovir	Acebutalol, amantadine, cimetidine, clonidine, disopyramide, midazolam, procainamide, prazosin, quinine, quinidine, vecuronium, verapamil
OCT2	<i>SLC22A2</i>	Amantadine, memantine	Desipramine, procainamide, quinine
OCT3	<i>SLC22A3</i>	Cimetidine	Clonidine, desipramine, imipramine, prazosin, procainamide
OCTN1	<i>SLC22A4</i>	Quinidine, verapamil	Cephaloridine, cimetidine, procainamide, quinine
OCTN2	<i>SLC22A5</i>	Pyrilamine, quinidine, valproate, verapamil	Cephalosporins, cimetidine, clonidine, desipramine, procainamide, pyrilamine, quinine
OAT1	<i>SLC22A6</i>	Methotrexate, acyclovir	$\beta$ -Lactam antibiotics, NSAIDs, diuretics
OAT2	<i>SLC22A7</i>	Zidovudine	$\beta$ -Lactam antibiotics, NSAIDs, diuretics
OAT3	<i>SLC22A8</i>	Zidovudine, cimetidine, methotrexate, salicylate	$\beta$ -Lactam antibiotics, diuretics, NSAIDs, quinidine
OAT4	<i>SLC22A11</i>	Azathioprine, cimetidine, methotrexate	$\beta$ -Lactam antibiotics, diuretics, NSAIDs
MRP1	<i>ABCC1</i>	Etoposide, methotrexate	Indomethacin, sulfinpyrazone
MRP2	<i>ABCC2</i>	Furosemide, indomethacin, methotrexate, vinblastine	Cyclosporin
MRP3	<i>ABCC3</i>	Methotrexate	
MRP4	<i>ABCC4</i>	Adefovir, azidothymidine, methotrexate	Sildenafil
MRP5	<i>ABCC5</i>	Adefovir, 6-mercaptopurine	Sildenafil

ABC = ATP (adenosine triphosphate) binding cassette; MRP = multidrug resistance protein; NSAIDs = nonsteroidal anti-inflammatory drugs; OAT = organic anion transporter; OCT = organic cation transporter; SLC = solute carrier.

when determining age-appropriate pediatric dosage regimens. In young children with decreased renal function, clearance is significantly reduced and the corresponding half-life significantly prolonged, necessitating longer dosing intervals. For example, the half-life of fluconazole in premature infants (88 hours) is considerably longer than in their full-term counterparts (19.5–25 hours). Consequently, fluconazole is dosed as follows. In infants younger than 29 weeks of gestation and younger than 14 days of age, dosing is every 72 hours. In infants younger than 29 weeks of gestation and older than 14 days of age or infants 30–36 weeks of gestation and younger than 14 days of

age, dosing is every 48 hours. Finally, in infants 30–36 weeks of gestation and older than 14 days of age, dosing is every 24 hours (Reference 98).

Although age-dependent changes in the clearance of para-aminohippurate (a prototypical substrate for renal transport) have been described, very few data describe the ontogeny of renal drug transporters in the human kidney. However, clear support is available for the assertion of age-dependent changes in the expression of renal transporters. The renal transporters responsible for regulating sodium chloride balance in the body serve to illustrate this point. The apically situated  $\text{Na}^+/\text{H}^+$  and  $\text{Cl}^-/\text{OH}^-$  transporters, together with the  $\text{Na}^+-\text{K}^+-\text{ATPase}$  and chloride transporters located

**Figure 10.** Average transcript expression levels of selected (a) Oat (organic anion transporter), (b) Oct (organic cation transporter), and (c) Mrp (multidrug resistance protein) genes in male and female rodent kidneys.

on the basolateral surface of the tubule, all show diminished activity in fetal and young animals (References 99–102). There is little evidence to implicate the presence of unique transporter isoforms in the young or a difference in the affinity of these transporters for their respective substrates with age. Rather, differences in activity appear to be related to the existence of these transporters in lower abundance along the entire length of the nephron in the young (References 99–101).

Although these renal sodium chloride transporters are not directly involved in drug transport, a substantial number of other proteins situated on both the basolateral and apical surfaces of the tubule take on the task of facilitating diffusion or actively transporting drugs in the kidney (References 103–105). Table 1 highlights the predominant renal transporters that have been characterized to date and offers select examples of drugs that depend on these transporters for their elimination (Reference 103). Because there are no ontogeny data in humans, their known ontogenic profiles in rats (Oat [organic anion transporter], Oct [organic cation transporter]) and mice (Mrp [multidrug resistance protein]) are illustrated in Figure 10 (References 106–110). For reference, the analogous developmental stages between selected animal species and humans are detailed in Table 2 (Reference 111).

An additional, often overlooked route of drug elimination is biliary excretion. Immaturity in the expression of transporters responsible for the translocation of drugs and their metabolites across the biliary canaliculus restricts the biliary clearance of drugs during the first few weeks of life (Reference 112). To compensate, the fractional urinary excretion of many drugs that otherwise rely on biliary transport is increased in the neonate. Around 70% of a ceftriaxone dose is recovered in the urine of neonates compared

**Table 2.** Analogous Developmental Stages Between Humans and Selected Animal Species

Developmental Stage	Human	Rat	Dog	Pig
Neonate	Birth to 1 mo	Birth to 1 wk	Birth to 3 wk	Birth to 2 wk
Infant	1 mo to 2 yr	1–3 wk	3–6 wk	2–4 wk
Child	2–12 yr	3–9 wk	6 wk to 5 mo	4 wk to 4 mo
Adolescent	12–16 yr	9–13 wk	5 to 9 mo	4–7 mo
Adult	> 16 yr	> 13 wk	> 9 mo	> 7 mo

with children and adults (40% to 60%) (Reference 113). Similarly, the amount of cefoperazone recovered in the urine of preterm newborns (55%) is substantially greater than that of full-term neonates (18%) (Reference 114). Although compensatory clearance pathways exist, the overall rate of clearance for drugs eliminated through the bile will be reduced in the newborn.

## CONCLUSIONS

To provide optimal care for any special population, clinicians require knowledge of how physiology and pathology intersect to affect the disposition and action of drugs. Children represent a unique “special population” in whom processes involved in normal growth and development overlay the processes that govern disease presentation and progression. Consequently, a fundamental working knowledge of developmental biology is essential for any clinician who chooses to care for children. This knowledge enables the pediatric care provider to make rational recommendations for drug regimen selection when there are limited data in the product label to guide pediatric dosing.

It should be recognized that gaps in our knowledge will be present as long as there are drugs for which the sum total of all disposition processes have yet to be elucidated and known disposition pathways for which the impact of ontogeny has yet to be characterized. In these settings, data generated from carefully constructed clinical pharmacokinetic studies can be used to expand our knowledge of developmental biology. The thoughtful clinician transitioning into pediatric practice should, throughout his or her career, seek to accumulate and assemble both types of knowledge to construct the framework for optimal pediatric pharmacotherapy.

# CHAPTER 3

## INTRODUCTION TO NEONATOLOGY

Varsha Bhatt-Mehta, Pharm.D., M.S. (CRDSA), FCCCP

### LEARNING OBJECTIVES

1. Define the human neonate on the basis of gestational and postnatal age.
2. Understand the differences in physiologic development of neonates of varying gestational ages, and differentiate them from older infants and children.
3. Describe the most common disease states associated with premature and full-term neonates.
4. List the most commonly used medications and dosage forms in neonates and methods of administration.
5. Understand the differences in drug dosing and disposition in neonates compared with that in older infants and children.

### ABBREVIATIONS IN THIS CHAPTER

ADME	Absorption, distribution, metabolism, and elimination
ELBW	Extremely low birth weight
F <sub>IO2</sub>	Fraction of inspired oxygen
HBV	Hepatitis B vaccine
ICN	Intensive care nursery
NEC	Necrotizing enterocolitis
NRDS	Neonatal respiratory distress syndrome
PDA	Patent ductus arteriosus
VLBW	Very low birth weight

### INTRODUCTION

#### Evolution of the Science of Neonatal-Perinatal Medicine

##### *Historical Perspective*

In 1960, Alexander Schaffer coined the term *neonatology* (Reference 1). This term refers to the art and science of diagnosis and treatment of the diseases in the newborn infant. The science of neonatology is quite young, yet it has carved a niche of its own. The term *perinatal* defines the time between the obstetric and neonatal periods. Perinatologists specialize in maternal-fetal medicine. They take care of pregnant women

who are at high risk of pregnancy-related complications. In large academic centers, the perinatal obstetricians and neonatologists work side by side in perinatal centers, giving rise to the specialty of neonatal-perinatal medicine. The first neonatal intensive care nurseries (ICNs) were formed around the early 1900s. Mainly reserved for the premature infant, these ICNs provided “warmth, rest, diet, quiet, sanitation, space” (to use Florence Nightingale’s words), and other amenities that prevail today in the modern high-tech ICN and were essential to the growth and survival of the premature neonate.

#### Connection Between Neonatal ICN vs. Newborn Nursery vs. Home Care of the Newborn Infant

Neonatology bridges obstetrics with pediatrics. Since ancient times, care for pregnant women has relied on midwives, grandmothers, and other experienced female elders. This worked well for uncomplicated pregnancies, but disasters were common in complicated pregnancies, accounting for a significant number of maternal deaths. Specialty care was not provided to the neonate, resulting in high neonatal mortality, especially of premature neonates or those with congenital malformations. Today, the successful care of premature neonates requires a team of health care providers including obstetricians, perinatologists, and neonatologists.

#### Ethical Dilemmas of Neonatal Practice

The practice of neonatal-perinatal medicine is full of ethical dilemmas, including babies with congenital malformations, extreme prematurity, and birth depression. The lives of these babies can be prolonged by modern technology that provides life support for prolonged durations. However, the long-term neurologic outcome of such births is uncertain. Neonatologists face the ethical dilemma of how much life support to offer and for how long. In some cases, there may be a difference of opinion between the neonatologist and the family. Specialized ethics committees are required in such situations to determine the futility of the situation. Although discussions are ongoing, all health care professionals involved in the care of such infants must provide their full support to the treating physicians, who are ultimately responsible for the infant’s outcome.

## Epidemiology

During the neonatal-perinatal period, the mother and fetus grow at a fast rate. At birth, the fetus is required to make an abrupt transition from the protective environment of the uterus to the outside. This transition requires the baby to undergo significant physiologic stress. Thus, the highest number of neonatal deaths occur in the first 24 hours of life. Neonatal mortality rate, defined by the World Health Organization (WHO) as the number of deaths during the first 28 completed days of life per 1000 live births in a given year or period, is highest during the first month of life. Newborn, or neonatal, deaths account for 37% of all deaths among children younger than 5 years. The main causes of newborn deaths are prematurity and low birth weight, infections, asphyxia (lack of oxygen at birth), and birth trauma (Figure 1). These causes account for almost 80% of deaths in this age group (Reference 2).

Neonatal deaths may be subdivided into early neonatal deaths, occurring during the first 7 days of life, and late neonatal deaths, occurring after the seventh day but before 28 completed days of life. Perinatal mortality (early neonatal death), defined as the number of stillbirths and deaths in the first week of life per 1000 live births, is a useful additional indicator of maternal and newborn health care and a main component of perinatal mortality reports. Preterm birth is an important perinatal health problem across the globe. Developing countries, especially those in Africa and southern Asia, incur the highest burden in absolute numbers, although a high rate is also observed in North America. In 2005, 12.9 million births, or 9.6% of all births worldwide, were preterm. Around 11 million (85%) of these preterm births were concentrated in Africa and Asia, whereas about 0.5 million occurred in each of Europe and North America and 0.9 million in Latin America and the Caribbean. The highest rates of preterm birth were in Africa and North America (11.9% and 10.6% of all births, respectively), and the lowest rates were in Europe (6.2%) (Reference 3). Figure 2 shows the 2003 infant mortality rate by WHO regions. The infant mortality rate is highest in African nations, which lack access to the modern, technologically advanced ICNs (Reference 2).

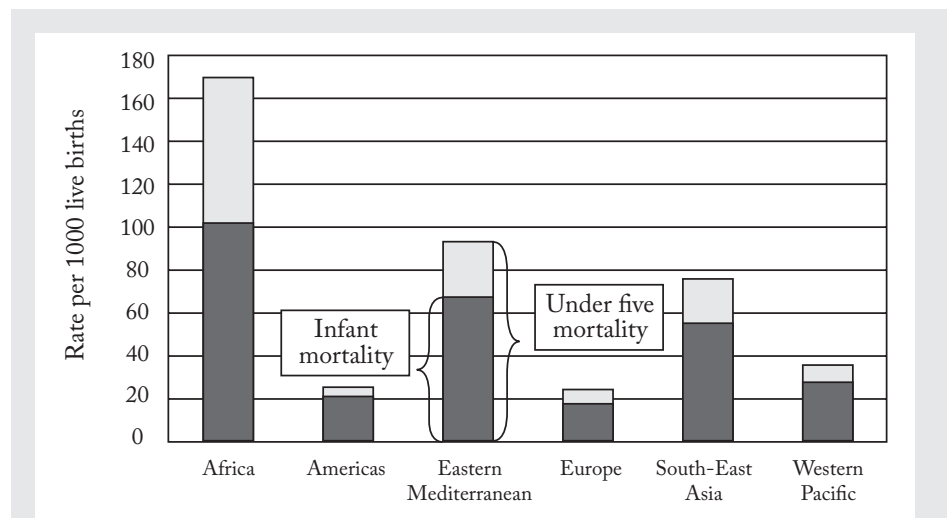

The most recent data on infant mortality in the United States come from the National Center for Health Statistics (NCHS), a branch of the Centers for Disease Control and Prevention (CDC).

**Figure 1.** Causes of neonatal deaths.

Source: World Health Organization. The Global Burden of Disease: 2004 update. World Health Organization, Geneva, 2008.

The trends in infant mortality in the United States remained steady between 2000 and 2005. In 2005, the infant mortality rate was 6.86 per 1000 live births (Figure 3). Infant mortality in the United States is highest among non-Hispanic black mothers, as seen in Figure 4. These data were recently published in the National Vital Statistics Report of the NCHS branch of the CDC. Because of their higher risk of death, infants at the low end of gestational age have a large impact on U.S. mortality rates. Figure 5 presents the distribution of live births and infant deaths by gestational age in the United States in 2007; infants younger than 34 weeks account for less than 5% of all infant births but greater than 50% of infant deaths.

## How Is the Neonatal Population Different from Other Pediatric Populations?

### Defining the Human Neonate

Gestation is defined as the period between conception and birth. In humans, full gestation lasts 37–40 weeks. Infants born before 37 weeks or 259 days of gestation are defined as preterm (or premature) neonates. The neonatal period commences at birth and ends 28 completed days after birth. A neonate is defined as a newborn infant during the first 28 days of life after full gestation. After 28 days, the neonate is referred to as an infant.

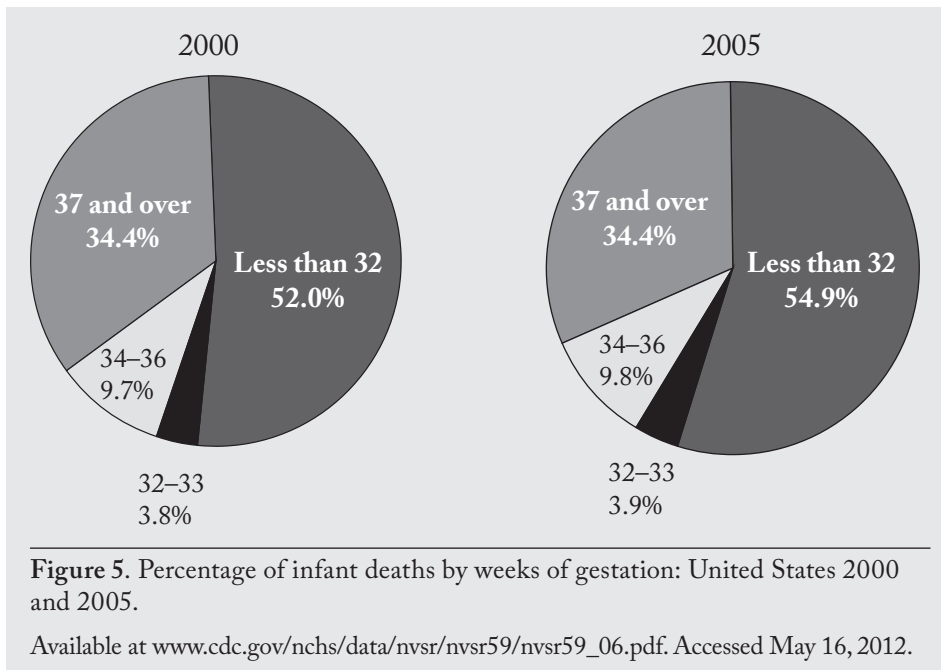

Premature neonates may be further divided into subgroups by either gestational age or birth weight. Defining premature infants by gestation is complicated because in many situations the weight and gestational age of the fetus may not correspond because there has been in utero growth retardation from several different causes (e.g., small-for-gestational-age infants who are small because of undernourishment in utero). Likewise, large-for-gestational-age infants weigh much more than anticipated at a given gestation.

The term *low birth weight* defines all infants born with a birth weight less than 2500 g. The term *very low birth weight* (VLBW) refers to infants weighing less than 1500 g, whereas the term *extremely low birth weight* (ELBW) refers to infants weighing less than 1000 g at birth. The care of VLBW and ELBW infants constitutes an important part of all ICNs and is a significant portion of the cost of care (Reference 4). Another term more commonly used in the past 5 years is *late preterm infant*. This term signifies infants born between 34 and 37 weeks' gestation, although there is some controversy surrounding the lower end of gestational age.

Despite these dilemmas, for consistency of care among health care providers in everyday practice, some general definitions are necessary to describe the premature neonates' age after birth. The most commonly used descriptions include postnatal age, corrected gestational age, postmenstrual age, and postconceptional age. Postnatal age refers to the actual chronologic age of the infant after birth. Corrected gestational age, postmenstrual age, and postconceptional age all refer to the same period expressed differently; it is the sum of gestational age and postnatal age.

### Multiple Gestations

The incidence of multiple gestations has increased during the past 2 decades, especially in some affluent countries, because of the increased number of pregnancies in older women as well as the increased use of fertility enhancement therapies. The number of births from twin

gestations was about 25 per 1000 live births in the mid-1990s, whereas that from higher-order multiple gestations was around 1.3 per 1000 live births (Reference 5). Fetuses of a multifetal pregnancy are more likely to be born prematurely.

Such pregnancies are also more likely to be complicated by pregnancy-induced hypertension, premature onset of labor, and antenatal and postpartum hemorrhages, among other complications.

#### ***Developmental Differences—Ontogeny of Organs and Organ Function***

The development and function of organs in an infant are a matter of gestational age and postnatal age. In a full-term neonate, the organs in the body are mature for age at the time of birth. In a premature neonate, birth has occurred before the internal organs of the body are fully developed. However, compared with infants and children, premature and full-term neonates are both still considered to have immature organ function.

The ontogeny of organs affects the absorption, distribution, metabolism, and excretion (ADME) of drugs (Reference 6). Developmental changes in surface area of the skin, gastrointestinal tract, and other mucosal surfaces such as the rectum and oral cavity can affect the rate and extent of drug absorption significantly in the neonatal period. Changes in body composition occur with increasing age. About 70% to 80% of a neonate's body weight is water. This affects the distribution of drugs significantly, resulting in larger volumes of distribution for water-soluble drugs in neonates compared with infants, older children, and adolescents. Conversely, lipid-soluble drugs do not distribute extensively in water, and they may be needed

in lower doses. The plasma binding proteins such as albumin and  $\alpha$ -1-acid glycoprotein are present in lower concentrations, especially in premature infants, resulting in much higher plasma concentrations of free or pharmacologically active drugs.

Hepatic metabolism of drugs is also limited and varies according to gestational age, especially in the premature neonate. Phase I oxidative metabolism and phase II reactions such as glucuronidation are slow in the premature neonate and mature only around 6 months of age.

The functional and anatomic maturation of the kidneys is a dynamic process in the neonate beginning around 9 weeks' gestation and continuing well into early

childhood. The glomerular filtration rate increases rapidly in the first 2 weeks of life in the term neonate. In the premature infant, this maturation is slower, thus affecting the clearance of compounds exclusively eliminated by the kidney. Dosage adjustments for drugs eliminated exclusively by the renal route are essential when renal function is compromised because of age, underlying illness, or both. (See the Introduction to Pediatrics and the Pediatric Pharmacokinetics chapters for more details.)

#### **Fundamentals in the Care of the Neonate**

##### ***Maternal Obstetric, Labor, and Delivery History***

A mother may be exposed to many prescribed and un-prescribed substances during the course of pregnancy as well as during labor and delivery that may adversely affect the neonate. In caring for the neonate, a detailed history of in utero drug or other substance exposure is critical because such substances may transfer to the infant through the placenta and affect the initial treatment of the newborn infant.

##### ***Placental Transfer of Drugs and Other Substances***

In utero, the fetus relies on the placenta (the fetus is connected to the placenta by the umbilical cord) almost completely for nutritional, respiratory, and excretory functions. The placenta grows in parallel with the fetus. During pregnancy, substances may cross the placenta by simple diffusion, facilitated diffusion (gradient-dependent diffusion), active transport (transfer requires specific transporters that use energy to transfer substances, mostly for lipid-insoluble substances), receptor-mediated endocytosis, and other mechanisms.

Most drugs travel across the placenta by active transport or passive diffusion. Exposure of the mother to anesthetic or analgesic agents, tocolytic agents, and nicotine, cocaine, or other substances of abuse can have adverse effects on the neonate. Knowledge of such history before the delivery of the neonate can help the care provider be prepared for successful resuscitation of the neonate.

## Neonate-Specific Considerations

### Neonatal Resuscitation

The transition from fetal to extrauterine life is a complex process that requires understanding of in utero physiology and potential complications that may occur during the process of labor and delivery. Most full-term and low-birth-weight infants transition from intrauterine to extrauterine life with little or no assistance. They are vigorous and cry at birth, breathing easily afterward. The remaining may require varying degrees of resuscitation for restoring cardiopulmonary function to allow adjustment to extrauterine life.

### Normal Physiologic Events at Birth

In utero, the fetal lungs are filled with fluid, providing an area of high resistance. The oxygenation of the blood occurs in the placenta. This circulation is maintained by two main patent fetal shunts—the foramen ovale and ductus arteriosus. These shunts provide connections to the right atrium and aorta, respectively, shunting the blood away from the pulmonary circulation. Relatively little blood reaches the lungs because of high pulmonary vascular resistance.

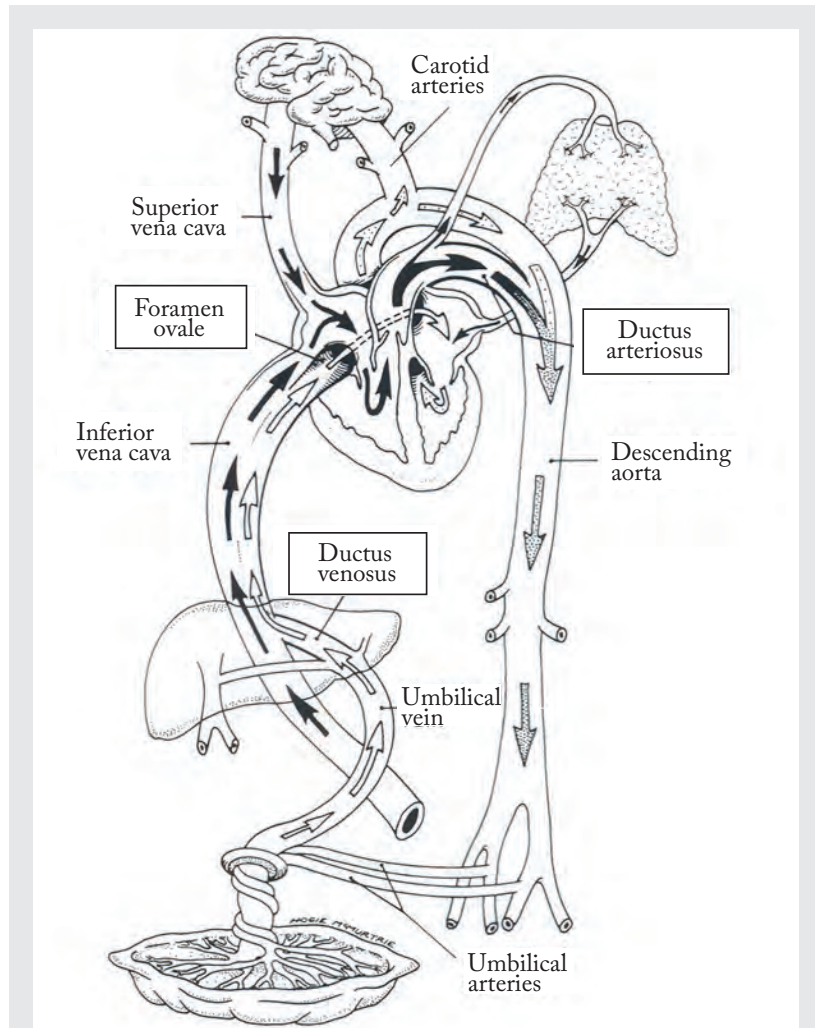

Clamping of umbilical vessels removes the low-resistance placental circulation and raises the systemic blood pressure. The pulmonary vascular resistance decreases with lung expansion and increased oxygenation, resulting in increased pulmonary blood flow (Figure 6). As a result, the pulmonary venous return and left atrial pressure increase. In full-term infants, this results in closure of the two fetal shunts, thus creating normal systemic circulation. This process takes about 24–48 hours. Anatomic closure follows in about 8–10 days, causing permanent closure of the shunts.

### Abnormal Physiologic Events at Birth

If the lungs fail to expand after birth and spontaneous respiration is not established, the result is residual lung fluid, hypoxemia and acidosis, and hypercapnia caused by inefficient breathing and pulmonary vasoconstriction,

leading to reduced pulmonary blood flow. The systemic vascular resistance does not increase. The fetal shunts remain open and continue to shunt blood. The direction of the shunting is dependent on the resistance present in the lungs and the systemic circulation. In such situations, complications arise, leading to the use of mechanical ventilation and blood pressure medications to support the systemic blood pressure.

An abnormal physiologic transition sometimes requires significant resuscitative measures in the neonate, including cardiopulmonary resuscitation with bag-mask ventilation, chest compressions, and use of medications such as epinephrine when indicated. The course of events that follows abnormal physiologic transition at birth can result in different types of complications in the premature and full-term infant. Some of these complications are discussed briefly later in this chapter.

### Initial Stabilization and Assessment

When an infant is born, the first step in the stabilization process is thermoregulation. Newborn infants have immature thermoregulatory systems and lack adequate body fat. The large surface area-to-body mass ratio is susceptible to cold stress. Both of these factors predispose the neonate to hypothermia. This is especially important in a term or preterm neonate who is hypoxic at birth. Hypoxia blunts the normal response to cold and can make the neonate hypothermic. Hypo- and hyperthermia both can lead to adverse neurologic consequences. It is therefore essential to gain control of body temperature as soon as possible. To prevent excessive heat loss from the body caused by external environmental factors, the neonate must be received in a warm blanket and dried immediately. The full-term neonate acquires the ability to maintain adequate body temperature soon after birth. In some cases, however, the neonate may need to be placed under a radiant warmer for 24–48 hours to maintain normal body temperature. Premature infants are initially placed under radiant warmers and then transitioned to thermoregulated incubators as soon as possible after stabilization. They stay in the controlled-temperature environment until they have acquired an adequate surface area-to-body mass ratio, typically around 2000 g of body weight.

### APGAR SCORES

Initial assessment of a newborn infant during the resuscitative phase includes assessment of appearance and vital signs, APGAR scores (Table 1) (Reference 7), gestational age assessment, and measurement of weight, length, and head circumference as well as a complete physical examination to identify any congenital anomalies. The weight, length, and head circumference measurements are plotted on corresponding sex-appropriate growth charts available for infants from birth to 36 months of age. The growth charts for full-term infants are easily available and reliable. The neonate's initial weight, length,

and head circumference are plotted on the day of birth, and the growth thereafter is followed through 36 months of life to determine whether it is normal. See the Introduction to Pediatrics chapter for examples of growth charts. There are separate charts for boys and girls. More charts can be viewed at the following Web site: [www.cdc.gov/nchs/data/series/sr\\_11/sr11\\_246.pdf](http://www.cdc.gov/nchs/data/series/sr_11/sr11_246.pdf) (Reference 8). Separate charts exist for premature infants beginning at 22 weeks' gestation. These charts allow a comparison of an infant's growth, first with the fetus as early as 22 weeks and then with the term infant to 10 weeks' corrected gestational age (Reference 9).

### GESTATIONAL AGE ASSESSMENT

The best estimate of gestational age is antenatal ultrasonography. If the infant's gestational age is uncertain, it can be determined to within around 2 weeks using a standardized scoring system such as the Ballard scoring method (Reference 10). The New Ballard Score is a set of procedures developed by Jeanne L. Ballard, M.D., to determine gestational age through the neuromuscular and physical assessment of a newborn infant, including the extremely premature newborn infant. The method uses score sheets for neuromuscular and physical maturity and assigns scores for each. The gestational age is derived from these scores.

### CARING FOR THE FULL-TERM NEONATE

#### Full-term Healthy Neonate

A normal nursery can provide routine care for healthy, full-term newborn infants born at 37 weeks or more gestation. Neonates born at 35 weeks' gestation weighing at least 2000 g and otherwise healthy may also be cared for in a normal nursery. Close monitoring for respiratory distress, poor color, diaphoresis, jitteriness, or abnormal tone should occur for the first 6–12 hours of life.

**Table 1.** APGAR Scoring System<sup>a</sup>

Sign	0	1	2
Heart rate	Absent	< 100 beats/minute	> 100 beats/minute
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Vigorous cry
Color	Pale	Cyanotic	Completely (whole body) pink

<sup>a</sup>In practice, patients are scored at 1 and 5 minutes of life. Maximum score = 10; minimum score = 0. Adapted with permission from Apgar V. A proposal for a new method of evaluation of the newborn infant. *Curr Res Anesth Analg* 1953;32:260–7.

### **Feedings**

These neonates should be offered feeding by mouth. Breast milk is the preferred nutrition for a newborn infant. Breastfeeding is initiated shortly after birth once the neonate shows signs of hunger. However, at times, breast milk must be avoided because of maternal intake of prescription drugs that may cross into breast milk and adversely affect the neonate. If breast milk is unavailable or the mother chooses not to breastfeed, an iron-fortified cow milk-based infant formula should be used. Most term infants will take 15–30 mL every 3–4 hours in the first 1–3 days of life and about 75–90 mL by day 5 of life.

### **Vitamin K**

The American Academy of Pediatrics recommends that every neonate receive a single intramuscular dose of 0.5–1 mg of vitamin K (phytonadione) within 1 hour of birth to prevent vitamin K-dependent hemorrhagic disease of the newborn. This is a neonatal condition caused by vitamin K deficiency, the combined result of a lack of unbound maternal vitamin K, immaturity of the fetal liver, and lack of vitamin K-producing bacteria in the infant colon. Clinically, the condition may arise abruptly in the early postpartum period with spontaneous nasogastric or intracranial hemorrhage. The condition affects up to 1 in 1000 neonates and carries 5% to 30% mortality, if untreated. The condition may be more common in breastfed infants and is more severe and of earlier onset in infants of mothers receiving anticonvulsives. Breastfed infants are at higher risk of developing hemorrhagic disease because of low concentrations of vitamin K in breast milk together with colonization of bacteria in the gut that are unable to produce vitamin K. Vitamin K does not cross the placental wall, resulting in low stores in the newborn infant.

### **Eye Prophylaxis**

All newborn infants should receive an application of a 1- or 2-cm ribbon of sterile erythromycin (0.5%) eye ointment for prophylaxis against gonococcal ophthalmia neonatorum, ensuring that the treatment reaches all parts of the conjunctival sac.

### **Newborn Screening**

Each state has developed guidelines for newborn screening. This is a preventive public health strategy used for early identification of treatable disorders that significantly affect health and development. The disorders screened vary from state to state depending on the prevalence of the disorders in each state. Some of the more commonly screened disorders may include disorders of amino acid metabolism, fatty acid oxidation disorders, organic acid disorders, endocrine disorders such as congenital

hypothyroidism and congenital adrenal hypoplasia, hemoglobinopathies such as  $\beta$ -thalassemia, cystic fibrosis, and galactosemia and biotinidase deficiencies. Screening for these disorders has had a significant impact on the morbidity and mortality from metabolic disorders.

### **Physiologic Neonatal Jaundice**

Neonatal physiologic jaundice (also referred to as indirect hyperbilirubinemia) is a condition in which the level of unconjugated bilirubin is increased because of the infant's inability to rapidly clear it from the body. It can occur in both premature and full-term infants. Jaundice, usually seen first in the face, progresses to the trunk and extremities. Because high bilirubin levels stain the skin and sclera of the eye yellow, the condition is often first recognized by parents who bring the yellow staining to the attention of the health care providers. Two-thirds of all newborn infants will appear jaundiced during the first few days of life. In most cases in which the infant is feeding well, this condition will resolve itself without intervention. Breastfed full-term newborn infants have higher bilirubin levels than formula-fed infants. Frequent breastfeeding every 2–3 hours helps resolve this problem.

When feeding cannot be established well in the first few days of life, which is most often the case in premature infants but can also occur in full-term infants, hyperbilirubinemia may become a pathologic issue needing intervention. If intervention is needed, the American Academy of Pediatrics guidelines for evaluation and treatment of jaundice should be followed (Reference 11). Untreated indirect hyperbilirubinemia can have severe neurologic consequences. Acute bilirubin encephalopathy can cause lethargy, hypotonia, and poor suck. In advanced stages, irreversible neurologic damage can occur and may sometimes lead to coma and death if left untreated for a prolonged time.

### **Immunizations**

All neonates (premature, low birth weight, and full term) born to mothers who are positive for hepatitis B surface antigen must routinely receive hepatitis B immunoglobulin (HBIG) (0.5 mL intramuscularly) and hepatitis B vaccine (HBV) (0.5 mL intramuscularly) within 12 hours of life. This prevents or significantly reduces the vertical transmission of the disease in infants born to mothers with a positive test for hepatitis B surface antigen. If HBV cannot be administered to a full-term infant together with or soon after HBIG, it should be administered within the first 7 days of life. For premature infants or sick low-birth-weight infants in whom the vaccine cannot be given within the prescribed period with HBIG, it must be given within the first month of life or at the earliest opportunity when the infant is clinically able to tolerate the

vaccine. All infants born to hepatitis B surface antigen–positive mothers should receive additional HBV at 1, 2–3, and 6–7 months of chronologic age for four doses total. Full-term neonates born to hepatitis B surface antigen–negative mothers should receive the vaccine by 2 months of age. For preterm infants weighing less than 2 kg born to hepatitis B surface active antigen–negative mothers, the optimal time to initiate the first dose of HBV is at 30 days' chronologic age if medically stable or at hospital discharge if stabilization occurs before 30 days of age (Reference 12). (For further details, please refer to the Pediatric Vaccines chapter.)

### Full-term Sick Neonates

Many full-term neonates are at risk of developing perinatally acquired infections. Neonatal sepsis in full-term newborn infants is rare, but it can be potentially life threatening. Risk factors for acquiring such infections include prolonged rupture of fetal membranes, maternal chorioamnionitis, maternal colonization with group B *Streptococcus*, prematurity, and maternal urinary tract infection. Thus, the most common organisms found in the perinatal period include group B *Streptococcus* and *Escherichia coli*. These sick full-term neonates require cardiorespiratory support and intensive nursing care. Such neonates are admitted to the neonatal ICN, where they are assessed for sepsis. Other common diseases found in such infants that may require ICN admission and close observation include transient tachypnea of the newborn period, meconium aspiration syndrome, neonatal seizure, neonatal hypoxic-ischemic encephalopathy, acute hypoglycemia in infants of diabetic mothers, and congenital surgical or cardiac conditions.

These neonates are cared for in the ICN until the underlying illness has resolved or been surgically treated and the infant is fully recovered, able to maintain temperature without assistance, and able to breathe on its own, with well-established nutrition to meet nutritional needs for growth and development.

## SELECTED COMMON DISEASES OF THE FULL-TERM NEONATE

### Infants of Diabetic Mothers

Diabetes mellitus is a common medical complication of pregnancy affecting 2%–3% of all pregnancies. Infants of diabetic mothers are generally large for gestational age or macrosomic. They are at risk of developing cardiomegaly, hyperbilirubinemia, and polycythemia, and they may have congenital malformations. Good control of maternal glucose concentrations during pregnancy is important for the well-being of the fetus. Because of the increased glucose demand by the growing fetus, the plasma glucose concentrations in normal and

diabetic pregnancies are lower than in the immediate postpartum period. For women who develop gestational diabetes, as well as for those who were diabetic before becoming pregnant, maintaining tight glucose control and glucose concentrations near normal values for adults is essential.

These infants may develop acute hypoglycemia (blood glucose less than 35 mg/dL in full-term infants and less than 25 mg/dL in premature infants) in the immediate postnatal period. Low glucose concentrations may cause lethargy, hypotonia, seizures, poor feeding, apnea, or jitters. Metabolic derangements such as hypocalcemia and hypomagnesemia are also common.

Fluids and electrolytes are the mainstay of treatment. Acute hypoglycemia should be treated with an initial bolus dose of glucose 10% (2–5 mL/kg), and early, frequent oral feeding should be instituted. Intravenous continuous glucose infusion, with electrolytes if needed, should be initiated to deliver an initial glucose load of 7–8 mg/kg/minute. This can gradually be weaned as oral feedings are established. Frequent blood glucose concentration checks are needed until a stable oral nutritional regimen is established that maintains blood glucose in the normal range (40–60 mg/dL). Symptomatic treatment of respiratory distress is essential.

### Meconium Aspiration

Meconium is the earliest stools of an infant. It is composed of materials ingested while the infant is in the uterus and consists of intestinal epithelial cells, lanugo, mucus, amniotic fluid, bile, and water. Meconium is almost sterile, viscous, and sticky like tar, with no odor. It should be completely passed by the end of the first few days of life, with the stools progressing toward yellow (digested milk). The presence of meconium in the amniotic fluid suggests an in utero asphyxia episode. Aspiration of this meconium can lead to significant morbidity and mortality if left untreated. The passage and aspiration of meconium are not seen in neonates younger than 34 weeks' gestation. At delivery, if the amniotic fluid is meconium stained, then aggressive suctioning of the meconium at the perineum is indicated. After the neonate is delivered, the oropharynx should be suctioned below the vocal cords to ensure that the meconium is not aspirated into the lungs. Meconium aspiration can lead to chemical pneumonitis and respiratory distress, with severe cases requiring mechanical ventilator support. Supportive measures may include the use of vasopressors for maintaining blood pressure, intravenous fluids, and sedatives and analgesics to keep the neonate compliant with mechanical ventilation. In severe cases, pulmonary hypertension may develop. Inhaled nitric oxide is often used as a pulmonary vasodilator in such cases.

## CARING FOR THE PREMATURE NEONATE

Premature infants are born at younger than 37 weeks' gestation. The shorter the pregnancy, the greater the risks of mortality and morbidity. Organ development corresponds directly to gestational age. The earliest gestational age at which the infant has at least a 50% chance of survival is generally believed to be 24 weeks, although rare exceptions exist. Surviving premature neonates are at risk of short- and long-term complications of gastrointestinal issues (necrotizing enterocolitis [NEC]), respiratory issues (respiratory distress syndrome and chronic lung disease), neurologic issues (apnea of prematurity, hypoxic-ischemic encephalopathy, retinopathy of prematurity, cerebral palsy, and developmental delay), cardiovascular issues (patent ductus arteriosus [PDA]), and hematologic issues (pathologic jaundice). In addition, premature neonates are at higher risk of infectious complications (sepsis and pneumonia).

In developed countries, all premature neonates are cared for in ICNs. Modern ICNs allow continuous cardiorespiratory monitoring, administration of intravenous fluids and nutrition, mechanical ventilator support, and administration of a variety of intravenous medications. However, premature infants cared for in an ICN are also at greater risk of nosocomial infections, which contribute to the morbidity and mortality of these patients.

### Selected Common Diseases and Complications of the Premature Neonate

#### *Apnea of Prematurity*

Premature neonates have an immature respiratory pattern because of an underdeveloped brain stem. Periodic breathing (short recurring pauses in respiration lasting 5–10 seconds) is common in prematurity and considered the normal respiratory pattern at that age. A respiratory pause that is prolonged (more than 20 seconds) with complete cessation of breathing or one that is associated with cyanosis and/or bradycardia is defined as apnea of prematurity. The problem increases in severity and frequency with decreasing gestational age. The causes of apnea with or without bradycardia and desaturation may be multifactorial and may include thermal instability, metabolic disorders (electrolyte abnormalities and hypoglycemia), central nervous system disorders (intraventricular hemorrhage, seizures, and encephalopathies), infection, decreased oxygen delivery to the brain (secondary to PDA, hypotension, shock), or airway obstruction (from an ill-positioned neck or a mechanical obstruction of the oropharynx), all of which should be ruled out when apneic episodes begin. Once other causes are ruled out, the diagnosis of true idiopathic apnea of prematurity is confirmed.

Treatment includes nonpharmacologic and pharmacologic measures. Nonpharmacologic measures include tactile stimulation, increasing fraction of inspired oxygen ( $\text{FIO}_2$ ), and use of respiratory support such as continuous positive airway pressure or mechanical ventilation.

Pharmacologic measures primarily include the use of methylxanthines, caffeine and theophylline, which theoretically increase the sensitivity of the chemoreceptors in the brain to carbon dioxide, although this mechanism has not been proved in the human neonate (Reference 13). Apnea of prematurity is generally resolved at greater than 34 weeks' corrected gestational age. At this time, all neonates should be challenged to breathe without the help of methylxanthines, and treatment should be weaned off, preferably before discharge (Reference 14). Further details about apnea of prematurity management are available in the Apnea of Prematurity chapter.

#### *Necrotizing Enterocolitis*

Necrotizing enterocolitis is among the most common gastrointestinal problems in the premature neonate. It is characterized by partial- or full-thickness intestinal ischemia. Although the terminal ileum is usually involved, NEC can occur in any part of the intestine. The exact cause of NEC is unknown, but factors leading to intestinal ischemia are implicated. Reperfusion injury after acute ischemia to the intestines has been proposed as a mechanism for injury. The most commonly known risk factors include prematurity, formula feeding (especially hyperosmolar formulas), neonatal stress, infection, and surgery in the newborn period. Feeding precedes NEC symptomatology in most NEC cases. It is unclear whether the volume or rate of feeding plays a major role in the pathogenesis of NEC. Overall, NEC appears to be a multifactorial disorder that requires a delicate balance between intestinal perfusion, intestinal flora, and type of enteral nutrition.

The clinical features of NEC are nonspecific. Temperature instability, lethargy, feeding intolerance, and abdominal distension are generally the first signs. Blood may be present in the stools. Apnea, bilious vomiting, and signs of shock may develop with advanced disease possibly caused by infection from enteric bacteria. An abdominal radiograph in NEC is characteristic with pneumatosis intestinalis (free air in the peritoneum) and portal venous gas in advanced disease.

Treatment includes bowel rest, nasogastric suction, intravenous fluids (including parenteral nutrition), and broad-spectrum antibiotics for about 2 weeks. Medications to support blood pressure may be necessary. Intestinal perforation warrants surgical intervention. Occasionally, portions of the intestine may become necrotic and require surgical removal. These infants have

permanent short bowel. Long-term complications of NEC include the formation of strictures in the affected part of the intestine and difficulty with feeding, especially in short bowel syndrome (Reference 15).

### *Neonatal Respiratory Distress Syndrome*

Neonatal respiratory distress syndrome (NRDS) is a condition produced by surfactant deficiency in the lungs. It is present to some extent in all premature infants born younger than 34 weeks' gestation. The extent of deficiency is inversely proportional to gestational age. The surfactant is a substance consisting of phospholipids and proteins that is naturally produced by the body. Its function is to produce surface tension at the interface of the alveoli and the air in the lungs and keep the alveoli open so that adequate gas exchange may occur. Neonatal respiratory distress syndrome is most common in VLBW and ELBW infants, although it does occur in low-birth-weight infants. The ELBW infants are intubated for mechanical ventilator support within minutes of birth. These infants may not exhibit the typical clinical course of NRDS.

Early signs and symptoms of surfactant deficiency include difficulty in initiating normal respirations, expiratory grunting, sternal and intercostal retractions, nasal flaring, cyanosis on room air, and tachypnea. Chest radiography shows a reticulogranular, ground-glass pattern with air bronchograms, which is characteristic of NRDS. Physiologically, there is reduced lung compliance, ventilation perfusion mismatch caused by decreased alveolar ventilation resulting in hypoxemia, and hypercarbia with metabolic acidosis if the hypoxemia is severe.

Treatment of NRDS consists primarily of surfactant replacement therapy and mechanical ventilator support. Premature infants may be administered surfactant as soon as the diagnosis of NRDS is confirmed by radiologic examination and intubation has been performed. In ELBW infants, it may be beneficial to administer prophylactic surfactant as soon as possible after intubation. Surfactant administration results in improved lung compliance with improved oxygenation and lower  $\text{FIO}_2$  requirements. Improved compliance allows effective ventilation at lower peak inspiratory pressures, thus reducing the potential for lung injury. Complications of surfactant treatment, such as oxygen desaturation and bradycardia, are common secondary to airway occlusion during surfactant administration. A rapid change in lung compliance may result in hyperventilation and overdistension, potentially increasing the risk of pneumothorax.

Several surfactant products are commercially available. These and other options for treating neonatal respiratory distress syndrome are described in detail in the Neonatal Respiratory Distress Syndrome and Bronchopulmonary Dysplasia chapter (Reference 16).

### *Patent Ductus Arteriosus*

Patent ductus arteriosus (Figure 6) is an essential shunt in utero. Once the fetus is delivered, successful transition from fetal to neonatal circulation is essential and occurs naturally in full-term neonates. Patent ductus arteriosus results when such transitions are incomplete or do not occur. The incidence of PDA is inversely related to gestational age. An untreated PDA can result in significant morbidity and mortality. Congestive heart failure and hypoperfusion of the brain (increased potential for intraventricular hemorrhage), kidneys (acute tubular necrosis), and intestine (potential for NEC) secondary to PDA can cause increased morbidity.

Clinical diagnosis of a PDA is made when a systolic murmur is detected together with a hyperdynamic precordium, bounding palmar pulses, increased pulse pressure, and signs of congestive heart failure (tachypnea, tachycardia, edema, and hepatomegaly). Occasionally, refractory hypotension or pulmonary hemorrhage is also seen. Chest radiography reveals pulmonary edema and an enlarged heart. Definitive diagnosis is made by an echocardiogram that shows a PDA with a left-to-right shunt detected by Doppler studies.

Treatment of PDA is warranted in neonates who are symptomatic from it. Management of PDA falls into three categories: medical, pharmacologic, and surgical. Medical management includes use of fluid restriction and diuretics to manage congestive heart failure and allow the PDA time to close physiologically. This approach is sometimes successful, with some PDAs closing permanently, whereas others close transiently and reopen, requiring a more definitive intervention. Fluid restriction severely restricts the caloric intake of an infant. Electrolyte abnormalities and need for higher mechanical ventilator settings are common with this approach.

Pharmacologic management includes the use of drugs that cause ductal closure. The ductus arteriosus is sensitive to prostaglandins. While in utero, its patency is maintained by the high levels of circulating prostaglandins produced by the placenta. The arterial oxygen concentration, which is low in utero, also plays a role in keeping the ductus open. Once the neonate is separated from the placenta, prostaglandin concentrations are decreased and oxygenation is established, increasing oxygen concentrations in the blood. Both of these factors aid in ductal closure. Although this process occurs as part of normal adaptation in the full-term infant, in premature neonates the circulating prostaglandin levels remain high after birth, allowing the ductus to remain open in the postnatal period.

Nonsteroidal inflammatory agents are useful in the treatment of PDA by inhibiting prostaglandin production. Both intravenous ibuprofen and indomethacin are effective in ductal closure. Intravenous ibuprofen has some advantages over indomethacin such as

reduced adverse effect on renal function compared with the severe oliguria often seen with intravenous indomethacin (Reference 17). Surgical ligation is indicated when pharmacologic treatment has failed or when it is contraindicated.

## OTHER COMMON CONDITIONS IN FULL-TERM AND PREMATURE NEONATES

### Neonatal Sepsis

Around 1–5 of 1000 newborn infants are afflicted with sepsis. The incidence increases to 40–50 in 1000 in infants weighing less than 2500 g, with further increase as birth weight decreases (References 18, 19). Neonatal sepsis at any stage carries significant morbidity and mortality. Surviving infants may sustain significant neurodevelopmental sequelae.

The pathogens responsible during early sepsis (younger than 5 days of life) are those vertically transmitted at birth. Group B *Streptococcus* and coliforms (*E. coli*) are the most common organisms colonizing the birth canal. Clinical signs and symptoms of neonatal sepsis are nonspecific and may include temperature instability, hypotension, frequent oxygen desaturations, apnea, increased work of breathing, and poor weight gain. Early sepsis is suspected in infants of mothers with chorioamnionitis, ill infants of mothers with unknown group B streptococcal status, prematurity when there is no obvious explanation for premature delivery, and prolonged rupture of membranes (generally 18–24 hours before birth).

Late-onset infections are generally those that occur after the first 5 days of life. The most common pathogens suspected in late-onset sepsis may be community acquired (*Streptococcus pneumoniae*, *Haemophilus influenzae*, or late-onset group B streptococcal infections) or hospital ICN acquired (coagulase-negative and coagulase-positive staphylococci, *E. coli*, *Enterococcus* spp., and *Klebsiella* spp.). Clinical signs and symptoms of late-onset sepsis are also nonspecific and may include manifestations such as lethargy, poor feeding, apnea, jaundice, cyanosis, hypotension, metabolic acidosis, and respiratory distress. Common risk factors include prolonged instrumentation such as the presence of indwelling central or peripheral catheters for intravenous access, endotracheal tubes for mechanical ventilation, repetitive or prolonged courses of antibiotics, and other nosocomial risk factors such as human handling of ELBW infants.

Prompt diagnosis of early- and late-onset infections and initiation of early empiric treatment until microbiologic results are returned are essential. Once the microbiologic results are known, therapy can be tailored on the basis of institution-specific susceptibility results. Doses and duration of selected antibiotic regimens

should consider efficacy, toxicity, and appropriate coverage of suspected organisms and the site of infection. A detailed discussion of the treatment of neonatal infections is available in the Neonatal Sepsis chapter.

### Seizure Disorders

In pre- and full-term infants, seizures can be caused by a wide variety of underlying conditions. Repetitive seizures are associated with increased morbidity and mortality and require prompt treatment. Neonatal seizures are relatively common and rarely idiopathic. In most cases, they are of consequence if there is an underlying cause that should be sought and treated. Neonatal seizures are clinically distinct from those in older infants and children. They are generally more difficult to diagnose clinically and may require electroencephalogram (EEG) monitoring. Neonatal jitteriness is sometimes confused with seizures. The two entities can be distinguished by the effectiveness of applying mild pressure to the body, which will stop jitteriness but not seizures. More than 50% of neonatal seizures occur on the first day of life (Reference 20). Risk factors include hypoxic-ischemic encephalopathy, electrolyte abnormalities, hyperbilirubinemia, inborn errors of metabolism, drug toxicity (including in utero exposure immediately before delivery, which should be suspected if seizures occur within a few hours of birth), drug withdrawal, and idiopathic neonatal seizures. Seizures in neonates can be subtle, focal, or generalized.

Diagnosis is made on the basis of the results obtained in a complete workup for metabolic derangements, labor and delivery history, toxicology screening to identify in utero drug exposure, and imaging studies of the brain, including a video EEG if warranted.

Treatment of neonatal seizures involves treating the underlying cause, if one is identified, as well as the seizures themselves. Etiology-specific therapy is critical because it may prevent further brain injury. This is particularly true for the seizures associated with some metabolic disorders (e.g., hypoglycemia, hypocalcemia, and hypomagnesemia) and with central nervous system or systemic infections. Furthermore, neonatal seizures may not be effectively controlled with antiepileptic drugs unless their underlying cause is treated. Pharmacologic management of the seizures themselves is aimed at halting seizure activity. Intravenous phenobarbital and phenytoin are used as first-line agents (Reference 21). Benzodiazepines may be used for immediate control of status epilepticus. Appropriate monitoring of plasma concentrations of drugs as well as adverse effects is essential. Other supportive measures such as vasopressors for hemodynamic support and mechanical ventilation for respiratory support may be necessary.

## CONSIDERATIONS FOR MEDICATION ADMINISTRATION IN THE NEONATE

Neonates in the ICN pose unique challenges to the system for prescribing, dispensing, administering, and monitoring medications, primarily because of the lack of available well-researched data on how to use medications effectively in this population (Reference 22). Issues of drug administration in the neonate can be categorized into three groups: ADME, choice of administration route, and dosage preparation and drug compatibility. Physiologic differences between children and adults are well recognized. In pre- and full-term neonates, these differences are enhanced a step further. In fact, the physiologic differences between pre- and full-term neonates are significant enough to warrant dosing modifications. Nevertheless, little is known about the ADME of many drugs used in this population. One must often use one's knowledge of the physiologic basis of drug effectiveness and the dosage form at hand to determine a safe and effective dose and route of drug administration in a neonate. (See the Pediatric Pharmacokinetics chapter.) The second issue is safe drug administration. Although many different administration routes are possible for many drugs, in neonates, there is a limitation on the use of these formulations because of insufficient absorption of the active compound by oral, rectal, or intramuscular routes. Most drugs in critically ill neonates are administered intravenously.

### Intravenous Access and Medication Administration (References 23, 24)

Intravenous drug administration requires the infant to have an intravenous catheter placed for drug administration. The catheter may be placed in a large vein (central venous catheter) or in a small peripheral vein. The insertion site has implications in drug administration because drugs with a high osmolar load may cause vein irritation if administered by the peripheral vein route. Decisions regarding drug concentrations and acceptable osmolarities must be made with knowledge regarding catheter placement. Most intravenous drugs used in neonates will require further dilution before administration to measure accurately. The dispensing pharmacists must provide a chemically stable, appropriately diluted solution that may be safely administered without the risk of vein irritation and fluid overload in the infant, who may have fluid restrictions merely because of size.

Intravenous access is often very limited in neonates. Once the drug is received at the bedside, a determination must be made about its compatibility with other solutions running through the intravenous catheter. Incompatibilities can result in precipitation of the drug in the catheter, and infused precipitate can act as a nidus for clot formation in the vein, leading to compromised

blood flow. Smart pumps are routinely used in ICNs for drug administration. Although these infusion pumps are designed for safe drug administration, errors in pump setting can lead to medication administration errors. A streamlined medication use process from prescribing to drug administration is necessary for the safe and effective administration of medications in the ICN (Reference 25).

### Drug Dosing in Neonates

Drug dosing in neonates is generally based on weight. Factors such as organ maturation may also be considered. Thus, neonatal dosing recommendations may be given on the basis of weight as well as postnatal age or postconceptional age. The ADME of a drug may vary depending on gestational age and/or postnatal age. There are few dosing guidelines available for commonly used drugs in the neonate. Neonatal pharmacy practitioners must be aware of the current literature and use their knowledge of pharmacokinetics and pharmacodynamics to determine a safe dose. Neonates will lose about 10% of their body weight in the first week of life. Thus, it is appropriate to use birth weight as dosing weight during this time. Once the neonate has regained birth weight, subsequent dosing may be based on actual weight. However, this may not always be possible in critically ill neonates who may have increased total body weight because of water retention and body edema. In such cases, an estimate of dry weight corresponding to the infant's gestational and postnatal age may be obtained from standardized growth charts available from sources such as the CDC.

## VITAL SIGN AND LABORATORY ASSESSMENT

### Temperature

It is unusual for neonates to develop fever except in response to environmental factors. Rectal temperature is less likely to be affected by environmental changes unless the changes are prolonged; rectal temperature is thus a better measure than skin temperature. A sustained rectal temperature of more than 38°C (100.4°F) requires further evaluation of the neonate for infectious or neurologic issues. Premature infants often become hypothermic in response to environmental temperature fluctuations. Prolonged hypothermia also requires further evaluation.

### Respiratory and Heart Rate

The respiratory rate in a full-term neonate is measured by counting chest movements for a full minute. The normal rate in a full-term healthy neonate is 30–60 inspirations per minute. Premature neonates may have respiratory rates at the upper end of normal range.

The heart rate in healthy full-term infants is generally 110–160 beats/minute. Premature neonates have resting heart rates at the upper end of normal range. Heart rate may vary significantly in sick full-term and premature neonates. Tachycardia, defined as a heart rate persistently greater than 160 beats/minute, warrants further investigation. In preterm infants, a heart rate persistently less than 90 beats/minute constitutes bradycardia that requires further investigation.

### Blood Pressure

Blood pressure varies widely at different gestational ages. At least three separate measurements are needed before diagnosing hypertension in a neonate. The range of normal blood pressures in the neonate depends on the method of measurement (invasive vs. noninvasive measurements) as well as gestational age. In general, the mean arterial pressures provide a better estimate of blood pressure than systolic or diastolic blood pressure alone because it considers both the systolic and diastolic blood pressure (mean arterial pressure =  $[(2 \times \text{diastolic}) + \text{systolic}] / 3$ ). The average systolic, diastolic, and mean blood pressure during the first 12 hours of life in normal newborn infants grouped according to birth weight have been described (Reference 26). Sick newborn infants may experience significant blood pressure fluctuations and may deviate substantially from the normal blood pressures shown in this reference.

Hypotension is more common in critically ill infants. The treatment threshold for hypotension varies significantly depending on whether the hypotension is compromising systemic perfusion measured by clinical indicators such as capillary refill, skin color, and urine output. Thus, the perfusion status of an individual infant is a far better determinant of the significance of hypotension.

### Laboratory Values

There are no neonate-specific reference ranges of laboratory values for commonly used tests such as blood chemistries, hematology tests, or liver function tests. These values in neonates are generally compared with those in older children or adults. The serum creatinine in the first 48 hours of life is not a reliable indicator of kidney function in the neonate because it often reflects the mother's serum creatinine. In the full-term infant, the values reflect true renal function in about 48 hours after feedings or intravenous hydration is established.

The reference ranges used also do not differ for pre- and full-term neonates. However, ELBW infants pose a particular challenge in maintaining a normal electrolyte balance because of their inability to conserve sodium and bicarbonate given their immature kidney function. These infants often have metabolic acidosis

and hypernatremia during the first few days of life. In premature infants, it is difficult to predict when renal function will become normal because renal dysfunction may be a consequence of prematurity as well as underlying illness. In the neonatal period, it is often more useful to follow trends in laboratory values rather than single values to assess the fluid and electrolyte status and organ function.

### FUTURE OF NEONATAL PHARMACY PRACTICE

Neonatal pharmacy practice requires skilled personnel with a clear understanding of the impact of the ontogeny of organ function on the ADME and the pathogenesis of neonatal disease states. Appropriately experienced and trained neonatal clinical pharmacy practitioners are vital to the safe and effective treatment of diseases in a very special subpopulation at high risk of adverse events. Despite advances in diagnostic technology and newer technologically advanced methods of drug preparation and administration, this population remains vulnerable to medication errors. Drug dosing in neonates continues to remain a challenge after more than 50 years of the inception of this science and continues to test the knowledge and skills of the neonatal practitioner, who must make clinical judgments on the basis of knowledge of the disease states, pharmaceutical dosage forms, and existing drug dosage information in older populations. The need for such skills is now recognized by pediatric health care professionals outside the pharmacy profession (Reference 27). Neonatal clinical pharmacy practitioners of the future will require advanced training and experience in domains such as epidemiology, pathophysiology, and pharmacotherapeutics of neonatal diseases, as well as in-depth knowledge of pharmacokinetics, pharmacodynamics, and pharmacogenomics. They will also need to understand the impact of interplay of these processes on drug disposition and issues in neonatal medication safety, as well as gain expertise in neonatal translational research, to contribute to the current gaps in knowledge of neonatal pharmacotherapeutics.

### CONCLUSIONS

Neonatal-perinatal medicine and neonatal pharmacotherapeutics have progressed significantly since the inception of these sciences in the twentieth century. Challenges of the twenty-first century are highlighted in hope that the advances in understanding of neonatal disease states at the molecular level will allow more targeted drug therapy and advances in neonatal pharmacotherapeutics.

# CHAPTER 4

## MEDICATION SAFETY

Amy L. Potts, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. Provide a background for the basis of medication safety as a national public health initiative.
2. Explain unique differences specific to pediatric patients that make them more vulnerable to adverse events.
3. Describe specific medication error preventive strategies and important considerations for pediatric patients.
4. Describe the role of automation and technology in medication safety.

### ABBREVIATIONS IN THIS CHAPTER

ADE	Adverse drug event
ASHP	American Society of Health-System Pharmacists
BCMA	Barcode medication administration
CDSS	Clinical decision support systems
CPOE	Computerized prescriber order entry
IOM	Institute of Medicine
ISMP	Institute for Safe Medication Practices
PPAG	Pediatric Pharmacy Advocacy Group
TJC	The Joint Commission

### INTRODUCTION

Medical errors are common and costly, and they may result in significant harm or injury (Reference 1). More than a decade ago, the Institute of Medicine (IOM) published its initial report *To Err Is Human*, which served as the catalyst for health care reform and patient safety. The IOM estimated that 44,000–98,000 people experience a medical error annually, making medical errors the eighth leading cause of death, with a multibillion dollar price tag. These alarming statistics provided the necessary leverage to make creating a safer health care system part of the national agenda and a public health concern (Reference 1). In 2001, the IOM released a follow-up report titled *Crossing the Quality Chasm*, which provided the blueprint for health care redesign with a focus on health care technology (Reference 2).

Overall, progress has been made to improve patient safety; however, complete reform of health care has not been achieved (Reference 2). The IOM's most recent progress report, titled *Preventing Medication Errors*, served as a more comprehensive analysis of quality and safety and provided the framework to advance the health care industry to a higher standard (Reference 3). The IOM summarized several recommendations as part of this health care improvement plan, including patient-focused care, medication management standards, implementation of technology, and improved communication among health care providers. The IOM also recommended more funding for medication safety research and additional oversight by regulatory organizations to provide incentives for institutions that have implemented best practices in the safe use of medications. Pharmacy-specific recommendations included monitoring of medication adverse events, patient education and discharge teaching, medication reconciliation, use of electronic prescribing, minimizing alerts from clinical decision support tools, and surveillance of patients at risk of adverse events.

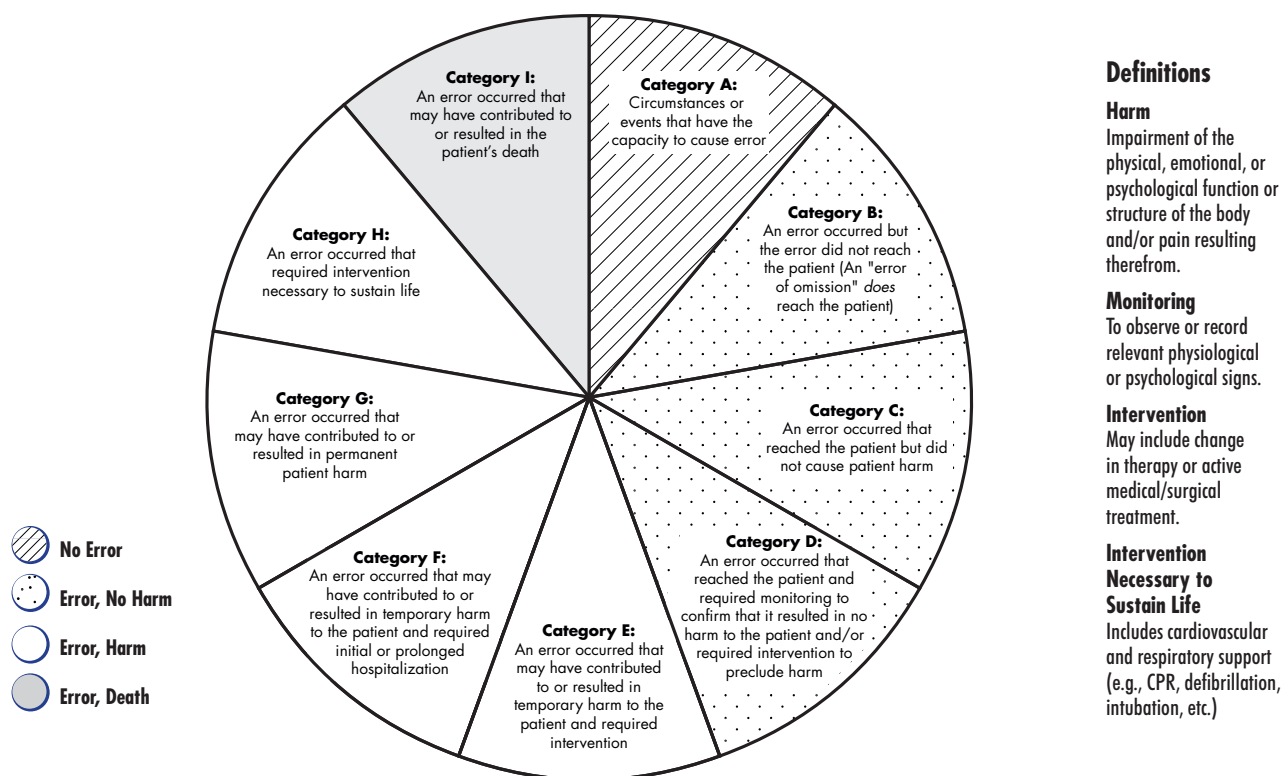

Medications are estimated to harm at least 1.5 million people annually (Reference 3). Pediatric patients are at highest risk because of several unique differences characteristic of this patient population. This chapter provides the foundation for a basic understanding of medication safety and a summary of key preventive strategies, with a focus on pediatric-specific considerations.

### DEFINITIONS

The National Coordinating Council for Medication Error Reporting Program (NCC MERP) defines a medication error as

any preventable event that may cause or lead to inappropriate medication use or patient harm, whereas the drug is in the control of the health care professional, patient, or consumer. Such events may be related to professional practice, health care products, procedures, and medication use systems including prescribing; order communication; product labeling, packaging, and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use. (Reference 4)

## NCC MERP Index for Categorizing Medication Errors

**Figure 1.** National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP) Index for Categorizing Medication Errors (Reference 5).

Copyright 1998–2011 National Coordinating Council for Medication Error Reporting and Prevention. All rights reserved.

The NCC MERP categorizes medication errors on the basis of severity, as shown in Figure 1. Medication errors may or may not result in harm to the patient. An adverse drug event (ADE) occurs as a result of harm caused by the use of a drug. Potential ADEs are events that could result in harm but did not harm the patient. Not all ADEs are the result of a medication error, but all medication errors have the potential to result in an ADE (Reference 6). When a medication error is intercepted before the medication is administered to the patient, it is referred to as a “near miss”. Near misses can provide an opportunity for systems to be reviewed for error-prone steps which allows institutions to be proactive instead of reactive to errors. Specific medication error types and common causes for medication errors are summarized in Table 1 and Box 1.

Adverse drug reactions (ADRs) are defined as unintended, undesired, or excessive responses to therapy that are typically unpreventable and may be associated with

a medication dosed normally over time or with a single dose. Adverse effects of a medication are not ADRs because they are expected and based on known drug properties. ADRs are the unexpected harmful effects of a drug when used appropriately. Pharmacists are responsible for monitoring and reporting ADRs as part of an organized medication safety program (References 6, 8).

### INCIDENCE/FREQUENCY

In 1984, the Harvard Medical Practice Study estimated that 3.7% of hospitalized patients experience an adverse event related to medication therapy. Of these, about 70% were preventable; 30% of patients experienced significant morbidity and mortality as a result (References 9–11). The Adverse Drug Event Prevention Study sought to further describe medication errors and ADEs. This study found that medication-related ADEs occurred commonly in adults at a rate of 6.5 per 100 patient admissions, and most were preventable. In

**Table 1.** Types of Medication Errors<sup>a</sup> (Reference 7)

Type	Definition
Prescribing error	Incorrect drug selection (based on indications, contraindications, known allergies, existing drug therapy, and other factors), dose, dosage form, quantity, route, concentration, rate of administration, or instructions for use of a drug product ordered or authorized by physician (or other legitimate prescriber), illegible prescriptions, or medication orders that lead to errors that reach the patient
Omission error <sup>b</sup>	The failure to administer an ordered dose to a patient before the next scheduled dose, if any
Wrong time error	Administration of medication outside a predefined time interval from its scheduled administration time (this interval should be established by each individual health care facility)
Unauthorized drug error <sup>c</sup>	Administration to the patient of medication not authorized by a legitimate prescriber for the patient
Improper dose error <sup>d</sup>	Administration to the patient of a dose that is greater or less than the amount ordered by the prescriber or administration of duplicate doses to the patient (i.e., one or more dosage units in addition to those that were ordered)
Wrong dosage-form error <sup>e</sup>	Administration to the patient of a drug product in a different dosage form than ordered by the prescriber
Wrong drug-preparation error <sup>f</sup>	Drug product incorrectly formulated or manipulated before administration
Wrong administration-technique error <sup>g</sup>	Inappropriate procedure or improper technique in the administration of a drug
Deteriorated drug error <sup>h</sup>	Administration of a drug that has expired or for which the physical or chemical dosage-form integrity has been compromised
Monitoring error	Failure to review a prescribed regimen for appropriateness and detection of problems, or failure to use appropriate clinical and laboratory data for adequate assessment of patient response to prescribed therapy
Compliance error	Inappropriate patient behavior regarding adherence to a prescribed medication regimen
Other medication error	Any medication error that does not fall into one of the above predefined categories

<sup>a</sup>The categories may not be mutually exclusive because of the multidisciplinary and multifactorial nature of medication errors.

<sup>b</sup>Assumes no prescribing error. Excluded would be (1) a patient's refusal to take the medication or (2) a decision not to administer the dose because of recognized contraindications. If an explanation for the omission is apparent (e.g., patient was away from nursing unit for tests or medication was unavailable), that reason is documented in the appropriate records.

<sup>c</sup>This would include, for example, wrong drug, a dose given to the wrong patient, unordered drugs, and doses given outside a stated set of clinical guidelines or protocols.

<sup>d</sup>Excluded would be (1) allowable deviations based on preset ranges established by individual health care organizations in consideration of measuring devices routinely provided to those who administer drugs to patients (e.g., not administering a dose based on a patient's measured temperature or blood glucose level) or other factors such as conversion of doses expressed in the apothecary system to the metric system and (2) topical dosage forms for which medication orders are not expressed quantitatively.

<sup>e</sup>Excluded would be accepted protocols (established by the Pharmacy & Therapeutics Committee or its equivalent) that authorize pharmacists to dispense alternative dosage forms for patients with special needs (e.g., liquid formulations for patients with nasogastric tubes or those who have difficulty swallowing), as allowed by state regulations.

<sup>f</sup>This would include, for example, incorrect dilution or reconstitution, the mixing of drugs that are physically incompatible, and inadequate product packaging.

<sup>g</sup>This would include doses administered (1) via the wrong route (different from the route prescribed), (2) via the correct route but at the wrong site (e.g., left eye instead of right), and (3) at the wrong rate of administration.

<sup>h</sup>This would include, for example, administration of expired drugs and improperly stored drugs.

**Box 1.** Common causes of medication errors (Reference 7).

- Ambiguous strength designation on labels or in packaging
- Drug product nomenclature (look-alike or sound-alike names, use of lettered or numbered prefixes and suffixes in drug names)
- Equipment failure or malfunction
- Illegible handwriting
- Improper transcription
- Inaccurate dosage calculation
- Inadequately trained personnel
- Inappropriate abbreviations used in prescribing
- Labeling errors
- Excessive workload
- Lapses in individual performance
- Medication unavailable

addition, a systems analysis of ADEs found that the most common system defects included a lack of communication and readily accessible drug and patient information in a timely manner (References 12, 13). A later study reported the incidence of medication errors in hospitalized adults as 5.3 per 100 medication orders, with most errors being preventable and occurring at the point of ordering (References 14, 15).

Adverse drug events occur more frequently in pediatric patients than in adults (References 16–18). In 2001, the incidence of medication errors in pediatric patients was reported as 5.7 per 100 medication orders. Furthermore, these researchers classified medication errors as actual or potential errors. They found that most (79%) potential ADEs in children occurred at the stage of ordering, with most involving dosing errors. The most common drug classes included intravenous anti-infectives, electrolytes and fluids, and analgesics and sedatives (Reference 16). Subsequently, a Sentinel Event Alert aimed at preventing pediatric medication errors was issued by The Joint Commission (TJC), which reported that the most common types of errors in children include dosing error (37.5%), omission error (19.9%), wrong drug (13.7%), and prescribing error (9.4%). The most common causes include performance deficit (43%), knowledge deficit (29.9%), procedure/protocol not followed (20.7%), and miscommunication (16.8%) (Reference 17).

## VULNERABILITY OF PEDIATRIC PATIENTS

Pediatric patients pose a challenge to the standard medication use process (MUP) by introducing complex steps and specialized clinical decision-making skills. Limited drug information is available for pediatric patients, who often require off-label use of U.S. Food and Drug Administration (FDA)-approved medications and extrapolation of safety and efficacy data from adult literature. Commercially available drug formulations are often unsuitable for pediatric patients. As described below, these differences make infants and children more susceptible to medication errors and related injuries (Reference 16).

### Developmental Differences

Pediatric patients can be further classified into neonates (term and preterm), infants, toddlers, children, adolescents, and adults on the basis of age. During each developmental stage, a pediatric patient has variable pharmacokinetic and pharmacodynamic parameters. Dramatic changes in both renal function and metabolism occur during the first year of life, posing unique challenges for health care providers when optimizing effectiveness and minimizing adverse effects. Neonates often experience significant changes in weight at least weekly, resulting in frequent calculations and dosing adjustments. Dosing is individualized on the basis of age, weight, or body surface area, requiring frequent calculation. Developmentally, smaller infants are unable to verbally communicate possible adverse events to caregivers, making it difficult to detect when an error has occurred.

### Limited Buffering Capacity

Pediatric patients have a limited buffering capacity compared with adults, with less ability to compensate to avoid harm or injury when errors do occur. For example, a small dosing error in an adult may have minimal consequences or even go undetected; however, the same dosing error could be fatal in a neonate, especially for high-risk agents such as electrolytes or anticoagulants (References 19–21).

### Lack of Commercially Available Dosage Forms

Drug formulations suitable for pediatric patients are not readily available from manufacturers. As a result, frequent manipulation of both oral and injectable commercial products is required. This most often includes oral extemporaneous preparations and stock dilutions. Manipulation of commercial products can lead to changes in bioavailability, stability, and sterility, increasing the risk of harm.

### Oral Extemporaneous Preparations

The lack of available dosage forms suitable for infants and children proves challenging for pharmacies that service children. Furthermore, the liquid preparations

that are available by the manufacturer are often unpalatable. Specialized compounding, which is timely, is not done in all pharmacies. The lack of pediatric-specific dosage formulations is also a large burden on families and caregivers. It is not uncommon for parents or caregivers to be asked to open and empty capsules to sprinkle the contents onto food. Caregivers may also be asked to crush tablets, dilute them in water, and give an aliquot of this preparation to their child. This process has significant risk and potential for error, especially in families with limited education or language barriers. This emphasizes the importance of discharge teaching and targeted patient education.

### ***Stock Dilutions***

A dilution of a commercial product may be required to meet the needs of pediatric patients, especially the neonatal population. Dilutions are typically used for doses measuring less than 0.1 mL to improve accuracy during medication dispensing and administration. For example, furosemide is a common diuretic used in pediatric patients. The recommended dose of furosemide is 1 mg/kg/dose. If the patient weighs less than 1 kg, his or her dose will be too small to measure using the standard concentration 10 mg/mL available from the manufacturer. As a result, the drug needs to be diluted to 1 mg/mL. The dilution process requires careful calculation and manipulation, both of which have a potential for error. In addition, when a stock dilution is made to prepare many patient-specific doses, an error in the dilution process may affect many patients or an entire patient care unit.

### **Multiple Concentrations**

The use of several concentrations for both oral and intravenous preparations can be confusing. Many drugs are available commercially in significantly different concentrations to meet the needs of very small infants as well as older children and adults. In fact, some medications are labeled “infant” or “pediatric” such as gentamicin, naloxone, and sodium bicarbonate. As a result, potential harm or injury can occur when the wrong concentration is used inadvertently. The result was fatal for the infants that received the wrong concentration of heparin and a 2-year-old girl whose life ended as a result of a compounding error when concentrated sodium chloride was mistaken for normal saline (References 19–21).

Similarly, dosing errors may also occur when using several concentrations, especially when doses are expressed in units of volume. For example, if the prescriber wrote a prescription for 1 teaspoon (5 mL) of amoxicillin, it would be unclear which commercially available concentration was to be dispensed—125 mg/5 mL, 250

mg/5 mL, or 400 mg/5 mL. If the prescriber wrote a prescription for 250 mg (5 mL) of amoxicillin, it would be clear that the 250-mg/5-mL concentration should be used. For methadone oral solution, dosing by volume may result in a 10-fold overdose if the prescriber does not adequately clarify the concentration to be dispensed. A 10-fold error with high-risk agents like narcotics or digoxin may result in significant injury or death.

For clarity, it is recommended that doses always be expressed in milligrams and milliliters—not just milligrams. Also worth noting is that, in the outpatient setting, the measuring of oral liquid preparations is inconsistent. For instance, some caregivers use oral syringes, cups, dosing spoons, or teaspoons for medication delivery, which results in variability of medication administration. It is important to consider this type of error and to ensure adequate understanding when providing patient/caregiver education. Community pharmacists play a large role in educating patients and caregivers about medications and their appropriate administration and use.

## **MEDICATION ERROR PREVENTIVE STRATEGIES**

The Institute for Safe Medication Practices (ISMP) has established its role as a leader in medication safety education and preventive strategies. The ISMP has provided the framework for developing medication safety programs and has published several tools to help practitioners implement these strategies (References 2, 22–24). Distribution of safety newsletters encourages the reporting of error-prone practice patterns and actual medication errors using a collaborative approach. The ISMP has become an invaluable external reporting system for both institutional and community settings that tailor to the needs of pharmacy and nursing.

The Pediatric Pharmacy Advocacy Group (PPAG) is an international nonprofit professional pharmacy association dedicated to promoting safe and effective medication use in children through communication, research, education, and advocacy. In 2001, PPAG, in collaboration with the ISMP, published guidelines for the prevention of medication errors in pediatric patients (Reference 25). This collaborative identified medication safety strategies specific to pediatric patients, highlighting unique challenges in this vulnerable population. Specific recommendations included the use of technology, with consideration for pediatric-specific customization and medication management standards as well as the impact of unit-based clinical pharmacists in medication error prevention. These recommendations were endorsed by the American Society of Health-System Pharmacists (ASHP) in support of established standards for pediatric pharmacy practice (References 7, 26).

The American Academy of Pediatrics (AAP) also published a policy statement that included medication error preventive strategies and organizational principles to define and guide the health care system for pediatric inpatients. The AAP defined the role of the pediatrician in helping to develop multidisciplinary medication safety programs and support for a culture of safety (Reference 27).

In summary, these organizations endorse the medication safety preventive strategies promoted by the IOM, which include support for a culture of safety, additional training and education, medication management standards, patient-centered care, and the judicious use of technology. In the next section, some of these principles will be discussed as they pertain to pediatric pharmacy practice.

## Culture of Safety

### *Transparency*

The first step in medication error prevention is establishing a culture of safety within the organization, focusing on systems, as opposed to individuals, to improve safety. A transparent quality improvement strategy encourages ADE reporting and allows frontline staff to offer recommendations for improving processes to enhance safety, optimize resources, reduce costs, or provide better workflow and efficiency. It is vital that the organization support nonpunitive actions when errors occur or are reported as part of its culture. There are still some institutions where staff receive corrective action and disciplinary consequences when errors are recognized or reported. Although practitioners should be held accountable, organizations should concentrate on system failures as opposed to individual performance. Errors are seldom the result of practitioner negligence. A high priority for each organization should be to establish best practices within the MUP to support its employees and minimize risk.

### *A Systems Approach*

The MUP consists of several steps including research and development, procurement, prescribing, transcribing, dispensing, administration, monitoring, and documenting. Figure 2 provides a summary of each step in more detail (Reference 28). The likelihood of error increases with each step in a process, especially when humans are involved. Human error, known as an active failure, occurs because of a single failure point within a system. An example of an active failure is nonadherence to policy or procedure. However, most errors occur as a result of several failures within a system called latent failures. Latent failures differ from active

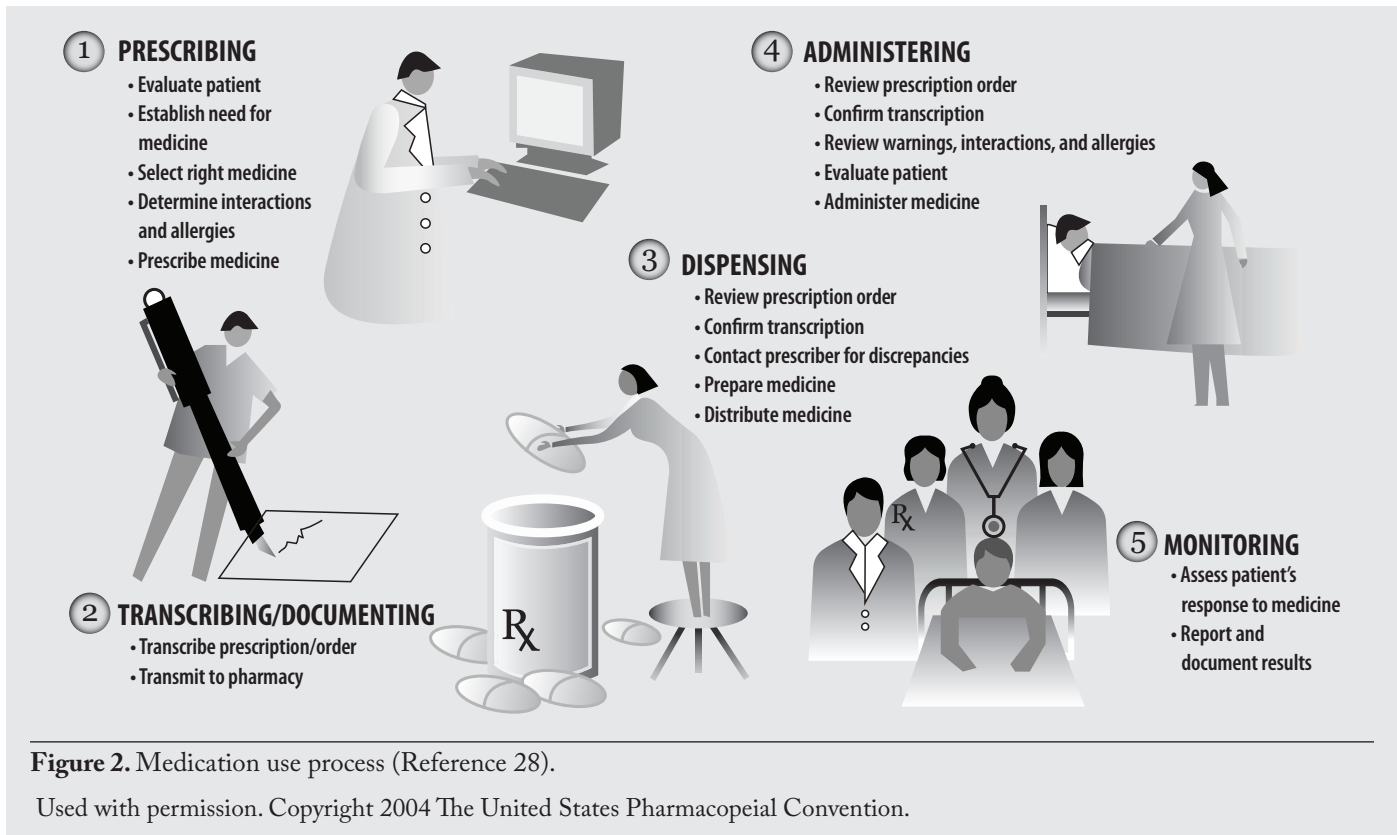

failures because they lie dormant within the system and often go undetected until an error occurs. These are considered the weaknesses or gaps of the system. Other tools used to evaluate risk or determine why an error occurred include failure mode effects analysis (FMEA) and root cause analysis (RCA). An FMEA is often performed prospectively to determine latent failures. This is usually done as a gap analysis for complex systems or processes within a system before an event occurs. An RCA is typically done retrospectively because of an event to determine the cause and effect of an actual error (References 29–31). As described below in more detail, system failures in training or education, standardization, communication, complexity, and limited technology may also increase the risk of medication errors.

## Training and Education

Organizations should develop age-based training and education programs that promote basic competencies required for pediatric pharmacy practice. Providing essential age-specific training to practitioners in areas such as developmental pharmacology, common drugs and disease states, medication safety, and pediatric-specific considerations establishes a basic foundation for practitioners who care for infants and children.

Pediatrics should be a required therapeutics course in the curriculum of schools of pharmacy. In academia, pediatrics is often an abbreviated course with minimal content, or it may only be offered as an elective course. Some pharmacy students are never exposed before graduation to the unique challenges and differences of pediatrics and medication therapy (Reference 32). Residency training is often necessary to gain the foundational knowledge base and clinical decision-making skills to apply to pediatric pharmacy practice. The development and expansion of residency programs in any organization can help promote pharmacy services that are more focused on pediatric patients. There are fewer pediatric pharmacy residency programs compared with more generalized pharmacy practice residency programs and other specialties. Some institutions provide only 1 year of training as either pediatric pharmacy practice or a higher-level specialty residency. Some institutions offer both a pharmacy practice and specialty residency program in pediatrics. This provides a more comprehensive pharmacy practice and specialized residency training experience, with additional exposure in a particular subspecialty (e.g., neonatal intensive care unit, critical care, oncology) after pharmacists complete 2 years of residency training in an exclusively pediatric environment.

## Medication Management Standards

The Joint Commission has established medication management standards that provide a basic framework for medication error prevention (References 33, 34). These standards, in conjunction with the national patient safety goals, provide guidance in drug ordering, administering, storage, and dispensing to optimize the MUP. Box 2 summarizes a checklist for organizations as a tool for evaluating medication management in the pediatric population (Reference 17).

A formulary management system provides a framework to establish safe and cost-effective medication use. Pharmacy must play a large role in formulary selection, procurement, management of drug shortages, and medication use evaluation. A standard approach to drug request and review for formulary consideration should be established. This should include, at a minimum, important efficacy and cost data, any potential safety implications, and similar formulary medications that can be removed (References 35, 36).

Several tools have been developed to aid in standardizing medication use. The ISMP serves as a resource for clinical practice and as a liaison to the manufacturers in recommending improved drug delivery systems and re-labeling or renaming a look-alike/sound-alike (LASA) drug. These include a standardized drug nomenclature (i.e., tall man lettering), problem-prone abbreviations and confusing drug names (i.e., LASA), and, most

recently, standardized concentrations for neonates (References 37–39). In addition to these tools, other medication error prevention strategies to promote safety should be established. This might include a process for medications that look or sound alike to be stored separately to prevent confusion.

The ISMP has also identified an extensive list of high-alert medications including anticoagulants, narcotics, insulin, neuromuscular-blocking agents, intravenous digoxin, dialysis solutions, and total parenteral nutrition. These drugs are more often associated with significant harm if used in error. Strategies recommended to improve safety with these agents include limiting access, making use of auxiliary labels and alerts, making independent double checks, and using standardization throughout the MUP (Reference 40).

The Joint Commission emphasizes the use of standardized concentrations and patient-specific medication dispensing in the most ready-to-administer form. These best practices are challenging for pediatric institutions where medication orders are complex with limited standard doses, and frequent manipulation of drug formulations are required to meet the needs of the patient. If comparing the doses dispensed for adults with the volume of pediatric workload, the additional steps in the dispensing process, including time, are often unaccounted for as part of the workload data. In addition, appropriate weight-based dosing must be verified

**Box 2.** Evaluation checklist for medication management in pediatric populations (Reference 17).

The following checklist is not meant to be comprehensive. Organizations may use it as a model, adding items based on recommendations from government agencies or professional associations.

- Protocols for drug evaluation, selection, storage, and administration are standardized for the pediatric population.
- Concentrations and dose strengths of high-risk medications are limited and standardized.
- When adult medications are used off-label for children, the drugs are prepared and dispensed in patient-specific “unit doses” or “unit-of-use” containers.
- A pharmacist reviews and verifies all pediatric medication orders (except in emergency situations).
- A pharmacist with expertise in pediatric medications is on-call at all times.
- Up-to-date references for pediatric medications are readily available in all areas where children may be treated.
- All pediatric patients are weighed at the time of admission.
- Weight is always recorded in kilograms.
- No high-risk drug is dispensed to a pediatric patient unless he or she has been weighed (except in emergency situations).
- Medication orders/prescriptions are standardized, and the guidelines for inclusion of all necessary information are enforced.
- If a computerized physician order entry system is used, it has been adapted to pediatric populations and provides alerts if necessary information is missing, a dose adjustment is required, and so on.
- Adult and pediatric doses or medications are stored separately, and products that have been repackaged for pediatric use are clearly labeled as such.
- Barcoding technology (if applicable) has been adapted to pediatric codes, such as small-volume, patient-specific dose labels.
- All staff who may be involved in the care of children receive specialty training, including medication risks and double checks to reduce those risks.
- Staff who educate parents and other caregivers about patients’ medications include all necessary information about side effects, administration method, and so on.

Copyright 2007 Joint Commission on Accreditation of Health Care Organizations.

for all inpatient and outpatient orders. These additional steps in the dispensing process should be considered when allocating resources, although they are difficult to quantify scientifically.

### Patient-Centered Care

Patient-centered care provides a comprehensive approach to medical management by incorporating all members of the health care team, with a focus on patients and their families/caregivers. Clinical pharmacists have emerged as providers in comprehensive drug management to patients and providers by optimizing medication therapy, monitoring for effectiveness and adverse effects, and promoting health, wellness, and disease prevention. Studies have shown that clinical pharmacy services improve patient outcomes and reduce cost (References 16, 41, 42). Establishing safe medication practices has also become the primary role of pharmacists, and ownership of continuous quality improvement efforts and measurement of medication safety are mainstays of current practice.

Unit-based clinical pharmacists establish a model for more comprehensive and patient-focused care. This approach has shown reductions in medication errors in both adult and pediatric patients through the provision of more accessible drug information, patient education, and medication reconciliation, together with other clinical pharmacy services (References 16, 41, 42).

Most recently, the ASHP Pharmacy Practice Model Initiative provided a summary of recommendations to advance pharmacy practice to meet the needs of changing health care systems. As part of this initiative, key stakeholders and leaders in pharmacy collectively established a blueprint for establishing pharmacists as having a direct patient care role. As drug therapy experts, pharmacists must leverage technology and clinical skills to optimize patient care and improve safety, focusing on drug therapy management (Reference 43).

### Implications of Technology

Implementation of technology provides a safer environment for patients through standardization of the MUP. This includes the use of computerized prescriber order entry (CPOE) with clinical decision support systems (CDSS), electronic medical records, pharmacy systems, automated dispensing cabinets (ADCs), smart infusion pumps, and barcode medication administration (BCMA). The ISMP offers self-assessment tools and guidelines to help organizations implement new modes of technology and evaluate existing systems for areas of improvement compared with best practices and national standards. However, many of the advances in commercial technology are marketed to adult patients; thus, caution and careful consideration must be used when

implementing them in the pediatric setting. In the following section, each of these tools and their impact on medication safety will be summarized, with pediatric considerations highlighted.

### **Computerized Prescriber Order Entry**

Computerized prescriber order entry has been established as a key piece of technology to reduce medication errors and has been endorsed by several leading patient safety organizations since the initial IOM reports were published. Although increasingly more common within the health care community, the implementation of CPOE remains a challenge. When implemented correctly, CPOE requires a reasonable timeline, resources, and capital funding, which are often barriers to progress. In addition, the use of CDSS and forced functions with CPOE is essential to provide necessary drug-drug and drug-allergy interactions, drug information, dosing recommendations, and warnings or alerts to ensure best practices of prescribers while using the tool. Forced functions allow a more streamlined approach to medication ordering, assisting in drug selection and dosing. For example, a drug that is only provided as an oral dosage form should not be orderable as an injection (Reference 44).

Studies in adults support CPOE as an important tool in medication error prevention (References 45, 46). Overall, CPOE provides more legible and complete medication orders with limited use of abbreviations. However, in pediatrics, data are limited and sometimes conflicting (References 47–54). One study found that medication prescribing errors and rule violations were almost eliminated and that potential ADEs were reduced 41% in critically ill pediatric patients (Reference 49). Another study found that CPOE implementation resulted in increased mortality, with subsequent studies showing conflicting results (References 50–52). In critically ill neonates, CPOE implementation has shown improved safety and reductions in medication prescribing errors (Reference 54). Box 3 summarizes factors associated with an “ideal” CPOE system (Reference 25).

Advanced clinical decision support tools provide additional guidance to the prescriber beyond what typically comes with the commercial software license (Reference 55). Examples include order set development and standardized ordering pages for error-prone medications (e.g., continuous infusions, total parenteral nutrition, patient-controlled anesthesia, anticoagulation), patient-specific code dosing sheets, P&T (pharmacy and therapeutics) initiatives, drug shortage alerts, FDA warnings and safety alerts, and customized dosing advisers. Alerts displayed to the prescriber should be carefully reviewed, monitored, and minimized to those requiring specific action or considered significant. Computerized prescriber order entry systems should have an established standard nomenclature that aligns

with best practices established by the ISMP and TJC. For example, the CPOE system should not allow trailing or leading zeros or abbreviations and should include tall man lettering as a system standard. Patient weight should only be entered using the metric system—kilograms, instead of pounds—which is often the source of dosing errors. In summary, CPOE with clinical decision support targets the most error-prone step of this process, ordering and prescribing, and reduces medication prescribing errors. Of importance, success is often related to a well-executed implementation plan and the feasibility of customization from the commercial software. Customization is essential to success in pediatrics, and pediatric-specific resources will need to be allocated for long-term development and maintenance.

### **Pharmacy Systems**

Ideally, the pharmacy verification system interfaces with the CPOE system, which eliminates the need to transcribe medication orders and supports a “paperless” process. For order verification, it is important for the

#### **Box 3. Functionality associated with an “ideal” CPOE system (Reference 25).**

- Prescriber order entry for verification by nurse and pharmacist
- Computer-generated medication administration records
- Current medication list that is readily accessible
- Two-way interface between pharmacy and other electronic documentation tools
- Access to archived patient information
- Age- and weight-based dosing recommendations
- Allergies and weight required and forced-upon order entry
- Access to vital patient information at the point of order entry
- Clinical decision support which provides appropriate patient-specific drug information (e.g., dose checks, allergy alerts, renal function, drug interactions and contraindications, laboratory warnings)
- Provide forced functions by limiting inappropriate options for order entry based on the drug that is ordered.

CPOE = computerized prescriber order entry.  
Reprinted with permission from the Pediatric Pharmacy Advocacy Group.

pharmacy system to require minimal manipulation of medication orders. For pediatric patients, most orders that are verified require frequent manipulation, which sometimes results in miscellaneous orders or other workarounds to accommodate the specific needs of these patients. This process introduces risk and often takes time away from other clinical pharmacy services and responsibilities.

Automatic dispensing cabinets help standardize the dispensing process at the unit level, providing quicker access to select medications. Consequently, however, the storage of LASA and high-alert medications may introduce risk, so consistent use of medication error prevention strategies should be established. Medications approved for override need to be monitored and approved through a formal process. Patient profiling and scanning on restock are both important aspects of the ADCs that should not be overlooked because they provide additional safety within the process.

### ***Barcode Medication Administration***

Medication administration errors are difficult to intercept and have the most potential for harm. Barcode medication administration is recommended as a tool to improve medication safety during drug delivery. This tool provides emphasis on the five patient rights: right patient, right drug, right dose, and right route, at the right time. A recent survey found that around 30% of hospitals nationwide have implemented BCMA, a significant improvement from less than 10% in 2005 (References 56, 57).

The benefits of BCMA on medication errors have not been well established in adult or pediatric patients (Reference 58). Recent studies have shown reductions in medication errors of between 27.3% and 87%, but a significant return on investment has been difficult to quantify (Reference 59). It is important to understand specific barriers and other obstacles in nursing workflow because these often create workaround or frustration with the system. Some researchers have studied the use of BCMA in several hospitals, identifying 15 workarounds by nursing. Also reported were 31 causes of these workarounds to BCMA. These causes included unreadable barcode labels, missing or unreadable armbands, malfunctioning scanners, non-barcode medications, failing batteries, uncertain wireless connectivity, and emergencies (Reference 60).

For pediatric patients, specific limitations of the system and other considerations need to be evaluated before implementation. For example, it is difficult to scan the armband of a swaddled neonate requiring temperature regulation in an incubator bed. In addition, barcoding from the manufacturer, which is the concept for the accuracy of these systems, is tailored specifically to adult dosage forms. Many of the pediatric formulations

are not conveniently available from the manufacturer; therefore, each institution must establish its process for patient-specific barcodes and be able to provide the resources to maintain this process.

### ***Smart Infusion Pumps***

Smart pump technology provides a safety net for appropriate medication administration of intermittent and continuous infusions. Pharmacists play an essential role in drug library development, which provides the guardrails for safe drug delivery. These parameters are based on published drug dosing recommendations and established clinical practices within the institution. Most companies offer electronic data collection to allow periodic review for continuous quality improvement. This provides a summary of drug use and clinical practice patterns. The number of overrides of the guardrails can be monitored, which helps identify questionable practices or the need to adjust the library to avoid unnecessary alerts. More importantly, the drug library can be customized to meet the needs of the institution and promotes the use of standardized concentrations. Pediatric settings often require more than one standard concentration to meet the needs of the large variability in size within the pediatric population. This requires a larger and more customized drug library compared with that in adult settings. This should be considered upon initial implementation, and resource allocation should be evaluated for the development and maintenance of subsequent updates.

### **MEASURING MEDICATION SAFETY**

It has been challenging for organizations to measure and track medication safety and methods to show the positive outcomes of specific improvement strategies. There are no standard medication safety indicators, and there is no suggested benchmark. Markers of performance, core measures, patient outcome data, regulatory and compliance standards, continuous quality data from technology (such as alerts and overrides), and medication events can be considered part of a medication safety program. For institutions that have implemented the use of technology, compliance with these systems and possible workarounds that need to be addressed may be considered.

Voluntary reporting is one way to identify potential failures within the MUP and make suggestions for improvement. However, reporting is solely voluntary and is significantly underestimated. Less than 5% of ADEs are actually reported through this process, and near misses are seldom included (Reference 61). Near-miss data help identify error-prone steps in a process before an event occurs. Occurrence reports should never be discouraged or used as a means to quantify medication error rate. Incident reporting should be rewarded as part of a non-punitive, just culture with the goal of increasing voluntary

reporting. Trending of these reports reflects the state of the culture versus how safe a system might be; therefore, the goal is always to increase reporting through a non-punitive system.

Occurrence reporting, when used in conjunction with other methods, is helpful in identifying vulnerability and risk within the MUP as part of a medication safety program. Adverse drug event surveillance tools, pharmacovigilance, and direct observation are more reliable in capturing ADEs (References 61–65). The use of known “triggers” to identify ADEs is effective and provides a way to prioritize patients on the basis of risk. These tools help provide more accurate and timely data in determining whether patients have experienced an ADE. Through a validated methodology and retrospective chart review, these events help determine system failures and opportunities for improvement. Unfortunately, this process is time-consuming and costly and still accounts for a small percentage of actual ADEs. An electronic “trigger tool” can provide real-time aggregate data by surveillance of all patients against the “triggers” without timely and costly chart review. The ADE surveillance provides additional utility to the framework of medication safety programs when used in collaboration with occurrence reporting and external reporting systems.

## CONCLUSIONS

Medication errors occur commonly, and most are preventable, with pediatric patients at highest risk. Infants and children offer unique challenges and developmental differences that make this population more vulnerable. Their needs require additional steps in the MUP and complex clinical decision-making skills. Promoting a culture of safety and systems approach to medication errors are necessary in developing medication safety programs. Additional training and education in the area of pediatrics will provide the necessary foundation of knowledge. For pharmacists, this includes age-based competencies or additional didactic and residency training in basic pediatric pharmacy practice. Pharmacists trained in pediatric pharmacy practice are essential for appropriate patient care of both outpatients and inpatients. Community pharmacists provide dose checking and unique dosage forms for pediatric patients, as well as patient/caregiver education. Clinical pharmacists providing consistent clinical services in an inpatient setting should be available at the unit level to the multidisciplinary team in support of patient-centered care. Technology provides a standardized approach for error-prone steps in the MUP such as ordering and medication administration. When used judiciously, technology has the potential to enhance patient safety. Because most systems are developed for adult patients, additional resources must be allocated to customize and maintain technology systems to meet

the unique needs of pediatric patients. Noncompliance and workarounds to the use of this technology should be evaluated to avoid unintended consequences and address vulnerabilities within the system. In addition, alerts and warnings should be kept to a minimum to avoid alert fatigue. Pharmacists play a key role in medication error prevention. Careful attention to the unique needs and vulnerability of pediatric patients should be a focus for patient safety standards and goals of national and regulatory agencies to provide children’s hospitals the resources and governance needed to create a safer culture and environment.

# CHAPTER 5

## COMMUNICATING WITH CHILDREN, ADOLESCENTS, AND THEIR CAREGIVERS

*Michelle Condren, Pharm.D., AE-C, CDE*

Verbal and written communications are essential components of health care that help ensure adherence to therapy, patient safety, improved outcomes, and patient satisfaction. Health care providers are trained in communication techniques for adults, but they often state that they do not have as much experience communicating health information to children. Although many principles of communicating with adults are also applicable to children, communicating with children requires a different approach that considers the developmental level of the child as well as the child-caregiver interaction. Because children are often dependent on an adult to assist with medication administration, it is important that adults receive education unique to their child to increase their confidence in the treatment. If the health care provider shows interest, takes the time to answer questions and address concerns, and involves the child in the communication, parents are more likely to be satisfied with the care received and to adhere to the prescribed treatment (References 1, 2).

It is as important to talk with children about their medications as it is to talk with their parents. However, community pharmacists report that they talk with children about their medicines only 20% to 30% of the time (References 2, 3). Medication education for children can occur in many settings including community pharmacies, hospitals, clinics, group education visits, schools, and health fairs. This chapter will review the benefits associated with communicating with children about medicines as well as techniques for delivering age-appropriate information and gaining rapport with this unique population; moreover, this chapter will provide tips for educating parents about their children's medicines.

### COMMUNICATION TO DECREASE ERRORS AND IMPROVE ADHERENCE

Once the medicine leaves the pharmacy, it is the responsibility of the parent and the child to ensure appropriate dosing and administration. As evidenced by previous studies, medical visits, and calls to poison control centers, many unintentional overdoses occur each year because of improper measurement and accidental ingestion. Difficulty measuring the proper dose could result from low health literacy or

a simple misunderstanding of the directions. Studies have shown that without intervention, only 50% of caregivers give an accurate dose of liquid medicines to the children in their care (Reference 4). This number can be increased to 95% using a 1- to 3-minute intervention of demonstrating how to use a dosing device, having the caregiver demonstrate use of the device, and providing pictogram-based information handouts (Reference 4). One study also concluded that the additional education resulted in an improved adherence rate of 62% to 91%.

In another study, parents were asked to measure 1 teaspoon or 5 mL of acetaminophen by a dosing cup, a dropper, a dosing spoon, and an oral syringe (Reference 5). When a dosing cup was used, most doses measured resulted in an overdose. This study also concluded that dosing errors with cups and dosing spoons were more common in parents with lower health literacy. Pharmacists should be aware of the challenges that caregivers face in administering medications and be proactive in providing information and appropriate dosing devices as well as ensuring caregivers' understanding of the medication and its administration.

### GENERAL COMMUNICATION PRINCIPLES FOR CHILDREN AND ADOLESCENTS

Children can generally begin providing and receiving information during health care visits at age 3 years, with an even greater level of involvement starting at age 7 years (Reference 6). However, many children have become accustomed to being silent observers during health care visits and may develop disinterest in or resentment toward their health care. The United States Pharmacopeia has developed a position statement outlining the principles for teaching children and adolescents about medicines (Reference 7). Included in those principles are that children want to know about medicines, so health care providers should be communicating directly with them about what they want to know as well as what they need to know. In addition, children should be encouraged to ask questions about medicines. An encounter with a child should always end with a question resembling "What questions do you have for me about your medicine?"

Communication with children can be for obtaining information, expressing empathy, relaying information, or confirming understanding. Each of these requires age-specific techniques that provide age-appropriate information and establish rapport as discussed in the following sections.

### Cognitive Developmental Stages

An important consideration when communicating with children is ensuring the message is delivered at a level they can understand. Identifying a child's developmental stage can help narrow the scope of information to be communicated and improve efficiency and effectiveness. One of the methods used to help identify a child's developmental stage is Piaget's classification of cognitive development. The four stages of cognitive development are as follows: sensory motor, preoperational, concrete operational, and formal operational. Table 1 describes Piaget's developmental stages and the ways in which to apply them to those receiving medication education. When applying any system for staging a child's developmental level, it is important to recognize that the stages are estimates and that they vary between patients. As children are exposed to situations and experiences, they may more quickly enter a new developmental stage than other children who have not had the same experiences (Reference 6). In addition, traditional methods of staging development do not apply to children with learning disabilities or disease states that impair development (e.g., autism spectrum disorders). Each child should be assessed individually for his or her level of development and educated at that level.

### Developing Rapport

Many children and adolescents are hesitant to talk to adults they do not know. Therefore, you should attempt to gain trust and let children know you are interested in them as individuals. General tips recommended to adults communicating with children of all ages include the following (Reference 8). (1) Sit at their eye level. (2) Begin by discussing something that is of interest to them. (3) Avoid commenting on characteristics about which they may be self-conscious (e.g., hair color, height, shyness). (4) Use a normal tone of voice. (5) Do not talk down to them. (6) Maintain a calm demeanor. (7) Give them your attention. (8) Listen actively. Additional items are summarized in Box 1. Consideration should always be given to differences in culture that may affect a person's likelihood of maintaining eye contact and his or her interest in self-care.

### Infants

The importance of gaining rapport starts in infancy. Although it is not possible to deliver medication education to infants, interacting with an infant's parents will be much easier if the infant is at ease. Adults should not lean over an infant's face or take the child from his or her parents if the infant is anxious about leaving his or her parent's arms. In addition, an adult should not force play with an infant. If the infant is interested in playing, he or she will reach out or make sounds. If the infant is distressed, he or she will likely become more anxious if you attempt to play with him or her. It can often be difficult to communicate with parents when their infant is irritable; thus, giving parents time to comfort their infant will be beneficial.

### Toddlers and Preschoolers

From ages 1–5, children are developing new skills and do not understand the importance of health care visits and listening to others. They often have difficulty communicating because they are learning new words and learning how to formulate sentences. Therefore, when obtaining information from them, patience is necessary to give children time to think about and communicate a sentence. When they become distracted or disruptive, a playful distraction, such as an opportunity to draw or play with a toy, is helpful to redirect them to a new activity. Because they do not have a good concept of time, it is important to avoid asking for a prolonged recall of information. Information should be delivered in simple terms, with brevity and honesty.

#### Box 1. General tips for communicating with children and adolescents (References 7, 8, 10, 12).

- Sit at or below their eye level.
- Begin by discussing something of interest to the child or adolescent.
- Remain calm and nonjudgmental.
- Be aware of their body language and respond if needed.
- Speak in a normal tone of voice.
- Allow them to express concerns and ask questions.
- Give them ample time to respond to questions.
- Give them your full attention.
- Listen attentively and repeat to ensure you understand them.
- Allow them to participate in decision-making about their medicines.

**Table 1.** Piaget's Cognitive Developmental Stages and How They Affect Medication Education (References 8, 9)

Approximate Age (years)	Developmental Stage	Features	Medication Counseling
0–2	Sensory motor	Do not see the connection between self and outside objects	Learning about medicines is not possible.
2–7	Preoperational	Can consider only a single aspect of a situation Can consider only the here and now Have no concept of cause and effect Have difficulty conceptualizing time Do not understand the connection between an action and their health Can use symbols or pictures to represent objects	Hands-on activities are the most effective. It is important to include the taste of medicine in your education to them. Example information to provide: This medicine will keep you from getting sick. You will take it when you wake up in the morning and before you go to sleep at night. Your mom or dad will help you take the medicine.
7–11	Concrete operations	Can focus on many aspects of a situation Can think about concrete events but have difficulty with hypothetical situations Can distinguish between self and effects of the outside world Can best understand concrete or observable situations Can understand that diseases are preventable Can see things from different points of view	Give them time to ask questions, and explain concepts to them. Include a discussion about the adverse effects of medicines that should be reported to parents. Example information to provide: This medicine will go into your lungs and make it easier for you to run and play. You will take it when you wake up and before you go to bed. If you do not take it two times a day, it will not work. You need to brush your teeth after using the medicine. Work with your mom and dad to make sure you take the medicine right and remember to take the medicine.
≥ 12	Formal operations	Capable of hypothetical thought and logical reasoning Understand how illness occurs and is affected by their actions Begin to understand they can have control of their health	Typically able to receive a message at the same level as an adult, but keep in mind they may be more embarrassed by certain topics. Example information to provide: This medicine works in your lungs to decrease mucus and swelling so that you can breathe better and have less cough. Because you are breathing things into your lungs every day that cause the problem, this medicine works only if used every day, twice a day. It is important to keep using this medicine even when you start feeling better because the asthma will still be there. Work with your parents to help make this part of your everyday routine.

### *School-Aged Children*

At this age, it will be easier to obtain information from children using open-ended questions and allowing them to explain how they perceive a situation. They will begin to provide a more accurate recall of symptoms and activities, and they will often give a more accurate account of their current symptoms than their parents. Because they have a better understanding of cause and effect by this age, they will have a greater need to know information and to have a chance to express their concerns and questions. School-aged children can begin contributing to the decision-making process about their treatment plan. If they state they do not like a medicine, they should be offered alternatives to choose from and educated on how the alternatives differ. Children at this age respond well to visual displays of disease states and medications and enjoy interacting with adults by way of games and challenges.

### *Adolescents*

Adolescents are the least likely to trust that adults have their best interest in mind and may be unwilling to provide a great deal of information. It is important to begin the conversation by asking about something that may be of interest to them rather than starting with your agenda. If they feel their viewpoint is not being considered or understood, they are likely to withdraw or even become angry. Before rapport is established, many adolescents will not maintain eye contact. This will improve as their trust in the provider increases.

The adolescent should be the primary person giving information during an encounter, and the parents should be asked to confirm or add information. It is important that they learn to advocate for their own health care and learn to communicate their needs. Adolescents will often provide information that may alarm or shock the provider. Of importance, remain calm and non-judgmental in these circumstances. When developing a treatment plan, it is critical to include adolescents in the decision-making process and affirm that their questions and concerns have been addressed.

Adolescents should be given an opportunity to talk with their health care provider in private. If you plan to ask adolescents about contraception, sex, alcohol, drug, or tobacco use, it is better to speak with them in private than in a parent's presence. This will allow them more comfort to speak freely and will let them know you have respect for their privacy and perspective. Common situations that require privacy and sensitivity when communicating with adolescents include counseling on the proper use of contraception, on drug interactions that may increase the risk of unintended pregnancy while using oral contraception, and on interactions between alcohol and medications. Adolescents may be unwilling

to talk about these issues in a first encounter, but they are likely to become more open after trust is developed in follow-up encounters. Parents may resist, but it is important to emphasize that adolescents need to learn to communicate with the provider and begin to take responsibility for their medical care.

### **Additional Communication Considerations for Children and Adolescents**

The technique and skill required for obtaining information differs from that required to deliver information. When obtaining information, open-ended questions are preferred. However, the questions must be specific and often need to be followed up with more straightforward, closed-ended questions. With closed-ended questions, children and adolescents may give responses that they think will make the provider happy (Reference 10). The provider may need to let them know it is acceptable to be honest. An example of a statement to help encourage truth in recalling medication adherence is this: "A lot of people have trouble remembering to take their medicine; do you find it hard to remember to take your medicine?" This can then be followed by more open-ended questions to obtain further details.

Children often refer to a medicine by appearance or color, and sometimes, they refer to it by what they use it for rather than by name. When interviewing the patient, if the child does not know the name of the medicine, it is important to ask if he or she can describe what it looks like. The pharmacist can then emphasize the importance of knowing the medication name and assess recall at future visits.

When providing medication information to children, it is important to select the most salient points and deliver them using the principles discussed in the previous sections. Studies have confirmed that children want to know the following information about their medicines (Reference 11):

1. How does the medicine taste?
2. When do I take the medicine?
3. How will it make me feel better?
4. How long will I take it?
5. What are the adverse effects?
6. Why am I taking the medicine?

Other important points to emphasize include informing children to tell an adult if they take too much medication or see someone else taking their medicine and encouraging them to tell an adult if they have any new feelings or adverse effects while taking the medicine.

When asking a child or adolescent to demonstrate a skill such as inhaler technique, smaller children may be fearful, embarrassed, or shy. Children who are fearful or anxious may be given the spacer to play with before

trying to demonstrate the technique so that they can learn that it is not a harmful object. For those who seem embarrassed, it is important to ensure as much privacy as possible and consider demonstrating the technique yourself before asking them to do so. It is also important to give children and adolescents choices—when a choice truly exists. For example, you do not want to ask, “would you like to show me how you use your inhaler?”, if you intend to have them show you, even if their answer is “no.” Rapport will be lost if you proceed with having them demonstrate the technique after they have responded that they are not interested. A more appropriate statement might be, “I need to watch you use your inhaler so I can make sure it is working; would you like to show me now or after we talk about your medicines?”

Effective techniques to assist children with medication adherence are patient-specific. Children and adolescents should be asked what they believe would help them remember to take their medicines because no single approach works for everyone. Potential methods to assist in remembering include posting dosing calendars with or without medication pictures on them, providing cell phone reminders or alarms, placing the medications in an area of high visibility, and using pillboxes.

## COMMUNICATING WITH PARENTS

Studies have shown that parental satisfaction with medical care is determined by the practitioner’s interpersonal skills. Parents who feel they were not treated with respect or that their fears were not addressed will be dissatisfied and less likely to follow through with medical advice (Reference 12). In interviews of parents during physician visits, 88% wanted to be addressed by their names rather than as “mom” or “dad” (Reference 13). Pharmacists are encouraged to ask parents how they prefer to be addressed. There is a fine

### Box 2. General tips for communicating with parents (References 7, 8, 10, 12).

- Inform them you will be talking with their child or adolescent.
- Learn their names, and use their names during communication.
- Provide guidance on how much involvement the child should have in administering his or her medication.
- Encourage them to provide their child with some autonomy when appropriate.
- Allow them to express concerns and ask questions.
- Respond respectfully about any misconceptions or irrational fears they may express.

### Box 3. Information needed to supplement medication information handouts.

- How to measure the dose
- How to administer the medicine
- How the adverse effects may manifest in a child
- How the warning labels apply to a child
- Reassurance that the medicine may be used for an indication other than those listed

balance between including the child in the encounter and ensuring that the parents feel included as well. It is helpful to let parents know that you plan to ask the child questions and provide them with information before starting. Box 2 provides a summary of items to consider when talking with parents or caregivers.

Written information dispensed with prescriptions is not phrased with a child in mind and can be frightening and confusing to parents. Many parents fear giving their children any medicines; thus, reading this information may cause them not to give the medicine. An example is the use of fluoroquinolones in children. The American Academy of Pediatrics recommends the use of fluoroquinolones in children if other alternatives do not exist for treatment of infection. However, many patient information handouts will state that these medications should not be used in children because of the lack of an FDA label-approved indication and because of safety concerns. Parents who see this information may be resistant to giving the medicine to their child unless they are educated on the data that exist and informed that no alternative exists. In addition, written information should be at the sixth-grade reading level to ensure understanding by those with low health literacy. It is estimated that most materials are written at a 10th- or 11th-grade reading level (Reference 14). Methods of assessing readability include the Flesch-Kincaid formula and McLaughlin’s Simplified Measure of Gobbledygook. The United States Pharmacopoeia has developed a guide to assist in developing and evaluating educational materials (Reference 15). This guide includes not only readability, but also the balance of words and pictures and the appropriateness of content for the child’s age. Parent-friendly medication information handouts are available that are more specific to children and are easier to read (Reference 16). These handouts are available in English or Spanish. Lexi-Comp online also provides pediatric-specific patient education handouts in 18 different languages. If these resources are unavailable, it is important to point out differences that may be relevant to the child compared with the information provided on the medication handout from the pharmacy. Examples are provided in Box 3. In addition, parents

may need assistance in determining how the information contained in a warning label may apply to their child. For example, the statement “do not operate heavy machinery while taking this medicine” has a different meaning for a child. In this case, parents should be counseled that their child should avoid tall playground equipment and should be careful riding his or her bicycle or any motorized toys while taking that medicine.

It is also important to determine who will be giving children their medicine. It is often given at school or by a grandparent, or it may be given at another house if the parents do not live together. If the person accompanying the child to the visit is not the only one to administer the medicine, he or she should be educated on the importance of providing all information to anyone who will be responsible for giving the child’s medicine. Too often, children are held responsible for transporting medicines between homes and remembering to take them, putting them at risk of not receiving the medicine consistently. Adequate information should be provided to the school to ensure the safe and appropriate administration of the medication in that setting.

Another important component of a health care encounter is to verify the identity of the person with the child. It is possible that another relative, a babysitter, or a stepparent will be with the child. In some cases, it may be necessary to contact the parents if they are not at the visit to ensure they have the information they need to safely use the medicine for their child. This practice will also help avoid uncomfortable moments that occur when the identity of the adult is assumed.

## CONCLUSIONS

Children and adolescents are important consumers of health care and should be provided the information they need to use medications safely and effectively. Pharmacists play an important role in communicating with children, adolescents, and their caregivers. The techniques discussed in this chapter will help facilitate effectiveness and efficiency in communicating with this unique population. With practice, communicating with children and adolescents will become a rewarding experience and will positively affect the health and safety of these vulnerable patients.

# CHAPTER 6

## DRUG FORMULATIONS

Vinita B. Pai, Pharm.D.; and Milap C. Nahata, Pharm.D., FCCP

### LEARNING OBJECTIVES

1. Know the legislative actions undertaken by the U.S. Congress to encourage the pharmaceutical industry to conduct drug trials supporting pediatric labeling of their drugs and develop a pediatric formulation.
2. Understand the need for extemporaneous formulations in infants and children.
3. List the most common extemporaneously compounded oral liquid formulations.
4. Know the different extemporaneous options available for providing a suitable dosage form for a child.
5. Know the methods involved in compounding an extemporaneous formulation and the factors that affect its use in clinical practice.

### ABBREVIATIONS IN THIS CHAPTER

ASHP	American Society of Health-System Pharmacists
FDA	U.S. Food and Drug Administration
FDAMA	Food and Drug Administration Modernization Act
PREA	Pediatric Research Equity Act
USP	United States Pharmacopeia

### INTRODUCTION

An estimated 74.5 million children, 0–17 years of age, resided in the United States in 2009. Of these, 21.3 million were 5 years or younger (References 1, 2). In December 2010, the *Wall Street Journal* reported that according to Medco Health Solutions, one of the largest U.S. pharmacy benefits providers, around 25% of children and 30% of adolescents between 10 and 19 years of age were taking a medication for a chronic condition in 2009 (Reference 3). Almost 7% of these were taking two or more drugs for long-term therapy. It was determined that the total number of prescriptions or refills dispensed to children and teenagers were as follows (from most to least): asthma drugs 45,388,000; attention-deficit/hyperactivity disorder drugs 24,357,000; antidepressants 9,614,000; antipsychotics 6,546,000; antihypertensives

5,224,000; sleep aids 307,000; oral hypoglycemic drugs 424,000; and statins 94,000. Many of these drugs, however, are not labeled for use in the 0- to 9-year-old age group and thus are not available in suitable dosage forms.

Research and development of most pharmaceuticals are focused on providing safe and efficacious drugs for adults. Initial efficacy and safety trials for most drugs often exclude infants, children, and pregnant women. Drugs routinely used in pediatric patients may not have U.S. Food and Drug Administration (FDA)-approved pediatric labeling. Without these trials, information regarding the effective dose per patient weight (milligram per kilogram per dose), the frequency of dosing, and the adverse effects of a drug in the pediatric population may come from pilot observations, from case reports or series, and by trial-and-error methods. Drugs without pediatric labeling are often unavailable in dosage forms suitable to administer to children. For example, tacrolimus is used as an immunosuppressive agent in adult and pediatric solid-organ and peripheral stem cell transplants. However, it is available only as a capsule. A liquid formulation has to be extemporaneously compounded for use in infants and children.

In 1997, the Food and Drug Administration Modernization Act (FDAMA) was signed into law (Public Law 105-115) (Reference 4). According to Section 111, pharmaceutical companies with a drug already on the market or submitting a new drug application to the FDA were offered an additional 6 months of patent protection (exclusivity to market that drug) in exchange for conducting requested trials in children. The goal was to encourage the pharmaceutical industry to conduct trials supporting the pediatric labeling of their drugs and develop a pediatric formulation for their product. In 2002, the FDAMA was reauthorized as the Best Pharmaceuticals for Children Act, and in 2007, it was signed into law (References 5, 6). Under this law, the FDA would accept, on a case-by-case basis, pediatric labeling directions for producing extemporaneous pediatric formulations as an alternative to a stable commercial formulation.

In 1998, the FDA mandated an assessment of new drugs, new indications, new dosing regimens, new active ingredients, and new dosage forms for pediatric patients, which in 2003 was formalized as the Pediatric Research Equity Act (PREA). In 2007, PREA was reauthorized. As of 2007, more than 130 products have received new pediatric labeling directions, but only 8% have new pediatric formulations, and another 8% provide information

on the preparation of suspensions or recipes for extemporaneous compounding (Reference 7). Despite the submission of pediatric studies by the industry, 22% of the products were not approved by the FDA for use in children for reasons such as “ineffective dosing, overdosing, ineffective drug action, or previously unknown side effects” (Reference 7). Thus, BPCA and PREA have had a limited impact on meeting the need for pediatric formulations of drugs commonly used in children. Both BPCA and PREA were introduced into Congress in March 2012 for reauthorization.

## NEED FOR EXTEMPORANEOUS FORMULATIONS

A pharmacist may need to compound an oral extemporaneous formulation for pediatric and adult patients unable to swallow solid dosage forms or receiving their medication through a nasogastric tube or gastrostomy tube. In addition, most children younger than 6 years, even when given specific training, are unable to swallow a solid dosage form such as a tablet or capsule (References 8, 9). Most pediatric drug doses are based on body weight (milligram per kilogram per dose) or body surface area (milligram per square meter per dose). Such individualized doses cannot be easily administered and titrated using the available solid dosage forms, which contain a fixed amount of drug, but they can be accurately and easily administered using a liquid formulation. For drugs requiring drug concentration monitoring (e.g., tacrolimus), dose adjustments to achieve safe and effective blood concentrations may result in doses that are not commercially available. However, such drugs can be provided to this patient population by extemporaneously compounding a liquid formulation of a suitable concentration using the commercially available solid dosage forms. In addition, the presence of an inactive ingredient or a high concentration of the inactive ingredient in a commercially available liquid dosage form may prevent the use of a particular drug in premature or full-term neonates (e.g., dexamethasone intensol containing 30% alcohol). Toxicity may not be observed after a single dose of this medication; however, toxicity because of the long-term administration and additive effects of alcohol from other concurrently used alcohol-containing drugs cannot be ignored.

Pharmacists also compound parenteral drugs extemporaneously. Parenteral drugs are supplied in a commercially available ready-to-use concentration, a concentrated solution requiring further dilution, or a dry, lyophilized powder for reconstitution. Some intravenous drugs (e.g., phenobarbital, morphine, furosemide, fentanyl) may be too concentrated for accurate measurement of the small doses (volumes) needed for treatment of neonates and infants. These doses may require further dilution before intravenous administration. For example, furosemide is available as a 10-mg/mL solution for injection. A neonate weighing 0.7 kg would require a dose

of 0.7 mg intravenously or 0.07 mL, which cannot be accurately measured with the commercial formulation. Under these circumstances, the intravenous drug requires further dilution with a suitable diluent to prevent errors in measuring the amount. The drug stability and sterility of this parenteral extemporaneous formulation must be documented before its use in patients.

## MOST COMMONLY PREPARED PEDIATRIC EXTEMPORANEOUS FORMULATIONS

Information regarding the most commonly compounded extemporaneous formulations for children in the United States is available through surveys published in the literature. A 1998–1999 survey of 57 small and large hospitals caring for pediatric patients identified the five most commonly compounded formulations as follows: spironolactone, captopril, ursodiol, metronidazole, and allopurinol (Reference 10). Oral, nasogastric, and gastric were the most common routes of administration of these medications. The same survey also identified 103 drug formulations prescribed by pediatricians that had no compounding and/or stability information.

In 2009, another survey was conducted to determine the scope and frequency of use of extemporaneous liquid formulations in children’s hospitals (Reference 11). The five most commonly compounded formulations in 20 pediatric U.S. hospitals identified by this survey were lansoprazole, spironolactone, captopril, sildenafil, and ursodiol. This survey identified a total of 231 drugs or drug combinations that were compounded into liquid formulations for 28% of all inpatient admissions during a 12-month period.

## OPTIONS FOR MEETING EXTEMPORANEOUS FORMULATION NEEDS

Pharmacists who frequently compound extemporaneous formulations will need informational resources providing formulation recipe, compounding method, storage conditions, and stability data. The most common and immediate resource is the United States Pharmacopeia (USP) (Reference 12). It contains official monographs of compounded preparations that include valid stability data to establish a beyond-use or expiration date. Compounding information supported by stability studies and beyond-use dates may be available in the package insert of drugs such as losartan, benazepril, lisinopril, and rifampin. This information usually is included in the package inserts of brand-name products because, most often, the manufacturer has a pediatric labeling for the drug.

Tertiary publications such as the *Pediatric & Neonatal Dosage Handbook*, which was designed as a dosing reference for neonates, infants, and children, and NeoFax, which is a reference specific for the dosing and

administration of drugs in neonates, contain necessary information regarding the extemporaneous compounding of a drug formulation (References 13, 14). *Pediatric Drug Formulations* and *Extemporaneous Formulations for Pediatric, Geriatric, and Special Needs Patients* are two tertiary publications that compile information regarding formulation recipes, methods of compounding, storage conditions, and stability data (References 15, 16). Primary peer-reviewed publications regarding specific formulations can be obtained by conducting a literature search through PubMed using search terms such as “extemporaneous drug formulations,” “extemporaneous compounding,” and “extemporaneous preparations children,” combined with the name of drug being researched.

Another resource for locating information about the compounding of extemporaneous formulations is the Investigator’s Brochures or reports, but these are usually not easily available or accessible because of their confidential or proprietary nature. Before using the compounding information from the Investigator’s Brochures or pharmaceutical industry-generated reports, pharmacists should ascertain that the formulation stated in the brochure is not being investigated for its stability, bioavailability, or bioequivalence through ongoing clinical trials. If such trials are under way, the formulation cannot be dispensed for routine patient care until trial results indicate successful achievement of the study goals. Manufacturers of the solid dosage forms can be contacted to obtain information regarding any preclinical testing of extemporaneous formulations. However, when a drug does not have pediatric labeling, the potential for legal liabilities may prevent manufacturers from providing information about formulations used in preclinical studies.

When compounding and stability information for an oral commercially manufactured product is unavailable, some pediatric hospital pharmacies may compound it as a suspension or solution. The liquid preparation is usually packaged in a tight, light-resistant container (amber plastic bottle) and stored at controlled temperatures to observe for signs of physical changes. For water-containing formulations prepared from solid ingredients, the USP-recommended beyond-use date is no later than 14 days for liquid preparations when stored at cold temperatures between 2°C and 8°C (Reference 17). The USP recommendations should be used with caution, especially because the stability of a drug in liquid depends on several physicochemical properties such as pH and oxidation-reduction reactions. For example, captopril (0.75 mg/mL) in cherry syrup is only stable for 2 days at room temperature or when refrigerated, and it is stable for 10 days or less in a 1:1 mixture of Ora-Sweet and Ora-Plus or Ora-Sweet SF and Ora-Plus, depending on the storage temperature. Thus, without the stability data, labeling these captopril formulations with a beyond-use date of 14 days according to the USP would

be inappropriate (Reference 18). Under these circumstances, preparing powder papers or using dosage forms intended for adults with or without alterations seems to be a logical option. The procedure for preparing powder papers includes crushing the tablets or opening the capsules, uniformly redistributing the contents with inactive ingredients such as lactose to achieve the required dilution, weighing out each powder paper, and then folding it. This is time-consuming and labor-intensive. In addition, the contents of the powder paper will still have to be reconstituted into a liquid before administration. Solid dosage forms without an extemporaneous formulation can also be administered by splitting or crushing a tablet and opening a capsule and administering the content with food. These modifications may result in a compromise in the physicochemical stability of the drug, an altered rate of drug absorption, and improper dosing because of the inaccurate splitting of tablets or spillage during reconstitution or mixing with a large amount of food that is not completely ingested by the patient. For a solid dosage form with a water-soluble active ingredient, crushing the tablet or mixing the contents of a capsule with a specified amount of water and drawing up the exact amount for a dose can be done. However, this process can be time-consuming and has the potential for calculation errors. Alternatively, the injectable solution of the same drug can be administered orally, provided both formulations contain the same salt form with similar bioavailability. However, the cost of the injectable solution can be a limitation to using this method.

## METHODS OF PREPARING DIFFERENT EXTEMPORANEOUS FORMULATIONS

The most commonly compounded extemporaneous formulation for children involves making a liquid formulation from a solid dosage form. This could be a solution or a suspension. For a more comprehensive review of preparing safe and effective extemporaneous formulations, the authors refer the reader to the American Society of Health-System Pharmacists (ASHP) Web site and other valuable resources (References 19, 20). The ASHP Web site provides guidelines that address areas of extemporaneous compounding through the following documents: (1) ASHP Technical Assistance Bulletin on Compounding Nonsterile Products in Pharmacies (Reference 21) and (2) ASHP Guidelines on Quality Assurance for Pharmacy-Prepared Sterile Products (Reference 22).

A suspension is the most commonly compounded oral formulation because most drugs (active ingredients) are not completely water soluble. Even when the active ingredient is completely water soluble, the inactive ingredients (excipients) may not be soluble. A suspending agent that can uniformly suspend the active and inactive ingredients after shaking for a time is necessary to

accurately withdraw a dose and should be used in the compounding recipe. Adding a suspending agent to a formulation with soluble active but insoluble inactive ingredients allows a more pharmaceutically elegant preparation. Without a suspending agent, the insoluble ingredients will settle rapidly. This may result in the caregiver's inaccurate assumption that he or she is unable to withdraw a uniform dose from the preparation. Preparation of an extemporaneous liquid dosage form from tablets involves crushing and triturating them in a mortar into a fine powder while capsule contents are emptied into a mortar and mixed well. The powder is then levigated into a smooth paste using small portions of the selected vehicle. This selected vehicle usually consists of a combination of a suspending agent and a sweetening agent. The uniform paste is mixed with the rest of the vehicle in geometric proportions with constant mixing until the desired volume is almost achieved. The mixture is then transferred to a measuring device (graduated cylinder), and the selected vehicle is added to make up the required volume according to the recipe. The preparation should then be transferred to an appropriate container, such as an amber bottle, and labeled with a beyond-use date under storage conditions, as indicated in the stability studies. Prescription bottles should not be used as measuring devices because the graduation marked on these bottles is inaccurate.

Ingredients (raw materials) used in compounding extemporaneous formulations should always be of USP or equivalent grade. Carboxymethylcellulose and methylcellulose are common suspending agents. A carboxymethylcellulose sodium suspension is easier to compound, but it has a pH of about 10. The preparation of a methylcellulose suspension is difficult and time-consuming. However, the advantage of using a methylcellulose 1%/simple syrup suspension (1:1) is that it is an inert, nonreactive, and pH-neutral (pH 6.8) vehicle. Most pharmacists in the United States prefer to use commercially available ready-to-use vehicles. A vehicle can be easily prepared by combining Ora-Plus (Paddock Laboratories, Minneapolis, MN), a carboxymethylcellulose-containing suspending agent, with Ora-Sweet (Paddock Laboratories) syrup, in a 1:1 volume. Ora-Sweet SF (Paddock Laboratories), a sugar-free syrup vehicle, can be used instead of Ora-Sweet. All three have an acidic pH, which should be considered in compounding suspensions when drug stability data are unavailable for the preparation. Ora-Blend and Ora-Blend SF, marketed by the same manufacturer, are sweetened (with sugar or sugar free) suspending agents, eliminating the need to prepare a 1:1 mixture of Ora-Plus with Ora-Sweet or Ora-Plus with Ora-Sweet SF. Other available vehicles include SyrSpend SF (Gallipot, St. Paul, MN),

SyrSpend SF Alka, SyrSpend SF Cherry, SyrSpend SF Alka Cherry, SyrSpend SF Grape, and SyrSpend SF Alka Grape.

Certain characteristics of an oral liquid dosage form such as taste, odor, palatability, texture, color, and sweetness may enhance a patient's acceptance of his or her medication therapy. Children usually prefer a sweet taste with fruity flavors. Choice of flavoring agents may also depend on the characteristic taste of the drug itself because certain flavoring agents mask certain tastes well. Cocoa-flavored vehicles may mask bitter-tasting drugs, whereas fruit or citrus flavors may mix well with sour or acidic-tasting drugs, and salty drugs can be made more palatable if masked by raspberry- or orange-flavored vehicles. Formulations can be made to taste sweet using vehicles such as Simple Syrup USP or Ora-Blend. Flavored vehicles such as SyrSpend SF Cherry or SyrSpend SF Grape can also be used. Adding a flavoring agent to an extemporaneous formulation when it was not used in the original formulation could alter the stability and concentration of the medication. If additional flavoring is needed, the agent can be added to each dose immediately before administration of the dose. Adding coloring agents may make the formulation esthetically more appealing. However, the stability of the formulation may be affected by the presence of these chemical coloring agents because most of the dyes are affected by the formulation pH, presence of oxidizing or reducing substances, or exposure to light. Thus, many institutions do not add coloring agents to extemporaneous formulations.

## FACTORS THAT AFFECT THE USE OF EXTEMPORANEOUS FORMULATIONS IN CLINICAL PRACTICE

### Stability

A stable extemporaneous formulation is one that retains the characteristics and properties it possessed at the time of preparation throughout its storage and use (i.e., shelf life). An extemporaneous formulation should be physically, chemically, microbiologically, therapeutically, and toxicologically stable during its shelf life. Stability is affected by temperature, radiation, light, humidity, particle size, pH, water and other solvents, container properties, and other chemicals that may be present in the formulation. All compounded preparations require a beyond-use date labeling (i.e., the date beyond which a compounded preparation is not to be used, which is determined from the date of preparation). Several factors determine this beyond-use date.

The expiration date for a commercially manufactured product cannot be directly extrapolated to assign a beyond-use date for a nonsterile preparation compounded from it.

Physical stability includes the lack of change in color, odor, taste, texture, and consistency of the preparation. This can be tested by storing the compounded formulation at various commonly used storage conditions (temperatures and containers) and periodically (e.g., at weeks 0, 1, 2, 4, 8, and 12) testing for components of physical stability. The most common storage temperatures for medications include room temperature (20°C–25°C), refrigerated temperature (2°C–8°C), and freezer temperature (-25°C to -20°C). Storage containers generally consist of amber plastic prescription bottles unless specified in the stability studies.

Chemical stability of drugs in an extemporaneous formulation (both sterile and nonsterile) involves the measurement of the active ingredient(s) to ensure its potency during storage and use. During storage, no more than a 10% change in the active ingredient concentration should occur. Pharmacists should consult and apply specific and general stability documentation and literature when available. Testing for chemical stability involves the use of certain analytic methods. The analytic method should be accurate, efficient, specific, reproducible, and stability-indicating. No single method can be used to test all drugs. Many analytic tests are not available in the pharmacy or a health care facility; thus, they may need to be outsourced to contract laboratories. A contract laboratory chosen for conducting analytic tests should follow USP General Chapter standards using official methods and techniques for testing. The chemical stability of the active ingredient(s) is usually reported as a percentage of the initial concentration. In general, formulations with storage conditions and beyond-use dates, which preserve the potency of the active ingredient(s) within 90% to 110% of the initial concentration, should be used; however, the USP monograph for the specific drug should be consulted for acceptable variance for each active ingredient being evaluated.

Most pharmacies involved in dispensing extemporaneous formulations will lack the resources to undertake such chemical stability studies. Instead, they may have to rely on books, peer-reviewed publications, or a commercially available or institution-specific computer database with recipes for extemporaneous formulation recipes. A search of the literature for stability data on an extemporaneous formulation may reveal several studies using different compounding agents, storage conditions, and duration of stability for the same drug. All stability data must be carefully interpreted with respect to the particular compounded formulation. Ease and convenience of compounding, duration of stability of the formulation, easy availability of the compounding ingredients, and cost are factors to consider in choosing a particular recipe as your institution's primary formulation for a compounded

product. Formulations with limited demand and a shorter duration of stability should not be prepared in large amounts to avoid waste of unused medications.

Because most extemporaneous liquid preparations are aqueous, they are at risk of contamination with microorganisms that can multiply during storage. These microbes may include molds, yeasts, and bacteria. The susceptible preparations should be protected using preservatives. An effective preservative should be non-toxic, inhibit the growth of microorganisms likely to contaminate the preparation, be sufficiently water soluble to achieve the necessary concentration, be in an ionized form to penetrate the microorganism, be nonirritating and nonsensitizing, have adequate stability, be compatible with all the other ingredients of the formulation, and be nonreactive with the container and closure used to dispense the formulation. The most commonly used preservatives include derivatives of benzoic acid such as sodium benzoate and methylparaben and derivatives of sorbic acids such as potassium sorbate. Ora-Plus contains potassium sorbate and methylparaben. If the alcohol content in alcoholic and hydroalcoholic extemporaneous formulations is sufficient to prevent microbial growth, these may not need additional chemical preservatives. However, a high alcohol content may preclude the use of these products in certain pediatric patients, especially premature neonates and newborns. Necessary caution must be used while compounding so that the pH is not altered and the preservative is not diluted below its effective concentration.

## Sterility

Sterility testing is required for compounded parenteral products. All hospitals are required to comply with the USP's Revised General Chapter <797> Pharmaceutical Compounding—Sterile Preparations Guidelines, which set practice standards to ensure that compounded sterile preparations are of high quality and prevent harm or fatality to patients caused by microbial contamination, excessive bacterial endotoxins, and errors caused by the presence or absence of labeled ingredients or presence in inaccurate amounts (Reference 23). Most pharmacies involved with the compounding of sterile preparations have undertaken major renovations to their "Clean Rooms" while actively training and evaluating their personnel in aseptic manipulation skills. The guidelines assign compounded sterile preparations three risk levels on the basis of their probability of microbial contamination and physical and chemical contamination. These risk levels (low, medium, and high) refer to the quality of the compounded sterile preparation immediately after the final aseptic manipulation or immediately after the final sterilization. These guidelines offer pre-administration exposure duration and temperature limits (beyond-use date and storage temperature) in the absence of direct testing results or appropriate information sources that

justify different limits. For a more comprehensive review of sterility requirements for extemporaneously compounded parenteral formulations, the authors refer the reader to the USP's Revised General Chapter <797> Pharmaceutical Compounding—Sterile Preparations Guidelines (Reference 23).

## **EFFICACY AND SAFETY OF EXTEMPORANEOUS FORMULATIONS**

The ultimate goal of preparing an extemporaneous formulation is to make it effective and safe in patients. Care must be taken to maximize safety; for example, a sustained-release tablet should not be crushed when preparing a liquid formulation, and a preservative such as benzyl alcohol should be avoided in a formulation intended for a neonate. Propylene glycol, ethanol, and sorbitol are examples of other excipients that have been associated with adverse effects in pediatric patients and should be avoided in pediatric formulations. Ideally, extemporaneous formulations should be studied in patients to establish their efficacy and safety. However, such studies are generally cost-prohibitive because of lack of funding for the performance of clinical studies. Efficacy and safety data of an extemporaneous formulation obtained in adult studies may not be reproducible in a pediatric population because of specific characteristics of the formulation. Omeprazole, a proton pump inhibitor, is often administered by a nasogastric tube for stress ulcer prophylaxis in critically ill mechanically ventilated patients. An extemporaneous suspension of omeprazole in sodium bicarbonate is formulated to prevent degradation of the drug granules by the gastric acid. This suspension has been effective in preventing clinically significant upper gastrointestinal bleeding in critically ill adults, and it effectively maintained excellent control of the gastric pH (References 24, 25). In a study of mechanically ventilated critically ill pediatric patients, administration of the same extemporaneous suspension did not produce the expected gastric acid suppression, despite the use of recommended standard doses (Reference 26). The inadequate amount/volume of bicarbonate in the smaller pediatric dose to protect omeprazole degradation from the acid in the child's stomach was hypothesized to cause this difference in bioavailability and efficacy.

A concern about the use of many extemporaneous formulations is lack of bioavailability, efficacy, and safety data in pediatric patients. However, their use should be guided by justified need, application of principles discussed in this chapter, and documentation of stability data, which are increasingly available and shared within the professional community. Despite the lack of specific efficacy and safety studies, extemporaneous formulations should be prepared using general

principles already discussed in this chapter. Each formulation should be made specifically based on available data. For example, variations in the use of drug and excipients, method of preparation, and storage conditions can compromise stability as well as the expected efficacy and safety of the formulation. Patients receiving extemporaneous formulations should be monitored to ensure they achieve the expected clinical benefit and experience no untoward effects. Clinical experience should be shared through presentations at national meetings, discussions on Web sites, and publications in peer-reviewed journals. With the exception of non-sterile or contaminated products, safety concerns have seldom been reported with the use of extemporaneous formulations. Although no specific agency or group receives reports of adverse events associated with extemporaneous formulations, such occurrences should be reported to the FDA and be widely shared with health care professionals.

## **COST**

Reimbursement for the preparation and dispensing of extemporaneous formulations can be difficult, especially for community pharmacies, based on the patient's insurance carrier. Insurance authorization is often required, and the process can be time-consuming. For each extemporaneous formulation, the total cost includes the cost of the active ingredient(s), other ingredients needed to compound the formulation such as vehicles, and the pharmacist's compounding time. Reimbursement may not cover all the costs, especially if expensive ingredients such as injectables are needed. Thus, pharmacists preparing extemporaneous formulations should inquire with insurance carriers to determine how they will be reimbursed. Specialty pharmacies involved in compounding various extemporaneous formulations do not usually accept health insurance and will directly bill the patient for the total cost of the extemporaneous formulations.

## **CONCLUSIONS AND FUTURE PERSPECTIVES ON DEVELOPMENT OF PEDIATRIC DRUG FORMULATIONS**

The need for extemporaneous formulations will continue to exist both for new drugs under patent protection and for generic drugs. Pharmacists play an essential role in the preparation of stable, effective, and safe formulations for pediatric patients of all age groups. However, the challenge of finding adequate information and financial resources for conducting stability and sterility as well as efficacy and safety studies with all extemporaneously prepared formulations of new and generic drugs is likely to continue. The use of these preparations should

be monitored for efficacy and safety in patients, and these data should be shared through presentations at national meetings and publications in journals and books. Finally, funding agencies should provide resources to conduct studies with extemporaneous formulations to make important drugs accessible to infants and children as well as to adult populations with special needs.

# CHAPTER 7

## PEDIATRIC TOXICOLOGY

Mark R. Haase, Pharm.D., FCCP, BCPS

### LEARNING OBJECTIVES

1. Discover the methods of poisoning data collection and how they affect prevention and therapy efforts.
2. Evaluate the incidence of pediatric poisonings in the United States on the basis of the National Poison Data System Annual Report.
3. Evaluate the poisoned child.
4. Assess the efficacy of gastric decontamination methods.
5. Manage select pediatric poisonings.

### ABBREVIATIONS IN THIS CHAPTER

AAPCC	American Association of Poison Control Centers
AC	Activated charcoal
FabAV	Crotalidae polyvalent immune Fab antivenom
MDAC	Multiple-dose activated charcoal
NAC	<i>N</i> -acetylcysteine
NAPQI	<i>N</i> -acetyl- <i>p</i> -benzoquinonimine
SOI	Syrup of ipecac
WBI	Whole bowel irrigation

### INTRODUCTION

Despite increased educational efforts, childhood poisonings remain a common occurrence, though not a common cause of morbidity and mortality in this population (Reference 1). Each year, more than 2 million toxic exposures are reported, with more than one-half of them occurring in children younger than 6 years. Medical management of poisoned children is similar to that of adults, but there are important differences that need to be considered. This chapter will introduce the reader to the reporting system used to document epidemiologic trends in toxic exposure incidence and management, the evaluation of the poisoned child, decontamination principles, and the management of selected poisonings.

### EPIDEMIOLOGY

#### National Poison Data System

The National Poison Data System is the only comprehensive resource in the United States for poisoning surveillance. It is owned and managed by the American

Association of Poison Control Centers (AAPCC), and since 1983, the organization has used these data to publish an annual report (Reference 2). The current database holds data on around 50 million reported toxic exposures. Poison centers, typically staffed by pharmacists and nurses, serve all 50 states and several U.S. territories (poison specialists are available 24 hours/day and can be reached through the national poison hotline at (800) 222-1222). They provide data to the National Poison Data System from incoming calls by an online reporting system that allows real-time surveillance of poisoning data. In 2009, poison centers received almost 2.5 million calls for human exposures. In 1983, there were just over 250,000 calls, though for the past 15 years, the number has been more than 2 million (Reference 2). Of note, the database contains information from reported exposures only; many more exposures occur that are unreported, including those that cause serious injuries or fatalities (Reference 3). In addition, some clinicians manage poisonings without consulting a poison center, whereas therapeutic errors that result in toxicity may not be reported (References 1, 2). Nevertheless, these data are very important because they can help inform policy decisions in many areas, including direction of toxicology research; drug formulation safety and development; appropriateness of drugs for over-the-counter status; direction of health care professional education and poison prevention education for the general public; and detection of chemical and bioterrorism incidents (Reference 4). A wealth of information for health care professionals and the lay public regarding epidemiology, prevention, and management of poisonings is available at Web sites provided by the AAPCC and the Centers for Disease Control and Prevention ([www.aapcc.org/dnn/Home.aspx](http://www.aapcc.org/dnn/Home.aspx) and [www.cdc.gov/HomeandRecreationalSafety/Poisoning/index.html](http://www.cdc.gov/HomeandRecreationalSafety/Poisoning/index.html)).

#### Epidemiologic Trends

Historically, children younger than 6 years have accounted for about one-half of all reported exposures. In 2009, children younger than 3, 5, and 20 years accounted for almost 40%, 52%, and 65% of reported toxic exposures, respectively (Reference 2). Despite these high percentages, children account for only a small minority of fatalities, with less than 2% occurring in children younger than 6 years in 2009 when the toxin contributed in some way to death (total fatalities in this age group

as a percentage of all reported fatalities have decreased from 6.3% to 2.4% since 1985). In addition, a vast majority of exposures in children up to age 12 years have resulted in no to minor effects (Reference 2).

The type of poisons most often encountered by children has remained much the same for many years. Analgesics, cosmetics, and household cleaning substances are consistently the most common toxins encountered overall. In addition, foreign bodies, topical preparations, vitamins, antihistamines, cough and cold preparations, pesticides, and plants are often ingested (Reference 2).

## EVALUATION OF THE POISONED CHILD

For many reasons, an infant, toddler, or young child will ingest or be exposed to substances that an older child or adolescent will not. As children age, they become more mobile, allowing them to satisfy their natural curiosity and investigate things they could not before. They can mimic adult activities such as taking medicine. They may mistake pharmaceuticals such as ferrous sulfate for candy or household cleaning products for flavored drinks. Fortunately, in children, most exposures are without intent to harm, and most result in minimal, if any, adverse outcomes (Reference 2). However, any time a child presents with an altered level of consciousness, metabolic disturbance, neurologic dysfunction, or cardiac or pulmonary distress, it is important to include toxic exposure as part of the differential diagnosis (Reference 5). In many ways, the evaluation of a poisoned child is similar to that of an adult, but there are some important differences in supportive care, history, and evaluation.

## Supportive Care

Supportive care, always a key component in managing toxic exposures, begins with airway stabilization and should follow Pediatric Advanced Life Support guidelines (Reference 6). Some substances, such as tricyclic antidepressants, can cause rapid loss of consciousness and result in the need for rapid sequence intubation for airway protection, ventilation, and oxygenation. In addition, early antidote administration may be necessary, such as naloxone in opioid ingestions. Table 1 lists antidotes to selected poisonings. A more complete listing of available antidotes has been provided elsewhere (Reference 7).

## History and Physical Examination

A thorough history of ingestion in small children is usually easier to obtain than in adolescents. In general, caregivers provide as much detail as possible, including ingested volume estimates, tablet counts, containers of the substance in question, and a complete review of toxic substances in the vicinity of the child when the exposure occurred. The toxin involved and the time of ingestion are easiest to ascertain, whereas the amount ingested is typically more difficult to determine. These factors are important because they significantly affect the decision to implement decontamination strategies (Reference 8). It is important to inquire about other places the child may have been because more than 10% of toxic ingestions in children occur outside the home (Reference 1). A thorough history in an adolescent patient can be more difficult because the ingestion is more

**Table 1.** Antidotes for Selected Poisonings or Toxicities (References 7, 10)

Antidote	Poisoning or Toxicity
Atropine/Pralidoxime	Organophosphates/Carbamates
Dantrolene	Malignant hyperthermia caused by the disease process such as neuroleptic malignant syndrome or heat stroke; or caused by drug toxicity such as from monoamine oxidase inhibitors or baclofen withdrawal
Deferoxamine	Iron
Digoxin antibody fragments (Fab)	Digoxin
Flumazenil	Benzodiazepines
Edetate calcium disodium (EDTA)/dimercaprol (British Anti-Lewisite or BAL)/succimer (dimercaptosuccinic acid)	Lead
Methylene blue	Methemoglobinemia
Protamine	Heparin
Sodium and amyl nitrite/sodium thiosulfate	Cyanide
Sodium bicarbonate	Salicylates, tricyclic antidepressants
Vitamin K	Warfarin

likely intentional or the result of substance abuse, and these patients may not be as forthcoming. Any information obtained from the patient about the ingestion must be taken in context of the clinical condition of the patient (Reference 1). Other important contrasts between children and adolescents or adults are as follows: children more often present within a few hours of ingestion; multiple toxins are more likely involved in adolescent or adult exposures; in children, the toxin is more likely nontoxic; and children ingest a smaller amount in most instances (Reference 1). Although children more often encounter nontoxic substances or ingest an amount that results in minimal harm, there are several toxins or drugs that may cause serious harm or death in very small amounts (References 1, 9) (see Table 2).

The physical examination centers on mental status and vital signs, including pulse; respiratory rate, quality, and effort; blood pressure; temperature; skin tone and color; hydration status; peripheral pulses; and perfusion (Reference 10). A neurologic examination should be performed, including an evaluation of pupil size and reactivity. Many signs and symptoms of toxic exposures manifest in clusters called toxidromes (see Table 3). Specific toxins, identified from the history or presentation, may allow the caregiver to narrow the physical examination to focus on expected or possible complications of the poisoning.

### Laboratory Evaluations

Laboratory evaluations should be directed by the history and physical examination, though most patients

**Table 2.** Substances That May Result in Severe Toxicity in Children with Small Exposure (References 1, 9)

Substance	Potentially Significant Exposure in Children	Definitive Management or Antidote Beyond Supportive Care and Decontamination
Antihistamines	Diphenhydramine – 10–15 mg/kg	Benzodiazepines for seizures or delirium Sodium bicarbonate for arrhythmias
Benzocaine	¼ teaspoon of 7.5% gel in infants ½ teaspoon in older children	Methylene blue for methemoglobinemia
β-Adrenergic antagonists	Propranolol > 4 mg/kg (40-mg tablet in 10-kg infant)	Pressor support Glucagon, insulin, glucose for cardiovascular support
Calcium channel blockers	Diltiazem > 1 mg/kg	Calcium Pressor support Glucagon, insulin, dextrose for cardiovascular support
Camphor	5 mL of camphorated oil (1 g of camphor)	Airway management Seizure management
Clonidine	0.1 mg Chewing clonidine patch	Pressor support Arrhythmia management Seizure management Naloxone
Diphenoxylate/atropine	> 0.5–2 tablets	Naloxone
Methyl salicylate	> 150 mg/kg Several salicylate sources 1 mL of oil of wintergreen = 1400 mg of acetyl-salicylic acid	Dextrose and electrolytes Forced diuresis/alkalinization Seizure and cerebral edema management
Opioids	Hydrocodone 2.5 mg reported lethal in infants (1 teaspoon of hydrocodone/acetaminophen solution)	Naloxone Pressor support Seizure management
Sulfonylureas	Chlorpropamide – 250 mg Glipizide – 5 mg Glyburide – 2.5 mg	Intravenous dextrose Glucagon
Tricyclic antidepressants	10–20 mg/kg considered potentially lethal in infants and young children	Sodium bicarbonate, lidocaine, phenytoin, or magnesium for arrhythmias Seizure management

presenting with suspected poisoning should have serum chemistries and acid-base status assessed. If the history indicates the possibility of alcohol ingestion, serum osmolality may be useful. Ingestions of cardiovascular agents such as  $\beta$ -adrenergic blockers or calcium channel antagonists warrant an electrocardiogram (Reference 5). A chemistry allows a calculation of the anion gap  $[(Na - \{Cl + HCO_3\})]$ ; normal value 4–12 mEq/L. An elevated gap may indicate poisoning. A common mnemonic device to identify potentially causative mechanisms of an elevated anion gap is MUDPILES (M = methanol; U = uremia; D = diabetic ketoacidosis; P = propylene glycol; I = isoniazid, iron, infection; L = lactic acidosis; E = ethylene glycol, ethanol; S = salicylates) (Reference 10). Serum concentrations of acetaminophen (and, to a lesser extent, salicylates, ethanol, or iron) should be strongly considered because acetaminophen is so widely available in many products, and symptoms may not occur until several hours postingestion. Other specific serum concentrations are generally not required and should be dictated by the specific ingestion (Reference 5).

## DECONTAMINATION

Although gastric decontamination offers the only therapy available other than supportive care for many orally ingested poisons, there are few data to suggest any

effect on outcomes. Reasons for this include significant inter-patient variability (even in similar ingestions) and that most ingestions result in only minor to moderate adverse effects. Very large trials would be required to detect differences in outcome. This is especially true in children (Reference 11). The lack of evidence of efficacy has resulted in significant decreases in the use of gastric decontamination. In 1985, syrup of ipecac (SOI) or activated charcoal (AC) was given in almost 20% of child exposures, whereas in 2009, only 1.5% of children received these agents (Reference 2). This trend has also been influenced by statements from the American Academy of Pediatrics and the American Academy of Clinical Toxicology (References 12, 13). The American Academy of Pediatrics statement, a summary of the evidence for managing poisoning in the home, suggests that SOI not be used routinely in the home and that insufficient evidence exists to recommend use of AC in the home. The American Academy of Clinical Toxicology statement notes that evidence for improved outcomes with use is lacking and that use should typically be limited to patients who ingest a toxic substance up to 1 hour before administration. Table 4 summarizes gastric decontamination methods, but a brief discussion of each is provided in sections that follow. A review of decontamination techniques has been provided elsewhere (References 13, 14, 17, 21, 22).

## Syrup of Ipecac

Alkaloids obtained from the root of the *Cephaelis acuminata* or *ipecacuanha* plant activate the chemoreceptor trigger zone and act directly on the small intestine to induce vomiting (Reference 14). Administration of SOI has been shown to provide removal of drugs in both volunteers and overdosed patients (References 23–25). However, the percentage returned can be highly variable, and it wanes rapidly enough that recovery is likely to be insignificant by the time most patients receive SOI (Reference 26). An analysis of poison exposure data in children found that the use of SOI had no impact on either emergency department referral or outcomes (Reference 15). In addition, although the administration of SOI has been proven safe, rare serious adverse events can occur, and the potential for abuse exists, which can lead to myopathy, cardiomyopathy, and death with chronic use (References 27, 28). Because of this lack of impact on clinical outcomes and because, in many instances, ingestion by children results in no to minimal harm, SOI is no longer recommended for routine use (Reference 12). In the rare cases when SOI is considered, dosing is as follows: age 6–12 months, 5–10 mL; 1–12 years, 15 mL; adolescents and adults, 30 mL. Water may be offered after administration (Reference 14).

## Gastric Lavage

Because of a lack of evidence of effectiveness and a relatively high complication rate, routine use of gastric lavage is not recommended (Reference 17). Data made available since the first publication of the consensus statement in 1997 have not altered that recommendation (References 29–31). In addition, there are serious risks including delaying definitive antidote administration, aspiration, mechanical injury, hyponatremia, hypothermia, and death (References 18, 22). In the rare instance that a risk-benefit analysis predicts potential benefit to gastric lavage, it is recommended that it be performed within an hour of ingestion and continued until returns are clear (Reference 17). However, clear returns do not exclude a significant ingestion or guarantee that all toxin has been removed. In addition, the possibility remains that a significant amount of drug is still available in the stomach several hours after ingestion, though lavage appears variably effective at best in these situations (References 32, 33).

## Activated Charcoal

Activated charcoal is produced when substances high in carbon content (e.g., wood, peat) are heated and then treated with steam or carbon dioxide (Reference 13). This results in a high surface area that allows the adsorption of other substances. Activated charcoal remains the

only commonly used method of gastric decontamination (Reference 2). Current recommendations call for considering the use of AC within 1 hour in patients with a potentially toxic ingestion (Reference 13). Data available since the 2005 consensus statement have supported this recommendation, suggesting that AC provides minimal if any benefit in poisoned patients and decreased efficacy 1–2 hours postingestion (References 34–37). However, other data suggest AC can be effective in preventing sequelae and hastening the elimination of toxin, even when given after 1 hour postingestion (References 38, 39).

Administration of AC to children in the home has been investigated in an effort to increase efficacy by earlier administration. It appears it is feasible for parents and caregivers to administer safely. However, this has not been consistently shown, and considering risk of too-frequent and inappropriate use, home administration is not recommended (References 12, 40, 41).

An AC-to-drug ratio of 10:1 is recommended. However, in most poisonings, the exact amount of drug ingested is unknown. Thus, it is suggested that adults receive 25–100 g (providing adsorption of around 2.5–10 g of drug) and that children receive 0.5–2 g/kg, or as much as can be tolerated (Reference 11). If the 10:1 ratio is unlikely to be achieved with a maximally tolerated single dose, multidose AC or other decontamination methods should be considered. Activated charcoal is a relatively safe intervention. Vomiting is the most likely complication in children, and vomiting before administration and nasogastric tube placement appears to increase the risk (Reference 20). Complications that are more serious, such as aspiration or bowel perforation, are much less common (References 13, 19).

Multiple-dose activated charcoal (MDAC) is defined as the administration of more than two sequential doses (Reference 42). Multiple doses provide benefit by preventing prolonged absorption or enterohepatic recirculation (“gastric dialysis”) (References 43, 44). Drugs are present in the gastrointestinal tract not only because of ingestion, but also because of diffusion from the circulation back into the lumen of the gut. Drug concentrations in the circulation decline as metabolism and elimination occur, limiting the amount of drug that can diffuse back into the gut lumen. Administration of AC causes enhanced elimination of drug from the gut through adsorption and elimination in the stool. This results in a “sink,” described by an increased drug gradient between the circulation and the gut lumen, allowing more drug to diffuse into the gut lumen, where it can be adsorbed by AC and eliminated. Repeated administration of AC enhances this process of gastric dialysis of certain drugs.

There are scant clinical outcome data to support the use of MDAC. However, there may be benefit in treating poisoning from agents to which children are exposed, including phenobarbital, carbamazepine, theophylline,

**Table 4. Gastric Decontamination Methods (References 13–21)**

<b>Method</b>	<b>Mechanism</b>	<b>Indications</b>	<b>Contraindications</b>	<b>Adverse Effects</b>	<b>Comments</b>
Syrup of ipecac	Alkaloids emetine and cephaline activate vomiting center in CRTZ and act directly in small intestine; vomiting usually occurs within 20 minutes	Ingestions presenting within 1 hour with expected airway patency and normal mental status 1 hour after administration	Caustic, hydrocarbon, battery, and sharp ingestions; ingestions expected to cause altered level of consciousness; significant prior vomiting; nontoxic ingestion	Persistent vomiting, sedation, vagal bradycardia, delay of definitive therapy, esophageal tear, pneumomediastinum (rare); relatively safe when used appropriately	May be most useful in large ingestions when/where AC not effective; early administration can result in significant returns, so availability in remote areas may be prudent; alternative cause should be suspected for vomiting > 2 hours after dose; use requires expectation of normal state of consciousness at least 1 hour after use; because of very limited clinical utility, reported use has decreased from 15% of exposures in 1985 to less than 0.03% of exposures in 2009
Gastric lavage	Gastric intubation with 22–28 Fr orogastric tube; patient placed in left lateral decubitus position; 10–15 mL of warm saline per kilogram administered and removed	Life-threatening ingestions presenting within 1 hour; risk-benefit assessment recommended	Hydrocarbon, caustic ingestions, unprotected airway, patient at risk of hemorrhage or perforation	Airway or esophageal injury, hypoxia, electrolyte and core temperature disturbances	Saline should be used in children to prevent electrolyte disturbances; process is physically and emotionally traumatic in children; airway protection is imperative because children often vomit during tube placement; tube size in small children is prohibitive, contributing to decline in use of this method
Activated charcoal	Reversible adsorption, possibly by hydrogen/ionic binding, van der Waals forces; high surface area maximizes adsorption	Potentially toxic ingestions when administered within 1 hour	Caustic, alcohol, metal, hydrocarbon ingestions; ileus, gastric, or intestinal perforation	Vomiting (from AC or NG tube placement) more common if coadministered with sorbitol; aspiration, bowel injury rare but severe	Unpalatable because of thick, gritty texture; if not premixed, combine with water or cola in a 1:8 ratio, disguise preparation, or administer by NG tube; airway must be protected; sorbitol should only be given with initial dose, if at all
Whole bowel irrigation	Polyethylene glycol and electrolyte solution flushes gastrointestinal tract	Very large ingestions when poor outcome is likely; SR or EC product poisonings, particularly in those presenting > 2 hours after ingestion; ingestions when AC is ineffective; removal of drug packets from gastrointestinal tract	Ileus, gastrointestinal hemorrhage, perforation, obstruction, uncontrolled vomiting, diarrhea with volume depletion or hemodynamic instability	Vomiting, bloating, cramping; colonic perforation, esophageal tears, aspiration rare	Balanced solution prevents electrolyte imbalances; continue until effluent clear or no opacities on radiograph if present before therapy

AC = activated charcoal; CRTZ = chemoreceptor trigger zone; EC = enteric coated; Fr = French; NG = nasogastric; SR = sustained release. Reprinted with permission from Haase MR. Poisoning and envenomation. In: Richardson M, Chant C, Chessman KH, Finks SW, Hemstreet BA, Hume AL, et al., eds. *Pharmacotherapy Self-Assessment Program*, seventh ed. Pediatrics. amitriptyline, digoxin, and phenytoin (Reference 42). Publications since the 1999 American Academy of Clinical Toxicology position statement have shown mixed efficacy (References 34, 35, 39, 45). However, in large overdoses when protein binding is exceeded, enterohepatic recirculation occurs, or absorption or first-pass metabolism is slowed, MDAC may be clinically useful (Reference 11). If MDAC is employed, a standard loading dose should be given, followed by 0.5 g/kg every 4–6 hours for up to 24 hours or until the patient's condition has improved or drug serum concentrations are no longer in the toxic range (References 42, 46).

An important consideration is the potential for AC to adsorb not only the ingested poison, but also other agents used in managing the poisoning. For example, AC has been shown to cause a statistically significant decrease in the absorption of *N*-acetylcysteine (NAC) when administered concurrently. Clinically, this does not appear to be significant. However, the interaction can be minimized by separating the administration of the two agents by 1–2 hours or using the intravenous NAC preparation (Reference 47).

### Whole Bowel Irrigation

Whole bowel irrigation (WBI) is performed using a polyethylene glycol and electrolyte solution to essentially flush out the gastrointestinal tract. This preparation prevents electrolyte abnormalities associated with older cathartics such as sodium phosphate (Reference 48). Use should be considered in overdoses of sustained-release or enteric-coated drugs, iron, or other metal ingestions; in patients acting as carriers of illicit drug packages; and in those with mushroom or other plant ingestions (Reference 21). Since the publication of a position statement on WBI from the American Academy of Clinical Toxicology, there has been little published evidence of efficacy. Some investigations have used WBI in overdoses when it would not be considered clinically (e.g., acetaminophen), and use of WBI could potentially decrease the adsorptive capacity of AC (References 11, 49).

The solution can be given orally, but in children, it is often easier to administer by nasogastric tube. Small children should receive 0.5 L/hour, whereas older children and adolescents should receive 1.5–2 L/hour. The older patient should sit on a toilet, whereas diapers are required in small children and infants. Administration for 4–6 hours is usually necessary to achieve a clear effluent (Reference 21). Several products are available for WBI, including GoLYTELY, NuLYTELY, and Colyte, and these may be flavored for palatability. However, MiraLAX, commonly used for managing constipation in children, should not be used for WBI because it contains no electrolytes, increasing the risk of electrolyte abnormalities (Reference 48).

## REVIEW OF MANAGEMENT OF SELECT POISONINGS

A review of the management of multiple toxic exposures is beyond the scope of this chapter. However, poisonings occur that, although perhaps not the most common statistically, have several aspects of management unique to the pediatric population. Analgesics, particularly acetaminophen, are quite commonly ingested by children, and the toxic dose differs from that of adults on a kilogram basis. Antidote therapy for toxic alcohol exposure has changed in recent years, and additional pediatric data have guided the management of these exposures in children. Management of snakebites in children is similar to that in adults, but many issues need to be considered when administering antivenin to children. Care of children who have ingested or been exposed to these three toxins is discussed in the following paragraphs.

### Acetaminophen

When dosed therapeutically, acetaminophen has a very good safety profile in children (References 50–52). Acetaminophen is also widely available in many dosage forms and drug combinations. Therefore, it is not surprising that in 2009, there were almost 50,000 toxic exposures to acetaminophen in children younger than 6 years. Overall, acetaminophen was the fourth most common toxin associated with death, involved in more than 10% of adult poisoning fatalities. Nevertheless, outcomes in children were good, and no fatalities were reported in anyone younger than 17 years (Reference 2). However, acetaminophen is the most commonly identified cause of acute liver failure in children (Reference 53).

After absorption, around 90% of an acetaminophen dose is glucuronidated and sulfated. These metabolites, and a small percentage of unchanged drug, are eliminated in the urine. The rest is metabolized by the cytochrome P450 (CYP) system to a toxic metabolite, *N*-acetyl-*p*-benzoquinonimine (NAPQI). This metabolite is rapidly toxic to liver cells, but natural stores of glutathione conjugate it, and this complex is eliminated in the urine. In an overdose, glutathione stores become depleted, NAPQI is no longer detoxified, and direct liver damage results (Reference 47). In untreated patients, acetaminophen toxicity typically progresses through the following four stages. After ingestion, gastrointestinal symptoms such as nausea and vomiting predominate, though patients may be asymptomatic. No liver damage has occurred yet. Stage 2 may occur as early as 12 hours in large overdoses, but typically by 24–36 hours postingestion, there is evidence of acetaminophen-induced hepatotoxicity, defined as aspartate aminotransferase

concentrations greater than 1000 IU/L. Maximal liver damage occurs in stage 3, 3–4 days postingestion. Patients may experience fulminant hepatic failure, encephalopathy, coma, and hemorrhage. Alanine aminotransferase and aspartate aminotransferase may exceed 10,000 IU/L, and elevations in PT (prothrombin time) and INR (international normalized ratio) are possible. Renal toxicity can occur with or without the presence of hepatic toxicity, but it more often occurs shortly afterward. The incidence of renal toxicity is unclear and is thought to be a rare event; however, it has been reported to be as high as 8.9% (References 47, 54, 55). Death occurs in 3–5 days because of multiple organ failure. Survival to stage 4 should result in recovery of liver function, with laboratory values returning to normal within 1 month (Reference 47). Of note, although published data suggest a wide variation in outcomes, there is significant risk of fulminant or fatal hepatotoxicity in patients with acetaminophen poisoning who do not receive treatment. However, even without treatment, fatality rates likely do not exceed 20% (Reference 56).

The decision to initiate therapy for acetaminophen poisoning is dictated by the amount ingested. Acute ingestions of 7.5–15 g in adults or 150 mg/kg in children have conventionally been considered toxic. However, there are no data in children to support this, and it is unlikely that significant liver toxicity would occur with doses less than 200 mg/kg (References 57–59). With the recent FDA labeling of intravenous acetaminophen in the United States, frequent 10-fold dosing errors have been documented in countries where it has been available for several years, and toxicity has been reported in children with intravenous acetaminophen in doses well under 200 mg/kg (References 60, 61). It is suggested that in suspected dosing errors (or a single dose greater than 60 mg/kg) with this product, strong consideration be given to antidote therapy while a toxicologic assessment can be completed (Reference 60). Even though acetaminophen is absorbed relatively quickly and an effective antidote exists, gastric decontamination can be considered if the patient presents early after ingestion. Syrup of ipecac and gastric lavage are typically not indicated. Activated charcoal can be given within 1–2 hours after ingestion and may help keep serum concentrations below the treatment line of the Rumack-Matthew nomogram (Reference 47). The Rumack-Matthew nomogram (Figure 1) permits a single acetaminophen concentration obtained at least 4 hours after ingestion to be used to assess the risk of hepatotoxicity (Reference 47). The treatment line, at 25% below the dotted line in the figure, is used to justify antidote therapy. If the serum concentration is on or above the treatment line between 4 and 24 hours, therapy is initiated. Of

note, the Rumack-Matthew nomogram is validated only for use in single, acute, oral ingestions. Toxicity from the intravenous preparation or from chronic exposure cannot be reliably assessed by the nomogram. The toxicity risk of the extended-release acetaminophen product can be reliably assessed because peak acetaminophen concentrations occur in a time frame similar to that of immediate-release products. However, if the initial serum concentration is below the treatment line, it is prudent to repeat a measurement at about 8 hours after ingestion to confirm risk assessment because a small percentage of patients may cross above the treatment line.

Antidote therapy is provided with NAC. It can prevent hepatotoxicity by providing a substrate for glutathione production and binding NAPQI directly, and it can decrease present hepatotoxicity by free radical scavenging and antioxidant effects (Reference 62). *N*-acetylcysteine may be administered orally or intravenously. Some authors have suggested that the oral route be used in patients presenting within 8–10 hours of ingestion and that intravenous NAC be administered when presenting 10 hours or more after ingestion (Reference 63), whereas others have suggested the opposite is true (References 64, 65). However, in most instances, it appears efficacy should be equivalent, particularly when given within 8 hours (References 61, 64). One apparent advantage to intravenous administration is the 21-hour infusion time (150 mg/kg over 1 hour; then 50 mg/kg over 4 hours; then 100 mg/kg over 16 hours) compared with the 72-hour oral regimen (140 mg/kg  $\times$  1; then 70 mg/kg every 4 hours  $\times$  17 doses). This opportunity for decreased length of hospital stay offsets the higher cost of the intravenous NAC product. However, several authors have found that shorter courses of the oral product may be as effective as the traditional 72-hour regimen (References 66–68). Use of these shorter regimens would make the oral route more cost-effective.

Both formulations have proven safe in acetaminophen overdose. The most common adverse events with oral administration are nausea, vomiting, and diarrhea, whereas anaphylactoid reactions (rarely serious) are more common with the intravenous preparation (References 62, 65, 69). An additional consideration with standard dilution of the intravenous product is the potential for excess free water administration, resulting in hyponatremia and seizures. In younger patients, more concentrated solutions should be administered (References 70, 71). For example, in adults, the three infusions are given in volumes of 200 mL, 500 mL, and 1000 mL, respectively, resulting in

## Single Acute Acetaminophen Overdose Nomogram

**Nomogram:** acetaminophen plasma concentration vs time after acetaminophen ingestion (adapted with permission from Rumack and Matthew. *Pediatrics*. 1975;55:871-876). The nomogram has been developed to estimate the probability of whether a plasma acetaminophen concentration in relation to the interval post-ingestion will result in hepatotoxicity and, therefore, whether acetylcysteine therapy should be administered.

### CAUTIONS FOR USE OF THIS CHART:

1. Time coordinates refer to time post-ingestion.
2. Graph relates only to plasma concentrations following a single, acute overdose ingestion.
3. The Treatment Line is plotted 25% below the Rumack-Matthew Line to allow for potential errors in plasma acetaminophen assays and estimated time from ingestion of an overdose (Rumack et al. *Arch Intern Med*. 1981;141(suppl):380-385).

Figure 1. Rumack-Matthew nomogram.

concentrations ranging from about 40 mg/mL to less than 5 mg/mL. To prevent the development of hyponatremia in children, the product should be diluted to a concentration of 40 mg/mL for all three phases.

### Ethylene Glycol and Methanol

Ethylene glycol and methanol pose serious risks to children because they can be found in the home in several different products, and very small amounts can be deadly in small children (References 72, 73). Ethylene glycol is the primary ingredient in engine coolant, and the sweet taste increases the likelihood of significant ingestion in unsuspecting children and pets. Methanol can be found in solvents, antifreeze, fuels, and photocopying fluid, but it is most often encountered in windshield washer fluid (References 74, 75). In 2009, there were 4852 single exposures to ethylene glycol (10% in children younger than 6 years), and more than 1700 (23% in children younger than 6 years) single exposures to methanol were reported. There were 20 fatalities, but no fatalities were reported in children (Reference 2).

Aside from central nervous system depression, ethylene glycol and methanol are not in themselves responsible for the toxic effects. In the first several hours after exposure, patients with ethylene glycol ingestions may present with decreased mental status, ataxia, slurred speech, and, in larger ingestions, coma. During this time, ethylene glycol is metabolized by alcohol dehydrogenase to glycoaldehyde and then by aldehyde dehydrogenase to glycolic acid (most responsible for metabolic acidosis), which is further metabolized to glyoxylic acid and oxalic acid (References 74, 75). In the 12–24 hours after ingestion, these metabolites result in cardiopulmonary compromise such as respiratory distress, tachycardia, congestive heart failure, and cardiovascular collapse. From 1 to 3 days after ingestion, nephrotoxicity predominates because of calcium precipitation of oxalic acid in renal tubules. Significant hypocalcemia leading to tetany or changes in electrocardiogram may occur as well (References 73–75). Methanol is metabolized by alcohol dehydrogenase to formaldehyde and then by aldehyde dehydrogenase to formic acid, which is most responsible for metabolic acidosis (Reference 74). Symptoms in the first 12–24 hours after ingestion include depressed mental status and tachypnea. The accumulation of formic acid can result in hallmark visual disturbances such as blurriness (“snow field vision”) and blindness, which can be permanent (Reference 76). Other signs and symptoms can include gastrointestinal distress, headache, shock, and seizures (References 73–75).

Initial management includes supportive care and efforts to resolve metabolic acidosis. Laboratory evaluation should include serum chemistries, lactate, and ionized calcium. Serum ethylene glycol or methanol concentrations should be obtained if available, though at many institutions, this measurement must be sent to a reference laboratory, limiting clinical utility (though controversial, serum concentrations of ethylene glycol and methanol above 25 mg/dL are considered toxic). Anion gap and osmolar gap calculations can be completed to assist in diagnosing exposures. However, a normal gap does not rule out clinically significant poisoning (Reference 74). Gastric decontamination is, in a vast majority of cases, not recommended in toxic alcohol ingestions. Syrup of ipecac is not indicated because of central nervous system depression, and AC does not effectively adsorb alcohols (Reference 46). It may be useful to insert a nasogastric tube to aspirate stomach contents in intubated patients in some instances, particularly in large ingestions when absorption may be delayed (Reference 74). Other potentially helpful supportive measures include administering folic acid in methanol poisoning and giving pyridoxine and thiamine in ethylene glycol poisoning to enhance the elimination of toxic metabolites (References 73–75, 77–79). Folic acid or folinic acid can be given intravenously at 1 mg/kg (maximal dose 50 mg) every 4–6 hours for 24 hours or until methanol and formic acid have been eliminated. Pyridoxine and thiamine can be given intravenously in doses of 100 mg/day until ethylene glycol is eliminated. Data regarding the efficacy of these adjunctive therapies are limited, but the risk-benefit ratio is sufficiently low that they should be administered in all patients.

Definitive therapy is aimed at preventing the metabolism of ethylene glycol or methanol to its more toxic metabolites. Historically, the only available option has been ethanol. Ethanol has an affinity for alcohol dehydrogenase several times that of ethylene glycol and methanol (Reference 80). This prevents the accumulation of toxic metabolites and allows renal and pulmonary elimination of the parent alcohols. Ethanol has been used safely in children, and it can be given intravenously or orally, with the goal of maintaining serum concentrations of 100–150 mg/dL. This can typically be achieved by administering an intravenous loading dose of 8 mL/kg of 10% ethanol over 1 hour, followed by an infusion of 0.8 mL/kg/hour. Frequent serum ethanol concentrations will need to be obtained because of the variability in patient pharmacokinetics (Reference 80). However, there are several disadvantages. Administration of intravenous ethanol requires a central venous catheter because of the high osmolality. Ethanol can contribute to central nervous system and respiratory depression, and it may cause hypothermia, hypoglycemia, and hyponatremia,

necessitating intensive care monitoring (References 80, 81). In addition, repeated serum ethanol concentrations are required because metabolic rates vary significantly, and though ethanol can be used safely in children, the potential for significant adverse reactions exists (References 75, 82). If used, ethanol should be continued until ethylene glycol or methanol concentrations are below 25 mg/dL.

Fomepizole (4-methylpyrazole) was made available for use in the United States in 1997. It is a competitive alcohol dehydrogenase inhibitor with an affinity several thousand times that of ethanol for alcohol dehydrogenase (References 72, 83). Fomepizole is effective in the management of both ethylene glycol and methanol ingestions (References 81, 82, 84, 85). Several advantages of fomepizole over ethanol are as follows: no alteration in level of consciousness; no effect on blood glucose or electrolytes; no requirement of central venous access; and no requirement for intensive care if the patient is stable. Patients should receive a loading dose of 15 mg/kg, followed by 10 mg/kg every 12 hours for four doses, and then 15 mg/kg every 12 hours until serum ethylene glycol or methanol concentrations are below 25 mg/dL (Reference 83). A course of fomepizole costs about 4 times that of a course of ethanol. However, the lack of need for intensive care monitoring likely makes fomepizole more cost-effective than ethanol, and this drug has become first-line therapy in toxic alcohol ingestions (References 72, 81, 86, 87). The need for hemodialysis as a treatment modality has decreased significantly since fomepizole became available. However, hemodialysis still may be necessary in patients with severe acidosis, end-organ toxicity, serum concentrations of ethylene glycol or methanol above 50 mg/dL, large ingestions, or late presentation, in whom significant metabolite buildup has occurred and inhibition of alcohol dehydrogenase would be ineffective (References 73, 74).

### **Crotaline Envenomations**

Crotaline snakes (Viperidae, subfamily Crotalinae) include the rattlesnake, copperhead, and cottonmouth. These snakes are also referred to as pit vipers because they have a heat-sensing pit posterior to the nostrils. Additional features that distinguish the Crotaline snakes from nonvenomous North American snakes include a triangle-shaped head, visible fangs, and elliptical pupils (References 88, 89). It is estimated that 8000 snakebites occur annually in the United States (Reference 88). In 2009, 3381 envenomations caused by crotaline snakes were reported; 789 occurred in children younger than 19 years. More than 1200 of these envenomations were from rattlesnakes, of which three fatalities were reported—none in children (Reference 2).

Crotaline venom contains a large number of substances, including enzymes, peptides, amino acids, metallic ions, lipids, and carbohydrates. These components are present in varying quantities and potencies, depending on the age and nutritional status of the snake, geographic region, season, and climate. Once injected, venom is absorbed through lymphatic and venous drainage. The venom then results in local tissue damage, including capillary endothelial destruction, leading to leakage of plasma and red blood cells into tissues, causing significant edema, erythema, and ecchymosis (References 89, 90). After local tissue destruction, hematologic toxicity is the most prominent effect of venom and includes coagulopathy, hemolysis, and thrombocytopenia (References 88, 91). Prothrombin times may be extremely high, even early after a bite, and platelet counts may be very low. Although local and hematologic effects predominate, respiratory, cardiovascular, and neurologic effects may manifest as well. Symptom severity caused by envenomation is related to the amount of venom injected, which depends on fang penetration, the amount of time the snake is allowed to bite, and the length of time since the snake last expended venom. About one-fourth of bites are “dry,” meaning no venom is released by the snake (References 89, 90). The severity of the envenomation can be assessed by one of several scoring systems (References 92, 93). In general, scoring is as follows. (1) With minimal envenomation, there is local pain and swelling only, with no systemic manifestations. (2) With moderate envenomation, there is local tissue involvement in addition to non-life-threatening systemic signs and symptoms with possible coagulation abnormalities, but no evidence of bleeding. (3) With severe envenomation, there is local tissue damage in addition to altered mental status, hypotension, tachycardia, and coagulation abnormalities with severe bleeding or possible severe bleeding (References 72, 91).

After envenomation, symptoms usually occur within several minutes, if not immediately. Patient presentation includes fear, anxiety, intense pain (more than would be expected from the size of the wound), weakness, and dizziness. Those with more severe envenomations can present with altered mental status, tachycardia, visual disturbances, and a metallic taste (Reference 89). Prehospital supportive care involves first moving the victim away from the snake and then transporting the victim to a health care facility as soon as possible. It is not recommended to search for or to try to capture or kill the snake. Instead, the focus should be on calming the patient and keeping him or her warm, and the affected limb should be immobilized and positioned below heart level. Tight-fitting clothing and jewelry such as wedding bands should be removed. Application of ice or tourniquets, incision

or excision of the wound, or use of suction devices is highly discouraged (References 89, 90). Emergency department management involves first ensuring airway, breathing, and circulation. A detailed history of the event, as well as any comorbid conditions and allergy history, should be obtained. A detailed physical examination should be performed, and the initial laboratory evaluation should include a complete blood cell count, platelet count, coagulation studies, serum electrolytes, and urinalysis (References 89, 90).

Definitive therapy for crotaline envenomation was formerly provided with antivenin (Crotalidae) polyvalent, an equine-derived whole immune globulin antibody formulation. This preparation, in use since the 1950s, proved effective and significantly reduced mortality caused by Crotalidae envenomations. However, one-fourth to one-half of patients receiving antivenin (Crotalidae) polyvalent had an acute reaction, including vomiting, rash, dyspnea, cyanosis, and anaphylaxis, and the rate of serum sickness ranged from almost 20% to more than 80% of patients (Reference 94). Antivenin (Crotalidae) polyvalent is no longer manufactured.

In 2000, Crotalidae polyvalent immune Fab antivenom (FabAV) was approved for use. This product is indicated for treating the victims of envenomation by North American crotaline snakes. It is a monovalent ovine Fab derived by inoculating sheep with the venom of the western diamondback, eastern diamondback, Mojave, or cottonmouth rattlesnake, though case reports suggest efficacy against several other types of snake as well (References 94–98). The final product is a lyophilized mixture of antibodies from all four antivenins (Reference 99). Crotalidae polyvalent immune Fab antivenom binds venom that has reached the intravascular space, and the complex is eliminated renally. The Fab fragments are small enough to reach interstitial spaces, preventing further tissue damage (Reference 88).

The severity of the envenomation determines the FabAV dose. Of note, dosing is not based on the size of the child. Crotalidae polyvalent immune Fab antivenom works by neutralizing a specific amount of venom; thus, the dosing recommendations apply to both children and adults. From 4 to 6 vials, each containing 1 g of total protein, should be administered over 1 hour in 250 mL of normal saline. If the venom has been neutralized (no progression of local tissue damage; normalization of systemic signs and symptoms and coagulation disturbances), a maintenance regimen of 2 vials every 6 hours for up to 18 hours should be administered. If, after 1 hour, control of the envenomation is not achieved, an additional dose of 4–6 vials should be administered; this regimen should be repeated until signs and symptoms have ceased to progress. Ideally, administration should occur within 4–6 hours of the bite (Reference 99).

Although a relatively small amount of literature describes the use of FabAV in children, it has been shown to be effective in managing pediatric snakebite victims (References 100–103). Most patients achieve initial control with the first dose. Still, delayed complications, including recurrent coagulopathy, have been reported in children despite initial therapeutic success (References 104, 105). Follow-up within 1 week after discharge seems prudent. Crotalidae polyvalent immune Fab antivenom appears to be well tolerated in children. Overall, adverse events are less frequent with FabAV than with antivenin (Crotalidae) polyvalent because only about 10% to 20% of patients experience acute and delayed reactions (Reference 94). However, in children, adverse event rates appear to be lower (Reference 106). The infusion rate may contribute to adverse events, necessitating dose titration. It is recommended that the initial infusion be given at 25 mL/hour for the first 10 minutes. This may be increased as tolerated up to 250 mL/hour, though the infusion should be given over at least 1 hour (References 92, 99). Pretreatment with diphenhydramine may be considered, and epinephrine, albuterol, and corticosteroids should be available during an acute reaction.

An additional administration concern in children is volume overload, particularly in infants or in large envenomations requiring several doses of FabAV. Although there are no published reports of this occurring, caution should be taken in children with pulmonary, cardiac, or renal conditions. Some institutions provide the initial 4- to 6-vial dose in 2-vial increments in 100 mL of normal saline, which may guard against potential volume overload in small children (Reference 92). Such incremental dosing may also prevent waste if it is determined the entire dose is not necessary. This is important because acquisition costs are about \$1000 per vial or gram (References 92, 103). Time to reconstitute vials must be considered as well. The package insert recommends diluting vials in 10 mL of sterile water for injection before final preparation. This can take several minutes; thus, early notification of the pharmacy department is important in providing rapid administration. Some data suggest that diluting each vial in 25 mL of sterile water for injection and then hand mixing will result in significant decreases in reconstitution times (Reference 107).

## MANAGEMENT OF OTHER COMMON PEDIATRIC EXPOSURES

As noted, most pediatric toxic exposures result in minimal to no effects. Many calls to the poison center involve exposures to essentially harmless substances, such as cosmetics, toothpaste, and crayons (though it is of note that colognes and perfumes contain significant amounts of ethanol and can result in significant toxicity). Other common

exposures like household cleaners, foreign bodies (batteries), and cough and cold preparations, though usually not serious, can result in significant toxicity. A discussion of these exposures is provided in the following section.

### **Household Cleaner and Caustic Exposure**

In 2009, household cleaning substances were the third most commonly reported exposure in children younger than 6 years; in fact, these substances are the third most commonly reported exposure overall (Reference 2). Yet the number of children younger than 6 years requiring emergency department management of injuries from household product exposure has decreased by almost 50% in the past 15 years (Reference 108). Examples of household cleaner products encountered include bleaches, detergents, and soaps. Examples of caustics include acids and alkalis found in products such as toilet, drain, and oven cleaners.

In most pediatric exposures to these substances, there is no intent to self-harm, so ingestion or exposure quantities are likely to be limited, minimizing the risk of an adverse outcome. However, even with small to moderate exposure, symptoms may be observed. Ingestion of detergents and soaps may result in drooling, nausea, vomiting, gastric pain, and respiratory distress, if aspirated. Some products, if sufficiently alkaline, may result in esophageal injury, whereas strong acids are more likely to cause gastric injury (Reference 109). Bleach exposure would present in similar fashion, though the risk of esophageal injury is low with household-strength preparations (usually 3% sodium hypochlorite). Medical management in most children involves supportive care. Fluids may be offered to the asymptomatic or mildly symptomatic child, and observation is typically sufficient (Reference 110). Vomiting should not be induced (Reference 111). Neutralization, offering acidic beverages in alkaline ingestions and alkaline beverages in acidic ingestions, should not be performed. After large ingestions or ingestions of highly concentrated substances, endoscopy, surgical, and further medical intervention may be necessary (Reference 112).

### **Foreign Body Ingestion**

Foreign body ingestion can include coins, toys, and ornaments. Unless the object is composed of a significantly toxic agent (e.g., lead) or is aspirated, management usually consists of observation, though manual removal may be necessary in esophageal impaction. However, disc batteries, because of their composition, present further risk. In 2009, more than 3000 disc battery exposures were reported (Reference 2). Most batteries are obtained by children from products such as games, hearing aids, watches, calculators, and remote controls (Reference 113).

In most cases of battery ingestion, the disc passes the esophagus into the stomach. From there, it usually passes through the intestinal tract within 1–2 weeks and results in no symptoms. However, the battery may become lodged in the esophagus and result in serious and life-threatening complications such as burns, perforations, and fistulae (References 114, 115). This damage is caused by alkaline electrolyte leakage from the battery, pressure necrosis, and external current generation when the battery comes in contact with tissue (References 113, 116). Signs and symptoms include vomiting, diarrhea, abdominal pain, fever, refusal to eat or drink, and dysphagia (Reference 115). When impaction occurs, it should be removed immediately. Of note, in addition to the esophagus, one may encounter children with batteries lodged in the nose, ears, or other body cavities, and it is important in these cases to remove the battery as soon as possible as well. The larger the battery, the more likely impaction will occur. Battery diameter can range from just more than 5 mm to 25 mm, and children ingesting batteries of 20 mm in diameter or more are more likely to develop significant complications (Reference 113). In addition to the national poison hotline, a national battery ingestion hotline [(202) 625-3333] exists to provide guidance in managing an ingestion. The following Web site at the National Capital Poison Center provides further information: [www.poison.org/battery](http://www.poison.org/battery).

### **Cough and Cold Preparations**

There is little, if any, evidence to support the use of cough and cold preparations in children for the management of cold symptoms (Reference 117). In fact, evidence exists that these preparations are associated with fatalities and apparent life-threatening events (References 118–120). Pseudoephedrine is most commonly associated with fatalities. In most instances of death reported in these publications, the drug was given at home and at higher-than-recommended doses. Often, the child was given several drugs with similar ingredients, the dose measurement was inaccurate, an adult formulation was used, or the child was given doses by multiple caregivers.

In 2007, an FDA advisory panel recommended that these drugs be avoided in children younger than 6 years, though the FDA still recommends that they be avoided in children younger than 2 years. However, partly because of the advisory panel recommendation, manufacturers have voluntarily withdrawn cough and cold products intended for children younger than 2 years, and the Consumer Healthcare Products Association has updated labels to state that use should be avoided in children younger than 4 years.

Management of toxicity from these products is primarily supportive, as discussed earlier. Gastric decontamination, primarily AC, can be used if the patient presents early and the airway is protected. Symptomatic therapy may be necessary, including the management of hypertension, arrhythmias, and seizures.

## CONCLUSIONS

Although most toxic exposures occur in the pediatric population, serious or fatal outcomes are quite rare. The American Association of Poison Control Centers and the National Poison Data System provide health care professionals with information that can shape public health and educational efforts. Any pharmacist or health care professional involved in the care of children should be familiar with this resource.

Medical management of the poisoned child can be similar to that of an adult patient in many respects. However, obtaining an accurate history, particularly the amount ingested, can be difficult, making physical and laboratory examination and patient presentation key to effective management. Knowledge of and familiarity with available resources, especially the poison control center, will help clinicians of any experience level provide the best care for pediatric patients who have been poisoned.

# CHAPTER 8

## PEDIATRIC DERMATOLOGY

*Michelle Condren, Pharm.D., AE-C, CDE; and  
Jamie L. Miller, Pharm.D., BCPS*

### LEARNING OBJECTIVES

1. Provide general recommendations for skin care in infants and children.
2. Identify topical products that should typically be avoided in infants and children.
3. Recommend pharmacologic and non-pharmacologic treatment for diaper dermatitis.
4. Recommend treatment for seborrheic dermatitis of the newborn.
5. Recommend pharmacologic and non-pharmacologic treatment for dermatophytic fungal infections in children.
6. Provide recommendations for the pharmacologic and nonpharmacologic treatment of atopic dermatitis in children.
7. Provide recommendations for the treatment of acne in adolescence.

### INTRODUCTION TO SKIN CARE FOR INFANTS AND CHILDREN

Skin disorders in childhood are a common reason for health care use and self-care worldwide. Although some dermatologic conditions are unique to the pediatric population, many will continue into adulthood. However, the approach to therapy for skin disorders in children differs from that for adults because skin structure and function differ.

Skin is composed of the epidermis, dermis, and hypodermis. The outer layer of the epidermis, the stratum corneum, is responsible for preventing water loss and serves as the primary barrier to the penetration of medications and irritants. Children younger than 2 years are especially susceptible to skin damage, irritation, and systemic absorption of medications because they have a thinner and weaker stratum corneum and total skin layer (Reference 1). In addition, infants and children have an increased skin surface area-to-body weight ratio compared with adults. Preterm and term neonates are at increased risk because of an underdeveloped stratum corneum. Additional differences in the lipid component of the stratum corneum are observed until puberty, placing children at higher risk of bacterial and fungal skin infections (Reference 1).

General skin care for infants involves maintaining adequate hydration and avoiding products that may cause skin irritation. Gentle, fragrance-free soaps and emollients are recommended, with emollient application occurring after bathing. Certain products should be avoided that may cause irritant dermatitis or harmful systemic absorption. Table 1 includes a list of ingredients that should not be applied topically to children younger than 2 years and those with skin disorders, when possible (Reference 2).

Common dermatologic conditions in childhood include diaper dermatitis, atopic dermatitis, acne, warts, birthmarks, seborrheic dermatitis, and fungal or bacterial skin infections. This chapter will focus on common disorders requiring pharmacologic intervention. Treatment of bacterial skin infections will be discussed in detail in the Skin and Soft Tissue Infections chapter. For images of the conditions described, the Web site [www.visualdx.com](http://www.visualdx.com) provides helpful examples.

**Table 1.** Topical Products to Avoid in Neonates and Infants (References 1, 2)

Products That May Cause Local Irritation	Products That May Cause Systemic Effects
Cod liver oil	Betamethasone
Hexachlorophene	DEET (> 10%)
Iodine	Hexachlorophene, resorcinol
Isopropyl alcohol (> 4%)	High-potency topical corticosteroids
Lanolin	Isopropyl alcohol
Neomycin	Mercury
Nickel	Methylene blue
Phenol	Neomycin
Propylene glycol	Povidine-iodine
Resorcinol	Salicylic acid
Thimerosal	Silver sulfadiazine
Topical antihistamines	Tacrolimus, pimecrolimus
	Topical anesthetics (e.g., benzocaine, prilocaine)
	Urea

DEET = *N,N*-diethyl-*m*-toluamide.

## DIAPER DERMATITIS

Diaper dermatitis, commonly referred to as diaper rash, napkin rash, or nappy rash, is a non-specific term used to describe an inflammatory eruption of the skin in the diaper region. It is one of the most common skin disorders affecting infants and toddlers. The overall reported prevalence is variable at 7% to 50% (References 3, 4), but it is widely accepted that diaper dermatitis is underreported. Although thought of as occurring only in the pediatric population, it can occur in any individual requiring the use of diapers for a prolonged period.

Diaper dermatitis is usually the result of irritant contact dermatitis secondary to a combination of the following factors: presence of feces/urine, occlusive nature of the diaper, maceration of the skin, friction of the diaper, and alkaline pH of the skin (References 5–7). The occlusive nature of the diaper results in a moist environment, causing maceration of the skin and in turn decreasing the integrity of the barrier function of the skin. The decreased barrier function of the skin allows an increased permeability of irritants and microbial flora. Friction from movement, together with moisture in the diaper environment, further serves to physically break down the skin. The presence of feces (i.e., fecal enzymes), bile acid salts, and urine in the diaper also promotes the development of diaper dermatitis by acting as a direct irritant to the skin. In the presence of fecal urease, the urine is broken down to ammonia, contributing further to the basic pH of the diapered skin. The increase in pH subsequently results in an increased activity of the fecal enzymes (i.e., proteases and lipases) and further disruption of the barrier function of the skin. Secondary infection by either bacteria or yeast is thought to occur because of the decreased barrier function of the stratum corneum. *Candida albicans* may be present on the skin of infants with and without diaper dermatitis; however, extensive colonization can increase the severity of diaper dermatitis (Reference 8). *C. albicans* can be isolated in up to 80% of cases in which diaper dermatitis persists for 3 days or more (Reference 7).

Infants in cloth diapers are at greater risk of developing moderate or severe diaper dermatitis because cloth diapers do not possess the absorption capacity of disposable diapers and do not wick away the moisture as efficiently. In addition, by wicking away the urine, disposable diapers prevent the interaction of urine with fecal enzymes, decreasing the amount of ammonia produced. Studies have shown that formula-fed infants are more likely to develop moderate to severe diaper dermatitis compared with breastfed infants (Reference 5). Breastfed infants have lower stool pH and decreased levels of fecal enzymes. An additional risk factor associated with increased incidence of diaper dermatitis is the

use of antibiotics and the development of antibiotic-associated diarrhea. A child with diarrhea is at increased risk of diaper dermatitis because of repeated exposure of the skin to feces (Reference 3).

Eruptions in the diaper area can be attributed to a variety of skin conditions. Differential diagnosis includes allergic contact dermatitis, seborrheic dermatitis, intertrigo, psoriasis, and infection (e.g., candidiasis, bullous impetigo, scabies, folliculitis). Simple diaper dermatitis presents as erythema and mild scaling on the skin that is in direct apposition with the diaper, sparing the skin folds. It may also present as shiny plaques or papules. Mild cases of diaper dermatitis are often self-limiting, with a mean duration of 2–3 days per episode (Reference 5). Progression to severe dermatitis (i.e., Jacquet diaper dermatitis) will present as severe ulceration in the diaper area. Secondary infection with *C. albicans* presents as an intense erythematous rash that is often described as beefy red in appearance. Unlike contact dermatitis, the rash is present in the skin folds and perianal skin. The erythematous patches and plaques are often accompanied by papules and pustules called satellite lesions. In most cases, a clinical diagnosis can be made on the basis of presentation; however, a diagnosis can be confirmed by culture or by performing a potassium hydroxide preparation of a scraping from the lesion.

Secondary bacterial infections are most commonly *Staphylococcus aureus* or group A *Streptococcus*. *S. aureus* often presents as bullous impetigo, with scattered vesicles that, on eruption, form superficial erosions with a honey-colored crust. Group A *Streptococcus* presents as perianal patchy erythema. If a bacterial cause is suspected, cultures may be obtained in an effort to provide targeted therapy for the specific organism. If the diaper rash remains after 1 month of vigilant treatment for irritant, bacterial, and yeast dermatitis, a further workup should be performed to rule out immunodeficiency, nutritional deficiency, metabolic disorders, or abuse/neglect (Reference 7).

Prevention of diaper dermatitis begins with educating the caregiver/parent on proper diaper hygiene. Removal of the diaper immediately after defecation is optimal, which prevents interaction of the urine and feces and subsequent increase in skin pH. The diaper area should be gently cleansed with water and a cotton cloth or commercial baby wipes to remove the irritants. If commercial products are used, products containing preservatives, fragrances, alcohol, or aloe should be avoided because they can cause further irritation. After cleansing, the diaper area should be patted dry. If feasible, daily diaper-free time should be implemented to allow exposure of the diaper area to the air. Use of superabsorbent disposable diapers will decrease the frequency and severity of diaper dermatitis. Empiric application of a barrier protectant as a preventive measure is not

necessary for all infants. If the infant is prone to develop diaper rash or is at increased risk, barrier protectants such as zinc oxide, petrolatum, or dimethicone may be used prophylactically. The barrier preparations protect the skin from irritants by coating it with a water-repellent barrier and serve to reduce friction by providing lubrication. The ointments and pastes provide better protection because they are not as easily removed. The product selected should have minimal ingredients and no other additives, which can lead to sensitization of the skin. Talcum powder and cornstarch have been used to absorb moisture, reduce friction, and prevent chafing in the diaper area. This practice should be discouraged because of the risk of aspiration of airborne particles and development of pneumonitis.

Treatment of diaper dermatitis involves both non-pharmacologic and pharmacologic therapy. Barrier protectants should be initiated at the first sign of erythema to prevent further irritation to the area. The barrier protectant should be applied with each diaper change. The nonpharmacologic measures recommended for the prevention of diaper dermatitis are also recommended for treating diaper dermatitis.

If a diaper rash remains or continues to progress after 3 days of treatment with barrier agents, a topical antifungal agent such as nystatin, miconazole, or clotrimazole should be initiated. The antifungal agent should be applied two times/day, as described in Table 2, until 1 week after the eruption has cleared (Reference 5). Most cases of yeast dermatitis resolve within 10 days of initiating antifungal therapy, but some cases may take up to 3 weeks to resolve (Reference 7). Some prescribers

recommend application four times/day or with every diaper change if frequent diaper changes are required. Miconazole 2% and clotrimazole 1% are both available over the counter. Although not specifically labeled for candidal diaper dermatitis, nystatin ointment is available as a prescription product. An additional prescription product with specific labeling for candidal diaper dermatitis is a combination product of miconazole 0.25%, zinc oxide 15%, and white petrolatum. Other commercially available combination antifungal products, such as combination antifungal-corticosteroid products, should be avoided. These products, which contain high-potency corticosteroids, are contraindicated for use in the diaper area. If both antifungal and anti-inflammatory activity is desired, separate administration of the agents is required. Oral antifungal medications are not routinely recommended, and few data support their use. However, if an infant has concomitant oral thrush, oral nystatin suspension should also be initiated.

For cases that do not respond to conservative measures, topical corticosteroids can be applied to reduce the inflammation and pain. The corticosteroid should be discontinued immediately upon resolution of erythema. Only low-potency corticosteroids such as hydrocortisone 1%, hydrocortisone 2.5%, or desonide 0.05% should be used, with application one or two times/day for a maximum of 14 days. Mid- and high-potency steroids should not be applied underneath a diaper because this is an occlusive environment; as such, it will enhance the systemic absorption of corticosteroids and increase the risk of systemic adverse effects. In addition, the

**Table 2.** Topical Antifungal Agents (Reference 9)

Antifungal	Dosing Frequency	Indications
Butenafine 1% cream	Once daily	Tinea pedis Tinea cruris Tinea corporis
Clotrimazole 1% cream	Twice daily	Diaper dermatitis Tinea pedis Tinea corporis
Ketoconazole 2% foam, cream, gel	Once or twice daily	Adolescent seborrheic dermatitis
Miconazole 2% cream, powder	Twice daily	Diaper dermatitis Tinea pedis Tinea corporis
Nystatin cream or ointment	Twice daily	Diaper dermatitis
Terbinafine 1% cream, spray	Once or twice daily	Tinea pedis Tinea cruris Tinea corporis

occlusive environment of the diaper region results in an increased degree of skin atrophy. If combination therapy with both a topical corticosteroid and barrier protectant is used, the topical corticosteroid should be applied first.

If a secondary bacterial infection is suspected or no improvement in the rash is noted, the addition of topical mupirocin should be considered. Mupirocin provides gram-positive antibacterial activity, as well as some antifungal activity. For treatment of diaper dermatitis, mupirocin should be applied three times/day for 7 days.

For severe irritant dermatitis and excoriation secondary to diarrhea, applications of liquid antacids, sucralfate, or a compounded cholestyramine paste have been used (References 10, 11). Liquid antacids will act to neutralize the pH of the acidic stools. Such antacids should be applied four times/day and allowed to dry on the skin before applying a topical barrier product. Use of topical sucralfate has been reported in the adult literature, with a compounded 4% topical sucralfate preparation applied four times/day. The topical sucralfate acts as a physical barrier to protect the damaged skin. Cholestyramine paste can be compounded by mixing the powder with an ointment base to a concentration of 5% to 20%. Cholestyramine is thought to be beneficial because of its mechanism of action of binding bile acid salts (Reference 6).

## SEBORRHEIC DERMATITIS

Seborrheic dermatitis is an inflammatory skin condition that can affect areas of the skin with increased sebaceous gland activity (e.g., nasolabial folds, eyebrows, scalp, ears). It can occur at any age but often has a bimodal presentation in the pediatric population. In infants, specifically within the first 3 months of life, it typically presents as cradle cap, whereas in adolescents, it presents as scalp scaling (i.e., dandruff) or erythema and scaling on the scalp, face, and trunk. The overall prevalence of seborrheic dermatitis in children is estimated to be 10% in boys and 9.5% in girls, with the highest prevalence occurring in the first 3 months of life (Reference 12). Around 42% of infants have cradle cap (Reference 12).

The exact etiology of seborrheic dermatitis is unknown; however, it has been associated with fungal infections (i.e., *Malassezia furfur*, previously *Pityrosporum ovale*), increased hormone levels, nutritional deficiencies, and neurogenic factors (Reference 13). Support for the potential link with hormone activity is that it presents in early infancy when transplacental hormones are elevated, resolves spontaneously, and then returns around puberty when another hormonal flux occurs. No firm linkage has been established with the other proposed etiologies.

Infantile seborrheic dermatitis (i.e., cradle cap) presents as thick greasy scales that are white, off-white, or yellow on the vertex of the scalp. This condition is not pruritic and does not cause discomfort to the infant, although it can be bothersome to the parent or caregiver. In addition, some infants may present with mild scaling of the face, ears, and forehead and on the flexural folds (e.g., antecubital region, popliteal region). The presence of exfoliative and widespread dermatitis may be associated with immunodeficiencies (Reference 1). The prognosis of infantile seborrheic dermatitis is generally benign and resolves by age 1 year, although there is some association with development of seborrheic dermatitis as an adult (Reference 14).

Adolescent seborrheic dermatitis presents as mild, greasy scaling of the scalp (i.e., dandruff). In addition, an oily complexion with scaling and erythema can be present in the nasolabial folds, eyebrows, postauricular skin, glabella (i.e., T-zone), and trunk. Unlike infantile seborrheic dermatitis, adolescent seborrheic dermatitis may be pruritic.

Management of cradle cap should begin with non-pharmacologic therapy, which includes non-medicated, mild shampoo and loosening of scales with a soft brush. If ineffective, emollients such as petrolatum, mineral oil, or olive oil can be applied to the scalp to loosen the scales. The emollient should be applied for a minimum of 20 minutes, but it can be left on overnight. After removal of the emollient, the scales can be gently removed by scratching the scales with a soft brush or fingertips. For more severe cases, antidandruff shampoos containing selenium sulfide or pyrithione zinc can be applied to the infant's scalp. Selenium sulfide shampoo can be safely applied twice weekly for 2 weeks and then once weekly. Parents/caregivers should be informed that it may stain the scalp reddish brown. In addition, ketoconazole shampoo has been shown to be safe and effective in infants for the treatment of infantile seborrheic dermatitis when used twice weekly for 1 month (Reference 15). No detectable levels of ketoconazole or changes in liver function tests were noted in the patients studied. Topical corticosteroids have some benefit in decreasing the inflammation associated with seborrheic dermatitis. However, these agents should not be used as a first-line option for management of cradle cap because it is considered a self-limited condition, and there is a potential for enhanced systemic absorption and skin atrophy when applied to the thin skin of the head and face. If used, low- to mild-potency agents should be recommended, and application should be limited to a small area for a short duration.

As a preventive measure, adolescents with seborrheic dermatitis should be instructed to cleanse the affected areas regularly to remove excess oil from the skin. In addition, emollients can be applied for relief

of dry skin. Antifungal (i.e., ketoconazole) or antidandruff (i.e., selenium sulfide, pyrithione zinc) shampoos are first-line pharmacologic therapy for the management of dandruff. Ketoconazole 1% shampoo should be applied twice weekly, with a minimum of 3 days between shampoos, for 8 weeks. The shampoo should be applied to wet hair and massaged over the entire scalp for 1 minute; then, it should be rinsed out and reapplied for another 3 minutes before rinsing again. Ketoconazole 2% shampoo is intended for body-wide application and should be applied to the damp skin of the affected area and left in place for 5 minutes before rinsing. A 2% ketoconazole gel has also received U.S. Food and Drug Administration (FDA) approval for treatment of seborrheic dermatitis in children 12 years and older; it is applied once daily for 2 weeks. Antifungal creams (e.g., clotrimazole, miconazole, ketoconazole) are first-line pharmacologic therapy for application to the face and can be applied once or twice daily. A short course of a topical corticosteroid may be used to relieve erythema and pruritus. Topical calcineurin inhibitors (i.e., tacrolimus and pimecrolimus) have been evaluated in the adult population as a steroid-sparing therapy for resistant seborrheic dermatitis, showing some benefit; however, further studies to evaluate efficacy are needed in the adolescent population (Reference 16). Of note, it takes up to 1 week of daily use of topical calcineurin inhibitors before efficacy is noticeable.

## ATOPIC DERMATITIS

Atopic dermatitis, also known as atopic eczema, is the most common dermatologic condition in the pediatric population, affecting up to 20% of children (Reference 17). Most children are symptomatic before they are 5 years old. The etiology of atopic dermatitis is multifactorial, with genetics, environment, and immunologic factors playing a role. Children with a diagnosis of atopic dermatitis often have a family history of atopy. Environmental factors that have been associated with atopic dermatitis include allergen exposure (e.g., pollen, mites, pets, cow's milk), irritants (e.g., soap, wool), microbial colonization, and hard water (Reference 18). Atopic individuals are thought to have early IgE (immunoglobulin E) production and impaired immune response. Patients with atopic dermatitis have inherent abnormalities in the barrier function of their skin. This impaired barrier function allows greater penetration of allergens through the skin and increased irritation. In addition, they have decreased ability to retain moisture in the stratum corneum secondary to decreased amounts of intracellular lipids and ceramides. Overall, patients with atopic dermatitis have a

decreased threshold to pruritus that is typically worse in the nighttime hours. The mechanism of pruritus is not completely understood, but it is thought that histamine does not play a major role.

The clinical presentation of atopic dermatitis may differ given the age of the patient and the stage of the disease (Reference 18). In the first 2 years of life, it is characterized by pruritic, eczematous lesions that typically occur on the face, scalp, and flexor regions (i.e., antecubital space, popliteal region). The lesions become more lichenified in the childhood phase, from age 2 years to puberty, and they may involve the hands, feet, wrists, ankles, and flexor regions. The adult phase begins at puberty and affects similar regions of the previous phase, but the lesions are characterized by dry, scaling erythematous papules and plaques, and the lichenified areas are larger.

The prognosis for atopic dermatitis depends on the severity of the disease and the age of onset. This disease often involves chronic relapses, with the waxing and waning of inflammatory, pruritic lesions. Children with atopic dermatitis are at risk of the atopy triad of atopic dermatitis, allergic rhinitis, and asthma. One-half of children with atopic dermatitis in the first 2 years of life will have asthma in the following years (Reference 19). Atopic dermatitis can have a significant impact on both the child's and caregiver's quality of life. Itching at nighttime can affect sleep patterns, which in turn will result in daytime sleepiness and irritability. In addition, because of the visibility of the condition, children may feel the stigma of being different.

There is no cure for atopic dermatitis; treatment is aimed at amelioration of symptoms. The key to treatment of atopic dermatitis is prevention of an exacerbation. The mainstay of prevention is the use of emollients, which serve to increase hydration of the skin and provide a barrier. Emollients are most effective when applied continuously, whether or not inflammatory lesions are present. The maximal duration of benefit for emollients is about 6 hours; therefore, they should be applied often throughout the day (Reference 20). Ointments and creams should be recommended because they have greater occlusive properties versus lotions. Use of products that contain lanolin and fragrances should be discouraged because of the risk of contact sensitization, which may exacerbate the dermatitis. Other preventive strategies include avoidance of irritating factors or at least minimization of exposure to those agents. Exposure to water during bath time should be limited (i.e., 5 minutes or less), and tepid water should be used. In addition, mild fragrance-free soaps should be used. After bathing, the skin should be gently patted dry, and an emollient should be applied immediately to trap in the

remaining moisture. Furthermore, because scratching perpetuates dry, broken skin and can potentially introduce bacteria, fingernails should be cut short to prevent damage from scratching. In addition, cotton gloves can be worn to bed to prevent unintentional scratching while sleeping.

The treatment of acute flare-ups can be managed with topical corticosteroids as first-line therapy (Reference 20). A cross-sectional study of outpatient visits between 1997 and 2004 for pediatric atopic dermatitis noted that topical corticosteroids were underused, with topical corticosteroids prescribed in only 25% of visits from 2001 to 2004 (Reference 21). It is speculated that underuse of these agents is likely the result of concern for the adverse effects associated with topical corticosteroid use (e.g., skin atrophy, striae, systemic effects). The American Academy of Dermatology suggests that, if used appropriately, these agents are not associated with significant adverse effects. During the acute phase of the exacerbation, topical corticosteroids should be applied a maximum of twice daily because there is no further benefit with more frequent application—only an increased risk of adverse effects. Once the exacerbation is controlled (i.e., resolution of pruritus), therapy can be stepped down to a less potent preparation or discontinued. For acute symptoms, therapy with topical corticosteroids should be limited to 3–7 days (Reference 16). Chronic therapy should be limited to 2–3 weeks of continuous use. If chronic corticosteroid therapy is required beyond this period, then it is recommended to apply the topical corticosteroid on an intermittent basis at the lowest frequency of use that will control the symptoms. One example of an intermittent schedule is application of the topical corticosteroid twice weekly (References 18, 20). Topical corticosteroids, summarized in Table 3, are grouped according to potency, with group I being the most potent and group VII being the least potent. The vehicle in which the drug is contained can result in increased potency of the agent. Ointments compared with creams of the same corticosteroid have increased potency because of their occlusive nature and hydration of the skin. Increasing the solubility of the corticosteroid by adding propylene glycol can also increase the potency by increasing the amount of drug that is absorbed. These agents are often referred to as augmented. In children younger than 12 years, only low-mid to low-potency (i.e., groups V–VII) topical corticosteroids should be used. When selecting the appropriate potency, an agent with the lowest potency that will be effective for the condition should be a consideration because overdosing can increase the potential for adverse effects, and underdosing can delay benefit or result in a rebound exacerbation.

Wet wrap therapy may be used in patients with acute, oozing, and erosive lesions who are intolerant of standard topical therapy. This therapy consists of applying a layer of ointment or cream directly on the skin. The ointment or cream can be an emollient only, or it can contain a topical corticosteroid that is diluted. The area is then covered with a double layer of cotton bandages, with the first layer being moist. Application of a diluted topical steroid has resulted in greater efficacy than emollient alone (Reference 24). Recommendations for application time range from 3 to 24 hours. If the therapy includes application of diluted steroid cream, then therapy should be used once daily for up to 7 days.

Topical calcineurin inhibitors (i.e., tacrolimus, pimecrolimus) are considered second-line agents for short-term, intermittent treatment of moderate to severe atopic dermatitis in children older than 2 years. These agents target the inflammatory pathogenesis of atopic dermatitis by preventing the release of inflammatory cytokines and mediators. However, unlike corticosteroids, topical calcineurin inhibitors are not associated with skin atrophy, which allows their use on the face, eyelids, and intertriginous areas. As a result, these agents may be an appropriate alternative in children with facial atopic dermatitis. Topical calcineurin inhibitors should be applied twice daily to the affected area. Of note, only tacrolimus 0.03% has a labeled indication for children 2–15 years old, and the 0.1% ointment should not be used in this population. Long-term use of these agents is not currently recommended because there are limited studies evaluating use for prolonged periods. To date, the longest duration studied has been 2 years for pimecrolimus (Reference 25) and 4 years for tacrolimus (Reference 26). The most commonly reported adverse effect of these agents is a burning sensation at the application site in the first week of use. Use of these agents has been associated with an increased risk of infection and photocarcinogenicity. In addition, although rare in occurrence, malignancy and lymphoma are listed in a black box warning included in the agents' FDA-approved labeling. This black box warning is primarily the result of a lack of sufficient long-term safety data; no direct evidence of a causal link with cancer exists (References 16–18). Because of the concern for development of cutaneous malignancy, patients on topical calcineurin inhibitors should be encouraged to apply sunscreen regularly (SPF of 15 or greater) if exposed to ultraviolet radiation.

Systemic antimicrobials should not routinely be used for prophylaxis of infection. These agents should be reserved for diagnosed secondary infections. Likewise, use of systemic corticosteroids as long-term maintenance therapy should be avoided because the

**Table 3. Potency Ratings of Selected Topical Corticosteroids (References 9, 22, 23)**

Potency (Group)	Selected Representative Corticosteroids	Brand (dosage form)
Super (I)	Augmented betamethasone dipropionate	Diprolene 0.05% (ointment)
	Clobetasol propionate	Clobex 0.05% (lotion, shampoo, spray) Olux 0.05% (foam) Temovate E 0.05% (cream) Cormax 0.05% (ointment, solution) Temovate 0.05% (gel, ointment, solution)
	Fluocinonide, optimized vehicle Halobetasol propionate	Vanos 0.1% (cream) Ultravate 0.05% (cream, ointment)
High (II)	Augmented betamethasone dipropionate	Diprolene AF 0.05% (cream), Diprolene 0.05% (lotion)
	Betamethasone dipropionate	Diprosone 0.05% (ointment) <sup>a</sup>
	Betamethasone valerate	Beta-Val 0.1% (ointment) <sup>a</sup>
	Fluocinonide	Lidex 0.05% (ointment, gel, cream) <sup>a</sup>
	Mometasone furoate	Elocon 0.1% (ointment)
Upper Mid (III)	Betamethasone dipropionate	Diprosone (0.05% cream) <sup>a</sup>
	Triamcinolone acetonide	Kenalog 5% (ointment)
	Fluticasone propionate	Cutivate 0.005% (ointment)

		Cortizone-10 Maximum Strength 1% (cream, lotion, ointment) [2.5% cream, ointment, lotion]

<sup>a</sup>Brand name not available or discontinued in the United States.

risks of therapy exceed the benefits. A short-term course can be used for an acute flare-up in patients with persistent, refractory disease. Oral antihistamines have a limited role in the treatment of atopic dermatitis because the pruritus is not necessarily histamine-related. A sedating antihistamine (e.g., hydroxyzine, diphenhydramine) can be recommended for use at bedtime to assist with sleep. There is no firm evidence of the efficacy of second-generation, non-sedating antihistamines (e.g., loratadine, cetirizine) in

the management of atopic dermatitis (References 18, 27). Immunomodulating agents such as cyclosporine, azathioprine, and mycophenolate mofetil have been evaluated in severe cases of atopic dermatitis that are refractory to traditional therapy. Therapies that have not been proven efficacious for atopic dermatitis include delayed introduction of solid foods in infants, dietary restrictions, homeopathy, prolonged breastfeeding, and Chinese herbal therapy (Reference 28).

## PEDIATRIC ACNE

Acne vulgaris is a common dermatologic condition that affects up to 87% of teenagers during their adolescence (Reference 29). Although typically thought of as an adolescent condition, acne can affect children of any age (Reference 30). Acne can have a significant impact on the quality of life of affected individuals.

The pathogenesis of acne is thought to be caused by four primary factors: sebum production, *Propionibacterium acnes* (*P. acnes*) colonization, alteration in the keratinization process, and release of inflammatory mediators into the skin (Reference 31). These four factors are interrelated and interact in a complex manner to promote the characteristic and inflammatory lesions of acne (i.e., comedone, papules, pustules, or nodules). The typical sequence of events begins with the obstruction of the hair follicle and accompanying sebaceous gland (i.e., pilosebaceous unit) by the accumulation of keratinocytes after they have been shed. This results in the formation of a microcomedo, a microscopic precursor of an acne lesion. Further obstruction leads to the formation of non-inflammatory comedones that can be open (i.e., blackheads) or closed (i.e., whiteheads). Over time, *P. acnes* will begin to proliferate within the blocked follicle and break down the sebum to free fatty acids and peptides. The immune system will then mount an inflammatory response to *P. acnes*, releasing proinflammatory mediators, thus resulting in the inflammatory lesions of acne (i.e., papules, pustules, and nodules).

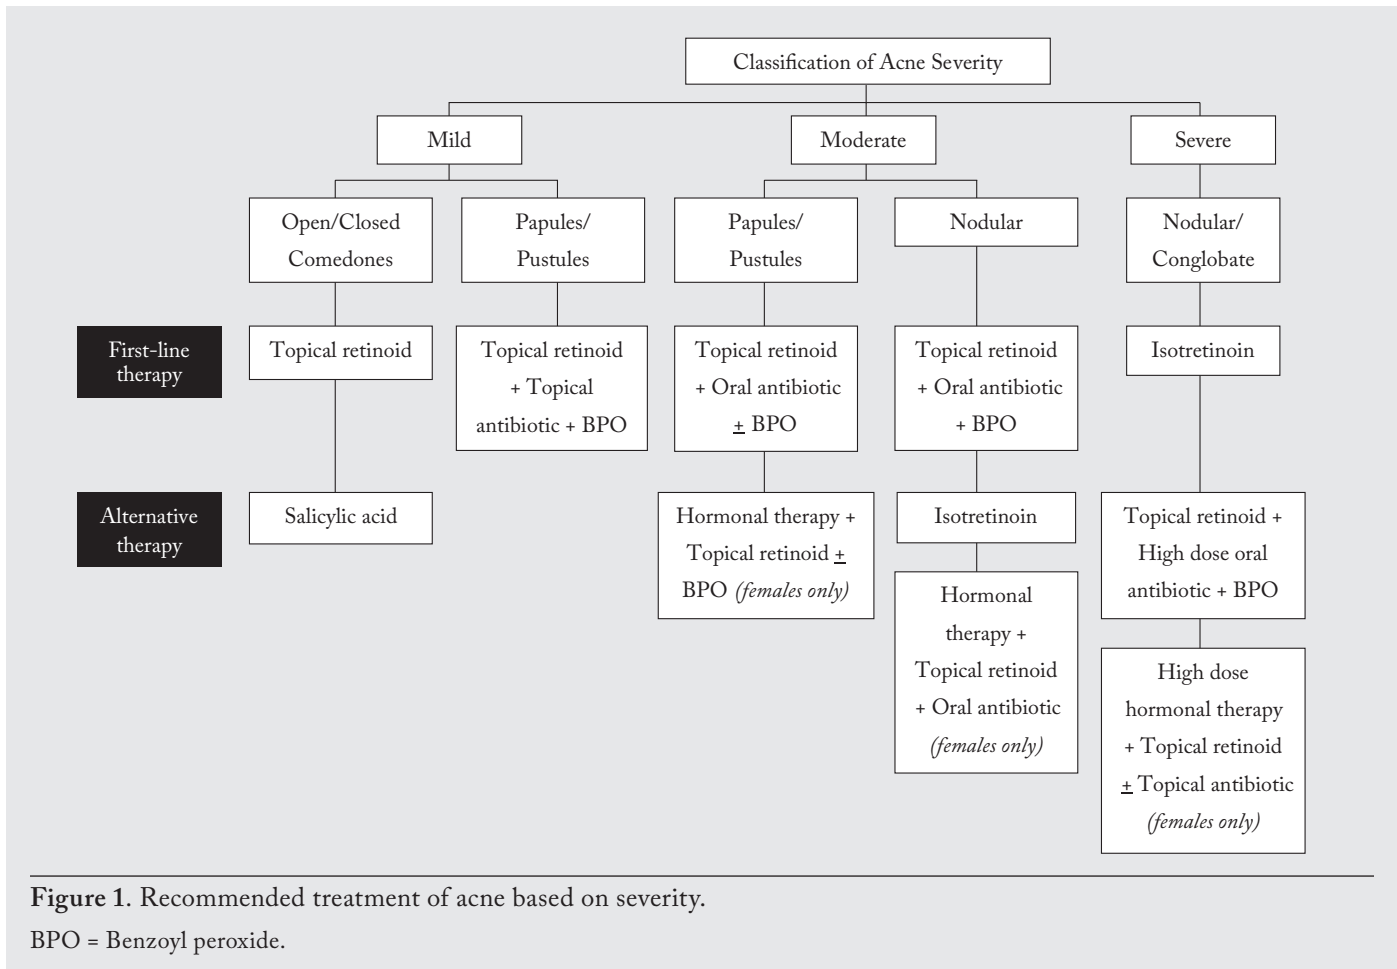

The assessment of acne involves the rating of disease severity, which in turn drives the treatment pathway. Proposed strategies rate the severity of acne on the basis of lesion count or on the basis of a grading system of the total clinical presentation by accounting for lesion type, location of lesion, and involvement. To date, there are more than 25 acne-grading systems (Reference 32); however, there is no consensus on a single classification or grading system for acne.

Neonatal acne (i.e., acne neonatorum) presents within the first 4 weeks of life and affects up to 20% of neonates (Reference 24). Neonates usually present with open or closed comedones on the forehead, nose, and cheeks. In addition, papules and pustules are occasionally present. Neonatal cephalic pustulosis, which may be described or referred to as acne, presents as erythematous papulopustules but lacks the presence of comedones. The exact etiology of acne lesions in neonates is somewhat controversial, but it is believed that acne neonatorum with comedones is caused by increased androgens and that neonatal cephalic pustulosis is associated with the overgrowth of *M. furfur* (Reference 1).

Infantile acne presents between 3 and 16 months of age and is much less common than neonatal acne (Reference 24). Compared with neonatal acne, infantile acne has lesions that are more inflamed and that appear predominantly on the cheeks. In addition to comedones, papules, and pustules, infantile acne is associated with the development of cystic lesions, which have a potential to cause scarring.

The American Academy of Dermatology has established treatment guidelines and recommendations (References 25, 33). Figure 1 summarizes the treatment approach to acne, and Table 4 summarizes the medications used for acne. Topical retinoids (e.g., tretinoin, adapalene, tazarotene) are considered the first-line treatment for acute management of mild to moderate cases of acne, whether non-inflammatory or inflammatory. These agents reduce the formation of microcomedones and comedones, possess anti-inflammatory activity, and promote normal desquamation of the skin. For individuals with papular/pustular eruptions of mild to moderate severity, a topical antimicrobial agent (e.g., erythromycin, clindamycin) added to a topical retinoid is recommended for acute treatment. The combination of a topical retinoid with an antibacterial agent will address three of the four major pathogenic factors of acne. These antimicrobial agents possess activity against *P. acnes* and decrease the colonization of the skin. However, there is some concern for the development of antimicrobial resistance with the use of antibiotic therapy, and it is strongly discouraged to use antibiotics as monotherapy. Adding topical benzoyl peroxide decreases the likelihood of the emergence of resistant strains of *P. acnes*. In addition, benzoyl peroxide provides antibacterial activity. Benzoyl peroxide is available in strengths ranging from 2.5% to 10%. Because this therapy can be irritating and drying to the skin, it is recommended to initiate therapy with a lower concentration. Stronger concentrations tend to be more irritating and may not necessarily be more efficacious.

For individuals with moderate to moderately severe acne, an oral antibiotic (e.g., doxycycline, minocycline, tetracycline, erythromycin) is recommended in addition to a topical retinoid. Minocycline is considered the most efficacious oral antibiotic in decreasing *P. acnes* colonization (Reference 33). However, the tetracycline antibiotics should not be used in children younger than 8 years because of the potential for binding to calcium and being incorporated in the matrix of the tooth and bone, resulting in tooth discoloration, enamel hypoplasia, and decreased bone development. For children younger than 8 years, the oral antibiotic of choice is erythromycin. If oral antibiotics are employed, their use should be limited in duration to 3–4 months, and the need for continuation should be assessed every

6–12 weeks (Reference 31). Many experts recommend against the concomitant use of oral and topical antibiotic therapy because of the increased risk of resistance and the minimal increase in therapeutic benefit (Reference 31).

There are commercially available fixed-dose products that contain a combination of therapeutic agents. These products are proposed to be more convenient for patient use by decreasing the amount of time involved in product application and will in turn promote greater adherence to therapy. A common adverse effect with combination therapy is increased skin irritation, including burning and peeling. Some data suggest that, among the retinoids, combination therapy with adapalene is best tolerated (Reference 31). In patients who are intolerant of topical retinoid therapy, topical salicylic acid can be used, although it is not considered as effective. Salicylic acid is a common ingredient in over-the-counter acne products and is available in a variety of dosage forms (e.g., creams, washes, lotions) ranging from concentrations of 0.5% to 2.0%. Other topical therapies that have limited benefit in the management of acne include azelaic acid, sulfur, resorcinol, aluminum chloride, and topical zinc.

Severe recalcitrant nodular acne requires treatment with isotretinoin. Isotretinoin decreases comedo formation by decreasing sebum production and possesses some anti-inflammatory activity. The FDA-labeled dose is 0.5–2 mg/kg/day in two divided doses for a maximum of 20 weeks. This duration can be exceeded if lower doses are used, with a maximal total cumulative dose of 120–150 mg/kg (Reference 33). Isotretinoin has several adverse effects that require monitoring throughout therapy. These include hypertriglyceridemia, hypercholesterolemia, and elevation of hepatic enzymes. Although rare, neutropenia can occur, which should be monitored periodically while receiving therapy. A causal link exists between the use of isotretinoin and the development of ulcerative colitis. The risk increases with the use of higher doses and longer durations. Overall, the absolute risk of patients who are exposed to isotretinoin is very low; however, patients should be made aware of this association. In addition, this agent has been associated with depression, aggressive behavior, and suicidal ideation. Although no direct relationship has been established in clinical studies, patients and caregivers should be informed to monitor for changes in behavior or mood.

**Table 4. Acne Products (Reference 9)**

<b>Class/Selected Agents</b>	<b>Brand Name(s)</b>	<b>Dosing</b>	<b>Comments</b>
<b>Topical Agents</b>			
<b>Retinoids</b>			
Adapalene 0.1%	Differin	Apply once daily in the evening.	Increased risk of photosensitivity reactions. Recommend application of sunscreen (SPF ≥ 15)
Tazarotene 0.05%, 0.1%	Tazorac	Apply 2 mg/cm <sup>2</sup> once daily in the evening.	
Tretinoin 0.025%, 0.05%, 0.1%	Retin-A, Avita	Apply once daily in the evening; start with 0.025% cream or 0.01% gel and increase concentration as tolerated.	
<b>Antibiotics</b>			
Clindamycin 1%	Cleocin T, ClindaMax	Apply a thin film twice daily.	Should not be used as monotherapy
Erythromycin 2%	Akne-mycin	Apply twice daily.	
Benzoyl peroxide 2.5%, 4%, 5%, 8%, 10%	Neutrogena Clear Pore, Benzac AC, OXY	Apply once daily; can gradually increase to two or three times/day, if needed	If excessive dryness or peeling occurs, reduce dose frequency or concentration. Recommend application of sunscreen (SPF ≥ 15)
<b>Keratolytic Agent</b>			
Salicylic acid 0.5% to 2%	Clean and Clear Advantage Acne Cleanser, Neutrogena Oil-Free Acne Stress Control, OXY face wash	Apply once or twice daily.	Available in a variety of dosage forms. Recommended in patients who cannot tolerate benzoyl peroxide. Do not use in children < 2 years.
<b>Combination Products</b>			
Erythromycin/Benzoyl peroxide	Benzamycin	Apply twice daily.	
Clindamycin/Benzoyl peroxide	Acanya, BenzaClin	Apply pea-sized amount once daily (Acanya). Apply twice daily (BenzaClin)	
Clindamycin/Tretinoin	Veltin, Ziana	Apply once daily.	Increased risk of photosensitivity reactions. Recommend application of sunscreen (SPF ≥ 15)
Adapalene/Benzoyl peroxide	Epiduo	Apply once daily.	Increased risk of photosensitivity reactions. Recommend application of sunscreen (SPF ≥ 15)

*(continued)*

**Table 4. Acne Products (Reference 9) (continued)**

Class/Selected Agents	Brand Name(s)	Dosing	Comments
<b>Systemic Agents</b>			
<b>Antibiotics</b>			
Tetracycline	—	Adolescents: 500 mg twice daily	Should not be used in children < 8 years because of effects on teeth and bone; increased risk of photosensitivity reactions. Recommend application of sunscreen (SPF ≥ 15). Avoid taking with calcium- or iron-containing products.
Doxycycline	Vibramycin	Adolescents: 50–100 mg/dose once or twice daily	
Minocycline	Minocin, Dynacin, Solodyn & Ximino (extended release)	Adolescents: 50–100 mg/dose once or twice daily Extended-release product (Solodyn): Children > 12 years: About 1 mg/kg daily: 45–49 kg: 45 mg once daily 50–59 kg: 55 mg once daily 60–71 kg: 65 mg once daily 72–84 kg: 80 mg once daily 85–96 kg: 90 mg once daily 97–110 kg: 105 mg once daily 111–125 kg: 115 mg once daily 126–136 kg: 135 mg once daily	
Erythromycin	E.E.S., EryPed	250–500 mg twice daily	Several drug interactions, inhibitor of CYP3A4
<b>Hormonal Therapy</b>			
Oral contraceptives	Ortho Tri-Cyclen, Estrostep Fe, Yaz	Take 1 tablet daily.	May take up to 4 months for efficacy
Spiroinolactone	Aldactone	50–100 mg twice daily	Potassium-sparing, can cause hyperkalemia
<b>Retinoic Acid Derivative</b>			
Isotretinoin	Claravis, Amnesteem, Sotret, Absorica	0.25–0.5 mg/kg/dose twice daily; maximal dose of 1 mg/kg twice daily	Do not use in pregnancy, iPLEDGE registration. Recommend application of sunscreen (SPF ≥ 15)

CYP = cytochrome P450; SPF = skin protection factor.

Isotretinoin is rated pregnancy category X and has a black box warning against use in pregnancy. Because of this teratogenic risk, all patients (male or female), prescribers, manufacturers, wholesalers, and dispensing pharmacies must be registered in the iPLEDGE risk management program. Females of childbearing age should have two negative pregnancy tests, a minimum of 19 days apart, before therapy initiation. According to the iPLEDGE program, two forms of contraception should be used 1 month before, during, and 1 month after isotretinoin therapy. Prescriptions can only be written for a 30-day supply, and a pregnancy test should be completed monthly.

Use of hormone therapy with estrogen-containing contraceptive agents can be considered in female patients with mild to moderate acne due to their antiandrogenic effects. Oral contraceptives with FDA approval for the management of acne include ethinyl estradiol/norgestimate, ethinyl estradiol/norethindrone, and ethinyl estradiol/drospirenone, although it is expert opinion that any estrogen-containing contraceptive would be equally effective (Reference 33). Patients should be educated that improvement in acne lesions may take up to 4 months with these agents (Reference 34). Another agent that has been evaluated in the treatment of acne because of its antiandrogen activity is spiroinolactone at

doses of 50–200 mg/day. Patients on this therapy should be monitored for hyperkalemia, specifically when high-doses are used.

After initial treatment of active lesions, maintenance therapy should be initiated to prevent a rebound exacerbation of acne. For all acne types, a topical retinoid should be recommended for maintenance therapy, with the addition of benzoyl peroxide if more antibacterial activity is needed. Adapalene 0.3% and adapalene 0.1%/benzoyl peroxide 2.5% have been studied most extensively for long-term use up to 1 year (Reference 31). Experts recommend applying the maintenance product to the entire affected area, not just to the area of concern. This is because microcomedones are not detectable by the naked eye, and topical retinoid therapy will decrease the formation of microcomedones. Use of antibiotics for maintenance therapy should be discouraged. Nonpharmacologic recommendations for the patient should include washing of the skin with a gentle cleanser twice daily and application of a noncomedogenic moisturizer. Individuals should avoid too frequent or too harsh washing because this may worsen the acne. Consumption of certain foods has anecdotally been associated with worsening acne; however, no studies support this belief. Therefore, according to the guidelines, dietary restriction is of no benefit in the management of acne (Reference 33).

Typically, treatment of neonatal acne is unnecessary, and parents/caregivers should be reassured that this is a transient condition that should resolve around age 3 months in most cases (Reference 30). Parents can be instructed to cleanse the face with a gentle soap and water. In more severe cases, neonates can be treated with 2.5% benzoyl peroxide lotion. If colonization with *Malassezia* is suspected, application of 2% ketoconazole cream twice daily for 1 week has been shown efficacious (Reference 1). The management of infantile acne is similar to that of older children and adolescents. First-line therapy continues to be a topical retinoid with or without benzoyl peroxide plus or minus a topical antibiotic. A small open-label study has shown that adapalene gel is both safe and efficacious for mild to moderate acne in children younger than 24 months (Reference 35). If an oral antibiotic is necessary, erythromycin is the medication of choice in this population because of the relative contraindication of tetracyclines. For severe, recalcitrant cases of infantile acne associated with scarring, use of oral isotretinoin has been reported in infants as young as 5 months, with doses ranging from 0.2 to 2 mg/kg/day in two divided doses (Reference 30). Administering this medication in the infant population may present some technical difficulties because it is commercially available only in tablet and capsule forms. Most cases of infantile acne will resolve by age 4–5 years.

## DERMATOPHYTE FUNGAL INFECTIONS

Ringworm fungi are dermatophytes that include species of *Microsporum*, *Trichophyton*, and *Epidermophyton*. These fungi are typically able to survive only in the stratum corneum, hair, and nails. The infections described in the following sections are considered *tinea*, or fungal infections that are further classified by the body region infected.

### Tinea Corporis

Tinea corporis, or ringworm that presents on the body, is typically caused by *Trichophyton* spp. It presents as a round, but irregular, scaly spot that develops a raised border and central clearing. The border may be red with raised papules. Lesions may be small or may appear to spread.

Topical antifungals, summarized in Table 2, are sufficient to treat most cases of tinea corporis. The antifungal should be applied to the lesion and the 2 cm surrounding it. Therapy continues for 14 days, or for 1 week after clinical resolution, to ensure fungal eradication. Newer therapies, terbinafine and butenafine, are fungicidal and are considered more effective than miconazole and clotrimazole (Reference 36). Combination products containing corticosteroids and antifungals are not recommended. Cases that are more extensive may be treated with systemic fluconazole, itraconazole, or terbinafine.

### Tinea Pedis

Tinea pedis, or athlete's foot, is caused by *Trichophyton* or *Epidermophyton* spp. It is less common in prepubertal children. Tinea pedis presents as a white area between the toes, or dry scaling accompanied by itching. Exposure to a moist environment predisposes the feet to fungal infections.

Terbinafine and butenafine produce higher cure rates and more rapid resolution than miconazole or clotrimazole (Reference 37). Treatment with terbinafine and butenafine typically requires 1–2 weeks. Miconazole and clotrimazole will require 2–4 weeks of treatment. As with tinea corporis, treatment should continue for 1 week beyond clinical resolution. Antifungal powders can be applied to the feet to decrease moisture. Nonpharmacologic therapy includes exposing the feet to air as often as possible.

### Tinea Cruris

Tinea cruris, also known as jock itch, is an infection of the groin caused by *Trichophyton* or *Epidermophyton* spp. It is most common in postpubertal males, but it is seen in females. The rash is typically reddish brown and symmetric with defined borders, typically sparing the scrotum. The rash is usually pruritic, and it may burn.

Treatment should consist of either terbinafine cream or spray for 1 week or butenafine cream for 2 weeks (Reference 36). Agents such as miconazole, clotrimazole, econazole, and ciclopirox are generally not

recommended for tinea cruris because their fungistatic nature requires a longer treatment and may present a problem with adherence to the regimen.

### Tinea Capitis

The most common fungal infection in children is tinea capitis, or tinea of the scalp, occurring in an estimated 4% of the U.S. population, with a higher incidence in those of African American descent and in developing countries (Reference 38). In the United States, most tinea capitis cases are caused by *Trichophyton tonsurans*, with some cases caused by *Microsporum* spp. Other countries typically have a predominance of *Microsporum* spp.

Children with tinea capitis present with itching, scaling of the scalp, or circular patches of hair loss. When more inflammation is present, there are pustules as well. Those with more persistent infection and inflammation may present with kerion lesions, which are boggy, tender, and pustular (Reference 38). A diagnosis can typically be made from clinical presentation, but a fungal culture can be obtained to confirm the diagnosis and identify the infecting fungus.

Treatment of tinea capitis requires prolonged systemic therapy to penetrate the infected hair shaft. Griseofulvin is considered the drug of choice in children, but fluconazole, terbinafine, and itraconazole are effective alternatives. Each agent has similar efficacy when treating *Trichophyton* spp., but terbinafine is inferior to griseofulvin, fluconazole, and itraconazole for treating *Microsporum* spp. (Reference 39). Treatment

of *Microsporum* infections requires longer therapy than does *Trichophyton*. Treatment regimens for tinea capitis are summarized in Table 5.

Griseofulvin is available in microsize suspension and tablets and in ultramicrosize tablets. Because of poor water solubility, griseofulvin should be given with a fatty meal to increase absorption. Common adverse effects include gastrointestinal upset (often leading to treatment discontinuation), headache, and rash. Dividing the daily dose may decrease the incidence of gastrointestinal complaints. More rarely, elevated liver function tests and granulocytopenia are reported. Monitoring a complete blood cell count and liver function is recommended for treatment lasting longer than 8 weeks.

Terbinafine is available as a 250-mg tablet or as 125-mg and 187.5-mg packets of granules for sprinkling on nonacidic food, such as pudding or mashed potatoes. An advantage of terbinafine is the shorter therapy duration required for *Trichophyton* spp., which may improve adherence. Common adverse effects include vomiting, nausea, loss of appetite, and itching. More rarely, elevated liver function tests and hepatic failure in those with preexisting liver disease have been reported. Liver function tests are recommended before initiating therapy and if terbinafine is continued longer than 6 weeks.

Fluconazole has a favorable safety profile in children and is available in liquid and tablet formulations, making it a reasonable alternative to griseofulvin. Common adverse effects include gastrointestinal issues, headache, and rash. Elevated hepatic enzymes are a rare complication of fluconazole therapy.

**Table 5.** Treatment Regimens for Tinea Capitis (References 38–40)

Antifungal	Dose	Treatment Duration (weeks)	Treatment Considerations
Griseofulvin microsize	20–25 mg/kg/day in one or two divided doses up to 1000 mg/day	6–12	Monitor liver function if duration exceeds 8 weeks.
Griseofulvin ultramicrosize	10–15 mg/kg/day in one or two divided doses up to 750 mg/day	6–12	Monitor liver function if duration exceeds 8 weeks.
Terbinafine	< 25 kg: 125 mg/day 25–35 kg: 187.5 mg/day > 35 kg: 250 mg/day	2–6	Monitor liver function before treatment and if duration exceeds 4 weeks.
Fluconazole	6 mg/kg/day OR 8 mg/kg once weekly	3–6 6–12	Limited data available
Itraconazole	Capsules: 5 mg/kg/day Oral solution: 3 mg/kg/day	2–6	Monitor liver function before treatment and if duration exceeds 4 weeks. A pulse regimen of daily dosing 1 week each month for 2–4 months has been studied in adults.

Itraconazole is available as capsules and liquid. The capsules should be given with food, and the liquid should be given on an empty stomach. Although an intermittent regimen involving daily dosing for 1 week each month for a total of two or four cycles has been studied in adults, there are no pediatric data to confirm the efficacy of this regimen. Common adverse effects include headache, rash, and gastrointestinal complaints. Elevated liver function tests were a rare complication of itraconazole therapy in tinea capitis studies.

Treatment should generally be continued until hair regrowth is evident or about 2 weeks after clinical resolution. The long therapy duration often results in non-adherence and treatment failure. Topical treatment with selenium sulfide or ketoconazole shampoo may decrease the carriage of spores, thus reducing transmission to others and reinfection. Shampoos should be used twice weekly for 2–4 weeks as an adjunct to systemic therapy.

### Tinea Unguium

Tinea unguium is a type of onychomycosis affecting the fingernails or toenails, usually caused by *Trichophyton rubrum* in children (Reference 8). Although it is generally considered a cosmetic problem, it can cause a loss of self-esteem and precipitate complications in those with underlying diseases such as diabetes. It is less common in prepubertal children and has a higher incidence in children with Down syndrome (Reference 8).

The clinical presentation includes discoloration and possibly flaking or dystrophy of the nail. Children typically have a distal presentation called distal lateral subungual onychomycosis (Reference 8). Other types of onychomycosis include proximal subungual and superficial white onychomycosis. The latter affects only the nail plate, not the nail bed.

In children with superficial onychomycosis and distal involvement not exceeding one-third of the nail bed, topical therapy with ciclopirox 8% nail lacquer may be

attempted. The lacquer is applied daily, with removal once a week, for 48 weeks (Reference 42). The cure rate is low, and relapse is common. In infants and young children, the nail bed is thinner, and topical therapies may be more effective (Reference 8). Topical therapy is also recommended for anyone who is not an appropriate candidate for systemic therapy.

Systemic therapy is recommended for most cases of onychomycosis. Treatment of the toenails requires a longer duration than for fingernails. The most effective therapy is terbinafine. Additional treatment options include itraconazole and fluconazole, with fluconazole as the least effective option. The fingernail will usually look normal before the fungus is eradicated, making it very important to emphasize that treatment should continue for the complete duration to avoid relapse. Table 6 summarizes treatment regimens for tinea unguium in children.

### MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a localized skin infection caused by a virus in the poxvirus family. It is usually seen in children, but it can present in adults more commonly as a sexually transmitted variant. Infection occurs after contact with an infected individual or an object harboring the virus. Swimming pools and baths are another source of transmission. Molluscum contagiosum is most common in children 2–5 years old and has a reported prevalence of 5% to 7% in elementary schools, resulting in almost 300,000 office visits each year (Reference 43).

Molluscum typically presents as one or many shiny, white or flesh-colored papules with a dimple in the center. With time, there may be crusting or fluid production as the lesion begins to destruct. Most cases will resolve spontaneously, but this may take up to 9 months because of the spread of the virus. In some cases, the

**Table 6.** Treatment Regimens for Tinea Unguium in Children (References 8, 42)

Antifungal	Dose	Duration
Terbinafine	< 20 kg: 62.5 mg/day 20–40 kg: 125 mg/day > 40 kg: 250 mg/day	Toenail: 12 weeks Fingernail: 6 weeks
Itraconazole capsules	Pulse with 5 mg/kg/day, 1 week/month Up to 400 mg/day	Toenail: 3 pulses Fingernail: 2 pulses
Itraconazole solution	Pulse therapy 3–5 mg/kg/day, 1 week/month	Toenail: 3 pulses Fingernail: 2 pulses
Fluconazole	3–6 mg/kg, one dose per week	Toenail: 26 weeks Fingernail: 12 weeks

lesions may persist for up to 4 years. They are generally not harmful, except that they can be spread to others. In addition, in individuals with atopic dermatitis, local irritation and inflammation often occur.

In those with normal immune function, therapy is not typically indicated. However, treatment may be helpful in the following situations: lesions associated with discomfort or itching, cosmetic reasons or social stigma, limiting spread to others, and secondary infections. Therapy may consist of physically destroying the lesions, applying topical treatments, or using systemic treatment. Physical removal with a sharp curette or liquid nitrogen is most effective, but this can be painful and can lead to scarring. Topical treatments may include cantharidin or imiquimod. Cantharidin is applied in the medical provider's office; then, it is washed off after 4–6 hours and repeated every 2–4 weeks until resolved (Reference 37). Imiquimod is applied nightly, 5–7 days/week, for at least 12 weeks. Imiquimod is slower acting, but it provides an advantage of being painless compared with physical removal. Other topical agents that have been used, but that are generally not recommended, are podofilox, retinoids, salicylic acid, and potassium hydroxide. Systemic cimetidine has been studied using 35 mg/kg/day for 4 months; however, no significant difference from placebo was observed. Currently, there is insufficient evidence to choose one therapy over another (Reference 43), but a recent survey determined that dermatologists usually use no intervention, or they use cantharidin, imiquimod, curettage, or cryotherapy (Reference 44).

## CONCLUSIONS

Because of the high prevalence of dermatologic conditions in childhood, pharmacists will have opportunities to help determine age-appropriate therapy and provide patient and caregiver education. Knowledge of the unique aspects of topical medication delivery and common irritants to avoid in infants and children will help ensure the best care for this population.

# CHAPTER 9

## CONGENITAL HEART DISEASE

Brady S. Moffett, Pharm.D., MPH

### LEARNING OBJECTIVES

1. Understand the basic pathophysiology of common congenital heart defects.
2. Be able to select and appropriately monitor pharmacotherapy for a patient with a congenital heart defect.
3. Understand the pathophysiology, diagnosis, and pharmacotherapy for treatment of low cardiac output syndrome.

### ABBREVIATIONS IN THIS CHAPTER

ASD	Atrial septal defect
BT	Blalock-Taussig (shunt)
HLHS	Hypoplastic left heart syndrome
LA	Left atria
LCOS	Low cardiac output syndrome
PDA	Patent ductus arteriosus
PGE	Prostaglandin
PLE	Protein-losing enteropathy
PVR	Pulmonary vascular resistance
RA	Right atria
SVR	Systemic vascular resistance
TGA	Transposition of the great arteries
TOF	Tetralogy of Fallot
VSD	Ventricular septal defect

### INTRODUCTION

Congenital heart disease is the most common birth defect, occurring in about 8 of every 1000 live births (References 1, 2). The first repair of a congenital heart defect occurred in 1945 in a patient with tetralogy of Fallot (TOF). Alfred Blalock and Helen Taussig created a Blalock-Taussig (BT) shunt (an attachment of the subclavian artery to the pulmonary artery [PA]) to treat the patient, and they subsequently published their experience (Reference 3). Since then, tremendous strides have occurred in the diagnosis, repair, and management of congenital heart disease (Reference 4). However, similar strides have not been made in the application of pharmacotherapy to pediatric patients with congenital heart disease.

Recent publications have shown a lack of data supporting pharmacotherapy in pediatric cardiology patients and considerable variation in practice, with several studies showing no effect of pharmacotherapy on patient outcomes (References 5–8). In addition, many patients with congenital heart disease have several cardiac defects, involvement of other organ systems (i.e., asplenia and intestinal malrotation in patients with heterotaxy syndrome), or genetic mutations (i.e., Down syndrome with complete atrioventricular canal) that can complicate pharmacotherapy (References 1, 2). Moreover, strategies for managing congenital heart disease are often subject to institutional bias. For example, institutions vary in their use of corticosteroids in the cardiopulmonary bypass circuit, recombinant factor VIIa to control postoperative bleeding, or peritoneal dialysis as a strategy for removing fluid and inflammatory mediators in postoperative patients, all of which could potentially affect pharmacotherapy (References 9–12).

Because the pharmacotherapy for congenital heart disease can be complex, a complete understanding of pathophysiology, hemodynamics, and pediatric pharmacology is necessary to appropriately use medications. This chapter aims to summarize the pathophysiology and pharmacotherapy for common congenital heart defects in pediatric patients. This discussion includes the epidemiology of congenital heart defects, clinical presentation, diagnosis, course and prognosis of the disease, and surgical or interventional procedures associated with the various defects. Each defect presented is evaluated as if a patient were presenting with an isolated lesion. Reality, however, is much more complex, and many congenital heart defects occur in combination with other comorbidities.

The pharmacotherapy for each congenital heart defect will be summarized with respect to the preoperative (or surgically unrepaired) period, the immediate postoperative period, and the long-term (or chronic) management of surgically repaired congenital heart disease.

Tables 1 and 2 summarize the surgical management, common complications, and basic pharmacotherapy for each of the lesions (Reference 13). Because a large portion of the pharmacotherapy for congenital heart disease is in the immediate postoperative period, the etiology, diagnosis, and treatment of postoperative low cardiac output syndrome (LCOS) will be addressed.

**Table 1.** Common Congenital Heart Defects and Surgical Repairs

Defect	Description of Lesion	Surgical (or Interventional) Repair
Patent ductus arteriosus (PDA)	Communication between pulmonary artery (PA) and aorta	Ductus ligation Coil or device insertion (interventional)
Atrial septal defect (ASD)	A communication between right and left atria by a hole in the atrial septum	Patch repair of defect <sup>a</sup> Device insertion (interventional)
Ventricular septal defect (VSD)	A communication between right and left ventricles by a hole in the ventricular septum	Patch repair of defect <sup>a</sup> Device insertion (interventional)
Tetralogy of Fallot (TOF)	PA stenosis, VSD, overriding aorta, right ventricular hypertrophy	VSD closure and repair of PA stenosis <sup>a</sup>
Transposition of the great arteries (TGA)	Switched locations of the PA and aorta, resulting in two separate circulations	Arterial switch operation <sup>a</sup>
Coarctation of the aorta (CoA)	Narrowing of the aorta. Grouped into pre- and postductal categories	End-to-end anastomosis surgery (if the coarctation does not involve carotid arteries) Patch repair surgery <sup>a</sup> (if coarctation involves carotid arteries)
Hypoplastic left heart syndrome (HLHS)	Absence of left ventricle and aortic narrowing (atresia)	Norwood procedure <sup>a</sup> (combination of PA and aorta to form a "neo-aorta," BT shunt, atrial septectomy) OR Sano modification <sup>a</sup> OR hybrid procedure
Bidirectional Glenn	Second stage of HLHS palliation	Takedown of BT shunt, anastomosis of SVC to PA <sup>a</sup>
Fontan	Third stage of HLHS palliation	Attachment of IVC to PA by an extracardiac conduit <sup>a</sup>

<sup>a</sup>Requires cardiopulmonary bypass to perform surgical procedure.

BT = Blalock-Taussig; IVC = inferior vena cava; SVC = superior vena cava.

**Table 2.** Significant Sequelae of Congenital Heart Disease Before and After Surgical Intervention

Defect	Preoperative	Immediate Postoperative	Long Term
Patent ductus arteriosus (PDA)	CHF, PHTN	None	None
Atrial septal defect (ASD)	CHF, PHTN	HTN	None
Ventricular septal defect (VSD)	CHF, PHTN	Systolic HTN, arrhythmias	None
Tetralogy of Fallot (TOF)	CHF, hypercyanotic episodes, chronic cyanosis, clubbing	LCOS, PHTN, HTN, VT, thrombus formation	VT, exercise intolerance
Transposition of the great arteries (TGA)	Cardiogenic shock, cyanosis	LCOS, coronary vasospasm	None (arterial switch)
Coarctation of the aorta (CoA)	Cardiogenic shock (neonates), CHF, LV enlargement	LCOS (particularly in neonates), HTN	HTN, recoarctation
Hypoplastic left heart syndrome (HLHS)	Cardiogenic shock, cyanosis	LCOS, arrhythmias, PHTN, cyanosis	Sudden death, low weight gain, poor feeding
Bidirectional Glenn	See long-term HLHS management	LCOS, arrhythmias, PHTN	CHF
Fontan	See long-term bidirectional Glenn management	LCOS, arrhythmias, PHTN, chylous effusions, thrombus formation	Arrhythmias, effusions, PLE, thrombi, plastic bronchitis

CHF = congestive heart failure; HTN = hypertension; LCOS = low cardiac output syndrome; LV = left ventricular; PHTN = pulmonary hypertension; PLE = protein-losing enteropathy; VT = ventricular tachycardia.

A brief overview of fetal versus neonatal circulation is included, but we will focus on the role each plays in neonatal congenital heart disease. Because the care of patients with congenital heart disease can be multifaceted, this chapter will only focus on the pathophysiology and pharmacotherapy related directly to congenital heart defects and will not cover areas such as postoperative pain and sedation management or infectious disease prophylaxis. In addition, the normal circulation and structure of the heart will not be presented, and the reader is encouraged to understand the anatomy and physiology of the normal heart before reading this chapter.

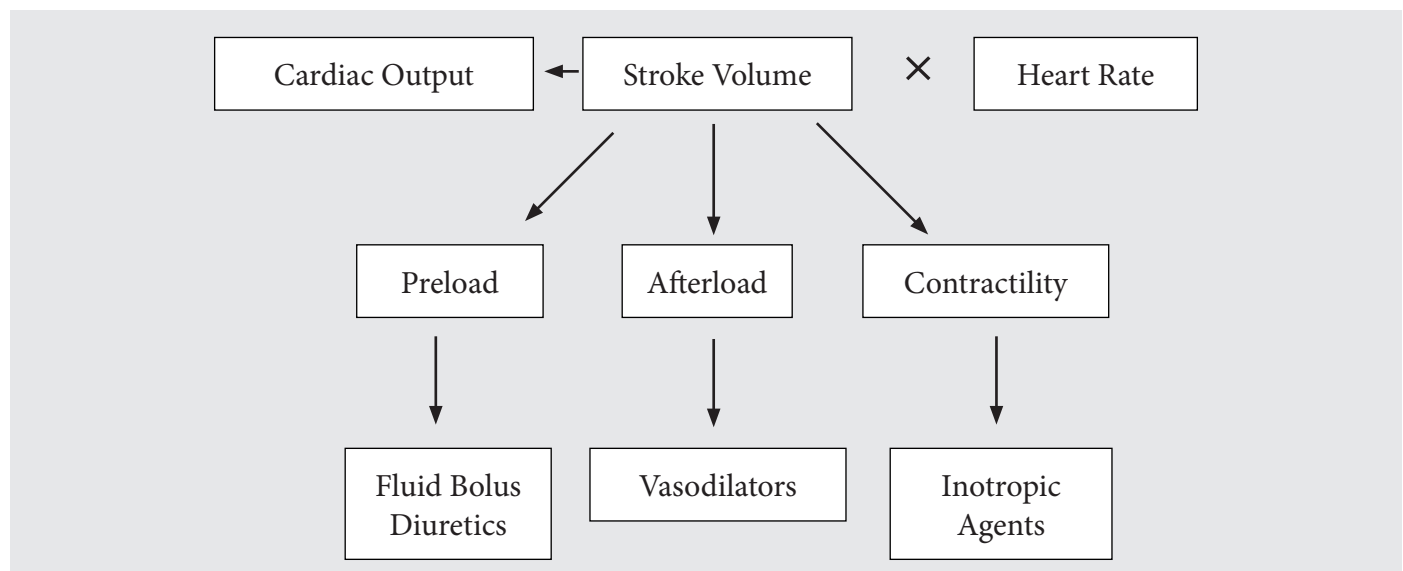

### LOW CARDIAC OUTPUT SYNDROME

The patient with LCOS is encountered primarily after surgical repair of congenital heart disease. Low cardiac output syndrome is often defined as the inability of the heart to deliver oxygenated blood to the end organs and tissues to satisfy demand or consumption (References 14–16). The primary etiology of LCOS is the myocardial “stunning” that occurs after cardiac surgery, together with higher circulating levels of interleukins and other inflammatory mediators. The use of cardiopulmonary bypass is often implicated in LCOS, as is aortic cross clamping during surgery (resulting in myocardial ischemia), myocardial tissue incision, and the use of cardioplegia solutions (References 14, 17).

Studies have shown a decline in cardiac output, an increase in pulmonary vascular resistance (PVR), and an increase in systemic vascular resistance (SVR) occurring 6–18 hours after cardiac surgery, particularly in neonates that have undergone cardiopulmonary bypass during surgery (References 15, 16, 18).

Low cardiac output syndrome is diagnosed on the basis of a collection of symptoms. Subjectively, patients may look gray or dusky, as opposed to pink, with a sluggish capillary refill time (greater than 3 seconds). They may also have cool peripheral temperatures compared with their core body temperature. Patients with LCOS will show signs of decreased end organ and tissue perfusion, including decreased urine output and metabolic acidosis, with elevated serum lactate levels from poorly perfused tissues undergoing anaerobic metabolism (References 15, 16, 19).

The role of pharmacotherapy in the postoperative patient with congenital heart disease is to prevent or minimize LCOS. The basis of pharmacotherapy is to manipulate stroke volume given the classic equation for cardiac output (cardiac output = stroke volume × heart rate) (Figure 1). Optimizing preload, reducing afterload, and augmenting contractility are, in general, methods by which pharmacotherapy is used to improve cardiac output. These methods will be discussed throughout this chapter, and a summary of medications used in the immediate postoperative period has been provided (Table 3).

**Figure 1.** Pharmacologic manipulation of cardiac output.

This diagram represents the common thought process for pharmacologic manipulation of cardiac output in a postoperative surgical patient with congenital heart disease. By optimizing preload, the myocardium will respond by increasing cardiac output, as demonstrated by the Frank-Starling curve. Reduction in afterload allows less resistance on ejection of blood from the ventricle, and an increase in contractility (inotropy) improves the force on which blood is ejected. Each of these areas can be manipulated pharmacologically to improve cardiac output.

**Table 3.** Common Continuous-Infusion Inotropic, Vasopressor, and Vasodilator Agents

Drug	Dosing	Mechanism of Action	Effects
Dobutamine	2.5–20 mcg/kg/minute	$\beta_1, \beta_2$ -agonist	Myocardial contractility, peripheral vasodilation
Dopamine	2–20 mcg/kg/minute	Dopaminergic (2–5 mcg/kg/minute) agonist $\beta_1$ (5–10 mcg/kg/minute) agonist $\alpha$ (10–20 mcg/kg/minute) agonist	Renal vasodilation (?) Myocardial contractility Peripheral vasoconstriction
Epinephrine	0.01–1 mcg/kg/minute	$\beta_1, \alpha_1, \beta_2$ -agonist (more $\beta_1$ and less $\alpha_1$ at lower doses)	Myocardial contractility, peripheral vasoconstriction
Fenoldopam	0.2–0.8 mcg/kg/minute	Dopamine-1 receptor agonist	Peripheral vasodilation
Milrinone	0.375–0.75 mcg/kg/minute	Phosphodiesterase-3 inhibitor	Myocardial contractility, vasodilation
Nesiritide	0.01–0.03 mcg/kg/minute	B-type natriuretic peptide	Vasodilation
Nicardipine	0.5–5 mcg/kg/minute	Dihydropyridine calcium channel blocker	Vasodilation
Nitroprusside	0.5–4 mcg/kg/minute	Generation of nitric oxide	Vasodilation
Norepinephrine	0.05–1 mcg/kg/minute	$\alpha_1, \beta_1$ -agonist	Peripheral vasoconstriction, myocardial contractility
Phenylephrine	0.1–0.5 mcg/kg/minute	$\alpha_1$ -agonist	Peripheral vasoconstriction
Prostaglandin E1	0.01–0.4 mcg/kg/minute	Direct effect on vascular smooth muscle	Vasodilation
Vasopressin	0.0003–0.002 unit/kg/minute	V1 and V2 receptors	Vasoconstriction, water retention

### Preload

Optimizing preload is essential for maintaining maximal cardiac output. If preload is too high, patients will experience venous congestion and edema, but if preload is too low, cardiac output is diminished. Monitoring of preload is based on the patient's physical examination (e.g., hepatomegaly, pulmonary edema), or it can be evaluated in patients with direct right atrial pressure monitoring (Reference 13). Appropriate preload can be titrated using crystalloid or colloid solutions administered as continuous infusions or intermittent boluses (Reference 20). Preload reduction usually occurs with diuresis. Loop diuretics are commonly used as the pharmacologic agent of choice for fluid removal in a cardiac patient (References 21–23). Furosemide may be administered as an intermittent or continuous infusion, but continuous infusions have shown benefit in maintaining diuresis while limiting exposure to medications (References 24, 25). Bumetanide and torsemide have also been used, but with less published literature (References 26, 27). Thiazide diuretics or spironolactone can also be used, particularly when patients begin to experience diuretic resistance (Reference 28). Potassium supplementation may be necessary in patients receiving high doses of diuretics (Reference

29). Hypochloremic metabolic alkalosis is an adverse event associated with high doses and long-term therapy with loop diuretics. The use of acetazolamide and/or chloride supplementation may be necessary in some patients to reverse the alkalosis (References 13, 30).

### Afterload

Reduction in afterload is primarily accomplished by medications that dilate the systemic vasculature. Dobutamine, fenoldopam, milrinone, nitroprusside, nicardipine, and nesiritide are examples of continuous-infusion agents that promote systemic vascular dilation. Milrinone is the agent listed with the most supportive literature associated with pediatric postoperative cardiac surgical patients, including pharmacokinetic data (References 17, 31–35). Patients taking these agents should be monitored for potential adverse events including arrhythmias (dobutamine), thrombocytopenia (milrinone), cyanide toxicity with high doses (greater than 2 mcg/kg/minute) of nitroprusside, and hypotension (all) (References 17, 31–44). Nesiritide has preload reducing effects, in addition to vasodilatory effects, but has been noted to cause acute kidney injury (References 45–54). The vasodilatory effects of fenoldopam tend to

be less potent than those of other agents, but reports have been published of its utility in increasing urine output in patients receiving high doses of diuretics (References 55, 56). Angiotensin-converting enzyme inhibitors (ACEIs) (e.g., captopril, enalapril) have also been used as oral afterload-reducing agents (References 7, 57–62). Enalaprilat provides an intravenous form of ACEI that may be used in patients who are unable to take oral medication. In particular, hypotension and acute kidney injury have been observed when using ACEIs in patients with congenital heart disease (References 13, 62–66).

Although this section has focused on systemic cardiac output, many patients also require pharmacologic manipulation of the pulmonary vasculature to improve cardiac output to the lungs. Agents such as nitric oxide, sildenafil, epoprostenol, and iloprost have been used to augment cardiac output to the pulmonary vascular bed (References 67–79).

### Inotropy

Increased contractility (inotropy) in the immediate postoperative period can be achieved with a wide variety of continuous-infusion medications. Dobutamine, dopamine, epinephrine, norepinephrine, and milrinone can be used to improve myocardial contractility. Catecholamines, such as epinephrine and norepinephrine, should be used in lower doses to improve contractility and minimize peripheral vasoconstriction and increased afterload. Dopamine may be used as an inotropic agent, but reports have associated its use with an increase in postoperative arrhythmias (References 80, 81). Dobutamine can be used as an inotropic agent with the beneficial effect of reduced afterload from peripheral vasodilation, but arrhythmias have also been noted with its use (References 36–38).

Catecholamine refractory shock can occur in patients with profound vasodilation and myocardial depression. Vasopressin is an agent that can be considered in patients with catecholamine refractory shock. Vasopressin is a potent vasoconstrictor that, when used at very low doses, has profound effects on the periphery and the coronary arteries (References 82–87). Bolus administration of hydrocortisone has also been shown to improve catecholamine responsiveness and hemodynamic parameters (Reference 88).

Pharmacotherapy should be applied in a selective manner that incorporates not only the patient's cardiac pathophysiology, but also other comorbidities and pathophysiologies that are present (Figure 2). Pharmaceutical management depends on the patient's cardiac pathophysiology, and nonpharmacologic options, such as peritoneal dialysis, new ventilator strategies, or mechanical support, are often employed (References

11, 12, 14). A comprehensive understanding of the pharmacology and physiologic effects of medications used for the prevention and treatment of LCOS is necessary to make informed decisions.

### FETAL VS. NEONATAL CIRCULATION

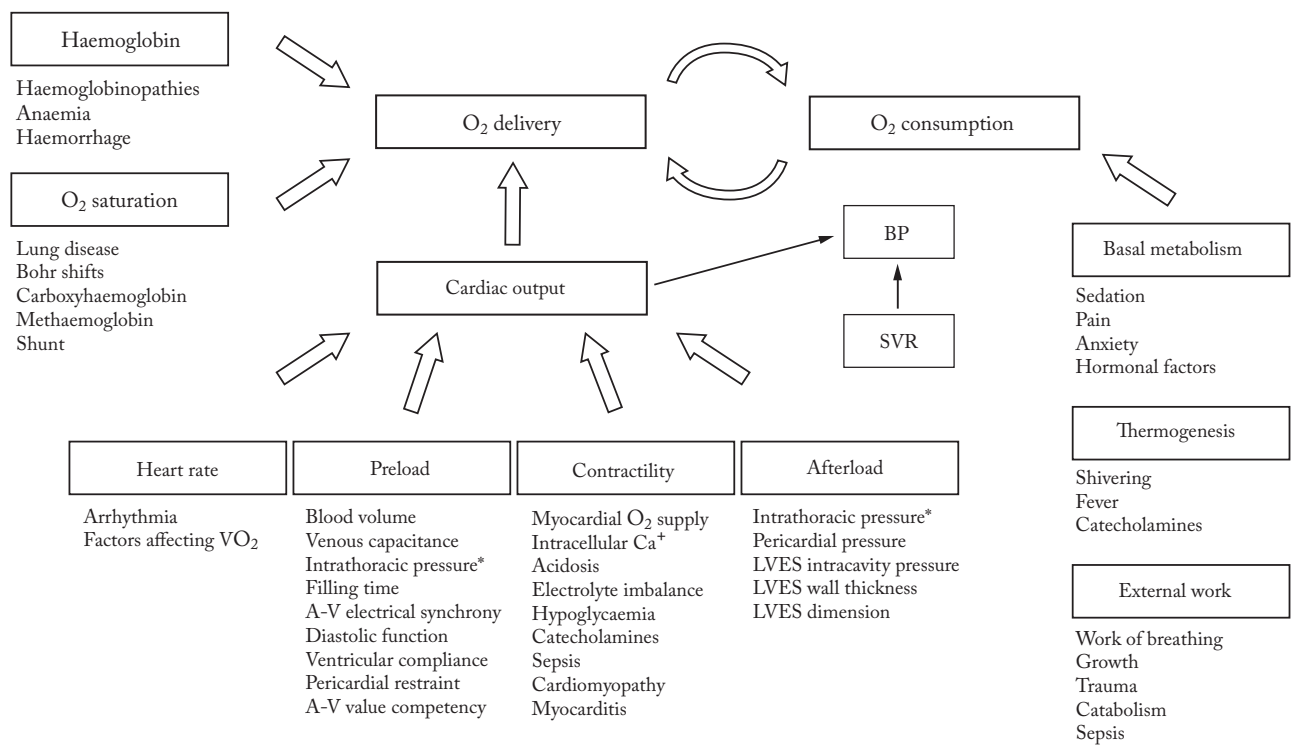

One of the primary differences between fetal circulation and neonatal circulation, as it pertains to congenital heart disease, is the oxygenation of blood by the placenta instead of the lungs. Fetal pulmonary vasculature is typically constricted, allowing only a small amount of blood to the lungs. The lungs are bypassed in utero by three shunts: the ductus venosus (connecting the inferior vena cava to the umbilical vein), the ductus arteriosus (connecting the PA to the aorta), and the foramen ovale (a communication through the atrial septum connecting the left atria [LA] and right atria [RA]). Oxygenated blood is delivered to the heart from the placenta and travels through the right atrium to the right ventricle and through the PA, where it is shunted across the patent ductus arteriosus (PDA) to the aorta. Only about 10% of the blood traveling through the fetal PA will actually pass through the pulmonary vasculature. Blood is also shunted from the right atrium to the left atrium (a right to left shunt) across the patent foramen ovale (PFO), and then it travels to the aorta and systemic circulation (Reference 89).

At birth, PVR drops because of lung expansion and inhalation of oxygen, a potent pulmonary vasodilator. The placenta is no longer responsible for oxygenation, and when it is removed, SVR increases, thereby increasing left ventricular and left atrial pressure. This increase in pressure, together with increased blood return from the lungs to the left atrium, causes the PFO to close. Closure of the ductus venosus occurs after the termination of umbilical blood flow, which decreases pressure in the inferior vena cava and right atrium. The production of prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), a potent vasodilator, drops, and the PDA begins to close, with complete closure occurring in about 96 hours. When these shunts have completely closed, the heart is considered to have mature circulation (Reference 89).

### CONGENITAL HEART DISEASE

#### Patent Ductus Arteriosus

A PDA is the connection between the PA and the aorta, which is necessary to bypass the pulmonary vasculature in utero. The PDA should completely close about 96 hours after birth because of a decrease in endogenous PGE synthesis (References 5, 6, 89) (Figure 3). A PDA that does not close spontaneously accounts for around 10% of all congenital heart disease, and a

**Figure 2.** Monitoring of cardiac output.

This figure represents the complicated assessment and treatment of postoperative low cardiac output syndrome for a patient who has undergone surgical repair of a congenital heart defect. The goal of treating low cardiac output syndrome is to improve the delivery of oxygen to end organs, adequately providing tissues with oxygen as needed according to demand. Pharmacologic manipulation of cardiac output focuses on optimizing preload, increasing contractility, and decreasing afterload. A-V (AV) = atrioventricular; BP = blood pressure; LVES = left ventricular end systolic; SVR = systemic vascular resistance.

Reprinted with permission from: Tibby SM, Murdoch IA. Monitoring cardiac function in intensive care. *Arch Dis Child* 2003;88:46–52.

PDA will occur in females twice as often as in males (References 1, 2). A PDA will occur as an isolated defect, without other congenital heart disease, in as many as 90% of cases. A PDA occurs more often in premature infants (8 per 1000 births) than in term infants (1 per 5000 births). However, a PDA may be more likely to close spontaneously in a premature infant than in a term infant (References 90–93).

A patient with a PDA will have left to right shunting (from the higher pressure of the aorta to the lower pressure in the PA), resulting in pulmonary overcirculation, congestion, and eventual heart failure or pulmonary hypertension. The degree of symptoms will depend on the size of the PDA, the age at presentation, and the relationship of PVR to SVR. Patients can be given a diagnosis of a PDA on the basis of auscultation, and it can be confirmed with echocardiography. Infants with a PDA may show signs and

symptoms of heart failure, including sweating while feeding, tachypnea, poor growth, or cyanosis. Closure of the PDA is important to minimize long-term morbidity and mortality (References 90, 92).

Choice of therapy modality is multifactorial and can depend on the age of the patient, size of the PDA, and other patient-related factors. Nonpharmacologic therapy for a PDA consists of interventional or surgical closure. Interventional closure consists of the insertion of a coil or device into the ductus arteriosus, thus closing it. Morbidity and mortality from this type of procedure is very low, but it requires specialized services (Reference 94). Surgical ligation of the PDA is also an option, typically reserved for patients who do not respond to pharmacologic therapy or those who have very large PDAs.

Before the closure of a PDA, pharmacotherapy is focused on reducing pulmonary congestion, heart failure, and pulmonary overcirculation. Restriction of fluids and use of diuretics is common practice (Reference

**Figure 3.** Patent ductus arteriosus.

This diagram represents the anatomic description of a PDA (A) and the movement of blood flow in a patient with a PDA (B). The arrows represent blood shunting from the higher-pressure (left) side to the lower-pressure pulmonary arterial (right) side, resulting in pulmonary overcirculation and congestion.

90). However, the use of loop diuretics, such as furosemide, should be approached with caution because they have been noted to increase PGE synthesis, thus potentially impairing closure of the PDA (References 95–97). Pharmacologic therapy for closure of a PDA consists of the nonsteroidal anti-inflammatory medications indomethacin (0.2 mg/kg/dose IV initially, with subsequent doses based on post-natal age) or ibuprofen (10 mg/kg/dose IV initially, followed by 5 mg/kg/dose IV at 24 and 48 hours) (Reference 66). By administering these agents, circulating concentrations of PGEs are decreased, thus promoting constriction and closure of the PDA. Intravenous indomethacin has traditionally been the agent of choice for pharmacologic closure of a PDA, and it is given in escalating doses during a 72-hour period. Recent publications have shown a lack of clinically significant differences between intravenous ibuprofen and intravenous indomethacin for closure of a PDA in a term infant, though ibuprofen may have fewer adverse events in preterm neonates, such as lower serum creatinine values and higher urine output (Reference 98). Indomethacin serum concentrations can be evaluated to potentially improve closure rates and minimize adverse events,

but not all centers have the capability to perform them (Reference 99). Adverse events associated with indomethacin and ibuprofen therapy include necrotizing enterocolitis, bleeding (including intracranial hemorrhage), and acute kidney injury. After closure of an isolated PDA, long-term survival is excellent, and a normal life span is expected.

### Atrial Septal Defect

An atrial septal defect (ASD) is a communication between the RA and LA through the atrial septum (Figure 4). Atrial septal defects comprise about 10% of all congenital heart defects and occur twice as often in females as in males (References 1, 2). Most ASDs occur in the middle of the septum (ostium secundum ASD), but others can occur close to the atrioventricular valves (ostium primum ASD) or close to the superior vena cava (sinus venosus ASD). Oxygenated blood is shunted from left to right into the RA, resulting in pulmonary overcirculation, right atrial enlargement, and, potentially, heart failure. In complicated cases with elevated PVR, blood may actually shunt from the RA to the LA, causing cyanosis (Reference 13). Most patients with an ASD remain asymptomatic, at least

initially, and some ASDs close spontaneously (Reference 100). Right atrial enlargement, caused by volume overload from the left to right shunt, can result in atrial arrhythmias, particularly in older children and adults. Symptomatology is often related to the size of the ASD; large ASDs may have significant shunting and should undergo surgical or interventional closure in the cardiac catheterization laboratory. Interventional closure carries less morbidity than surgical closure, but it can only be performed in select patients. Overall mortality for surgical or interventional closure is very low, and patients can be expected to have a normal life span after their procedure (References 101, 102).

Preoperative pharmacotherapy is limited in patients with ASDs associated with significant shunting because closure of the ASD is the curative course. Relief of symptoms including pulmonary congestion can be achieved with diuretics. Surgical closure of an ASD may require pharmacologic therapy to treat postoperative hypertension, which is not often observed after device closure. Angiotensin-converting enzyme inhibitors, nitroprusside, and  $\beta$ -blockers are all viable options for treating hypertension in the postoperative period. Anticoagulation after surgical or interventional closure is often indicated until endothelialization of the surgical patch or device has occurred. Typically, low-dose aspirin (1–5 mg/kg/day; maximum 81 mg/day) is used for 3–6 months after closure despite limited data on the efficacy of this practice. Patients without comorbidities can be expected to live a normal life span.

### **Ventricular Septal Defect**

A ventricular septal defect (VSD) is a communication between the left ventricle and right ventricle through the ventricular septum, which may occur anywhere along the septum (Figure 5). Ventricular septal defects are the most common congenital heart defect, comprising about 20% to 30% of all congenital heart defects (References 1, 2). Typically, oxygenated blood is shunted from left to right (a “restrictive” VSD), resulting in pulmonary overcirculation, congestion, heart failure, and, possibly, pulmonary hypertension (Reference 13). The degree (and direction) of shunting depends on the size of the VSD and the relationship between PVR and SVR. Patients with pulmonary hypertension may shunt unoxygenated blood from right to left into the systemic circulation. Ventricular septal defects can also occur in combination with other congenital heart defects and may be large enough (“non-restrictive”) to cause cyanosis because of the right to left shunting of unoxygenated blood to the systemic circulation (Reference 13).

Symptomatology is related to the size of the VSD and its associated comorbidities (i.e., pulmonary hypertension). Patients with very small VSDs may be asymptomatic, but otherwise, symptoms may include dyspnea, poor feeding, failure to thrive, or signs and symptoms of heart failure. Patients with a VSD are at increased risk of developing bacterial endocarditis, regardless of VSD size. Diagnosis of a VSD can be made by auscultation, and echocardiography is often used to confirm the diagnosis and determine the size and shunting direction of the VSD (Reference 89).

Surgical closure is the primary method for correction of a VSD, and surgical mortality is very low. However, up to 25% of patients with a VSD have spontaneous closure during childhood, and small VSDs are more likely to spontaneously close than a large VSD (Reference 103). Surgical intervention should take place in neonates and infants with failure to thrive and signs and symptoms of heart failure. In addition, children with pulmonary hypertension, regardless of the size of VSD, should undergo surgical or interventional closure.

The goal of preoperative pharmacotherapy in patients with a VSD is to minimize pulmonary congestion, prevent heart failure, and maintain growth. Various agents have been used to reduce afterload and minimize congestion. Hydralazine was initially the agent of choice, but recently, furosemide (or other diuretics), digoxin, and ACEIs have been used (References 60, 62, 104–108). Caution is warranted when using ACEIs because of the risk of acute kidney injury, particularly in very young patients with a VSD (References 60, 63, 65). Immediate postoperative management consists of maintaining cardiac output and management of postoperative hypertension. Patients may still be hypertensive after discharge and should be followed until resolution. Anticoagulation with aspirin at low doses can be used for 3–6 months after a surgical procedure to help prevent thrombus formation on the VSD patch. Patients without comorbidities can be expected to live a normal life span.

### **Tetralogy of Fallot**

The anatomic description of TOF consists of four components: pulmonary stenosis, aorta overriding the ventricular septum, right ventricular hypertrophy, and VSD (References 5, 6, 89) (Figure 6). Tetralogy of Fallot accounts for about 10% of all congenital heart defects and is the most common cyanotic heart defect in patients younger than 1 year (References 1, 2). The degree and frequency of shunting is based on the severity of the pulmonary stenosis. In patients with mild pulmonary stenosis, shunting can occur from left to right across the VSD and result in heart failure. These patients are often referred to as a “pink tet.” In

patients with moderate to severe pulmonary stenosis, blood flow is more limited to the pulmonary vasculature, resulting in desaturation, otherwise known as a “blue tet.” Presenting symptomatology in patients with TOF depends on the severity of pulmonary stenosis and the degree of right to left shunting. Neonates may be born with severe pulmonary stenosis that requires immediate surgical intervention. However, older patients may have mild pulmonary stenosis with only occasional symptomatology. Most patients will present within the first year of life, and signs and symptoms can include decreased growth or poor feeding, dyspnea on exertion, or decreased tolerance to physical activity. Older patients will also show signs of clubbing from chronic cyanosis.

When PVR is acutely greater than the pressure in the left ventricle, the shunting of unoxygenated blood from right to left occurs. This is termed a *hypercyanotic episode*, or “Tet spell.” Hypercyanotic spells often occur when patients are ill or agitated or when they have been unable to inhale enough oxygen to maintain

pulmonary vasodilation (i.e., crying). These are medical emergencies, and interventions are urgently required to shunt blood from left to right and into the pulmonary vasculature (References 109, 110).

Surgical intervention is the curative approach for TOF. The VSD is closed in such a way that the aorta then originates only from the left ventricle. To relieve the PA stenosis, infundibular masses can be resected, the PA can be augmented with a patch, or the PA can be completely replaced with synthetic valved conduit. Former surgical approaches included the preliminary use of a BT shunt, which connects the aorta to the PA, bypassing the stenotic region of the PA, and then moves on to a complete repair later. This approach is no longer used with great frequency unless the patient has specific morbidities that do not allow an immediate complete repair (Reference 13).

Preoperative management consists of minimizing right to left shunting and preventing heart failure. Patients at risk of having a Tet spell are often placed on propranolol, which minimizes the spasm of the infundibulum below the PA and relaxes the right ventricle

**Figure 5.** Ventricular septal defect.

This diagram represents the anatomic description of a VSD (A) and the schematic movement of blood flow in a patient with a VSD (B). The arrows represent blood shunting from the higher-pressure (left) side to the lower-pressure pulmonary arterial (right) side, resulting in pulmonary overcirculation, congestion, and heart failure. Left ventricular enlargement can also occur, secondary to increased blood return from the lungs to the LA and LV, resulting in systolic dysfunction and heart failure.

IVC = inferior vena cava; LA = left atria; LV = left ventricle; RA = right atria; RV = right ventricle; VSD = ventricular septal defect.

**Figure 6.** Tetralogy of Fallot.

This figure depicts the four components of tetralogy of Fallot: pulmonary artery stenosis, right ventricular hypertrophy, aorta overriding the ventricular septum, and ventricular septal defect. Patients experience hypercyanotic episodes (“Tet spells”) when pulmonary vascular resistance is elevated, and unoxygenated blood is shunted from right to left and to the systemic circulation.

Ao = aorta; IVC = inferior vena cava; LA = left atria; LV = left ventricle; PA = pulmonary artery; RA = right atria; RV = right ventricle.

and right ventricular outflow tract (References 111, 112). Treatment of a Tet spell focuses on elevating SVR and decreasing PVR. Older patients may have a characteristic known as “squatting” in response to a Tet spell, also referred to as the “knee-to-chest maneuver” (References 62, 108). By bringing the knees to the chest, SVR is increased, left ventricular pressure is increased, and blood is shunted from left to right. Pharmacologic interventions include oxygen (decreases PVR), morphine (decreases PVR), fluids (increases right ventricular filling and pulmonary blood flow),  $\beta$ -blockers, and intravenous phenylephrine (increases afterload).

Immediate postoperative management consists of maintaining cardiac output, treating postoperative hypertension, and ensuring adequate pulmonary blood flow. Inhaled nitric oxide has been used to improve pulmonary blood flow after surgical correction (Reference 113). Patients are often given low-dose aspirin for 3–6 months after placement of foreign material, such as a PA patch, or patients may take aspirin indefinitely if a pulmonary valve has been placed (Reference 114).

Long-term management of surgically corrected TOF focuses on prevention and treatment of heart failure, treatment of right ventricular dysfunction, and treatment of arrhythmias. The long-term survival for patients with surgically corrected TOF is good (estimated at 86% at older than 30 years), but it is still less than that for patients without congenital heart disease (Reference 1).

### Transposition of the Great Arteries

Transposition of the great arteries (TGA) is a defect in which the PA arises from the left ventricle, and the aorta arises from the right ventricle (Figure 7). This defect accounts for about 7% of all congenital heart defects, and it is diagnosed in infancy (References 1, 2). Patients may or may not have a VSD in conjunction with TGA. In utero, patients have a communication between the PA and aorta by the PDA and PFO. After birth, the PDA and PFO begin to close, and the patient can develop profound acidosis and shock caused by the lack of oxygenated blood flowing to end organs. Patients can be given diagnoses prenatally through fetal echocardiography, but often, they present in shock about 24–72 hours after birth, when the PDA begins to close. Echocardiography after birth can definitively diagnose TGA.

Surgical correction by the arterial switch procedure is the standard for patients with TGA. Surgery should occur in the first 1–2 weeks of life so that the left ventricle (which would be currently pumping to the pulmonary vasculature) does not become deconditioned and can handle the stress of pumping to a

systemic circulation (References 13, 89). The arterial switch procedure consists of removing the PA and the aorta and placing them in the appropriate location. In addition, the coronary arteries that were coming off the PA (in place of the aorta) are removed and reattached to the aorta in its new position. Before the arterial switch procedure, the Mustard procedure, which consisted of a complex series of intracardiac baffles to shunt blood to the appropriate vessels, was a common surgical approach. Patients with TGA in combination with pulmonary stenosis may still undergo the Mustard procedure to avoid placing the stenotic PA in the aortic position (Reference 116).

**Figure 7.** Transposition of the great arteries.

This diagram represents the anatomy of TGA, in which the aorta (Ao) arises from the right ventricle (RV), and the pulmonary artery (PA) arises from the left ventricle (LV). In utero, the PDA would connect the Ao and PA. After birth, once the PDA begins to constrict, two separate circulations form in the patient with TGA. (1) Un氧ygenated blood travels from the IVC/SVC → RA → RV → Ao → systemic circulation without going to the pulmonary vasculature. (2) Oxygenated blood travels from the pulmonary veins → LA → LV → PA → lungs without going to the systemic circulation. In summary, oxygenated blood never reaches the end organs, and un氧ygenated blood is continually recycled through the systemic circulation.

IVC = inferior vena cava; LA = left atria; PDA = patent ductus arteriosus; RA = right atria; SVC = superior vena cava; TGA = transposition of the great arteries. Reprinted with permission from: Lilly L. Pathophysiology of Heart Disease, 2nd ed. Baltimore: Lippincott Williams & Wilkins, 1998.

Preoperative pharmacotherapy of TGA consists of maintaining the PDA to ensure that oxygenated blood flows from the PA to the aorta. This is accomplished by using a prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) infusion to maintain ductal patency (Reference 117). Immediate postoperative pharmacotherapy should manage LCOS. Patients may also be placed on a prophylactic nitroglycerin infusion, as a coronary vasodilator, to prevent coronary vasospasm after their surgical manipulation. Long-term pharmacotherapy is minimal because patients should have normal circulation, and long-term survival for patients after the arterial switch procedure is good, cited at about 85% (References 118, 119).

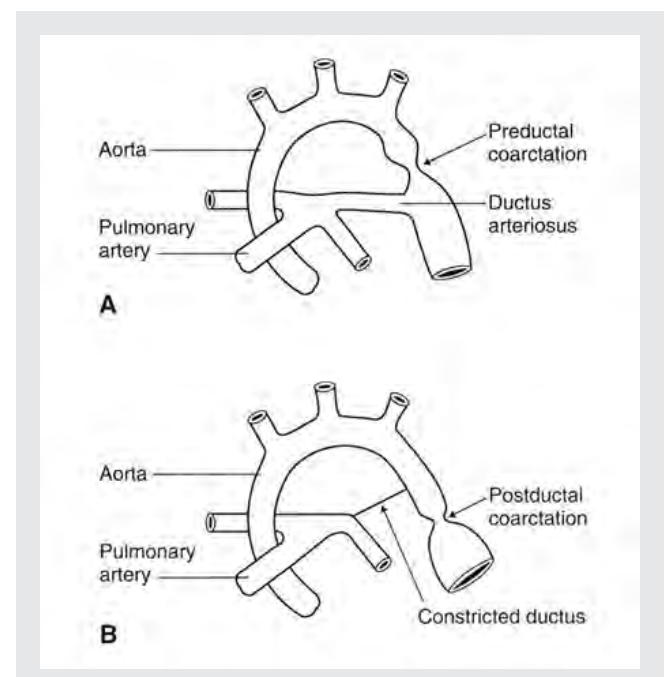

### COARCTATION OF THE AORTA

A patient with coarctation of the aorta has a narrowing of the aorta, which restricts blood flow to the systemic circulation (Figure 8). Aortic coarctations are often associated with other congenital heart defects and account for about 6% of all congenital heart defects. Coarctations are also typically divided into two categories: preductal and postductal (References 1, 2). Preductal coarctation occurs most often in a fetus with another cardiac anomaly that restricts blood flow to the aorta and is associated with aortic arch hypoplasia. Postductal coarctation occurs most often after birth, as an isolated lesion, and is most likely the result of ductal tissue in the aorta that constricts after birth (References 13, 89). Both forms of coarctation can result in decreased cardiac output and left ventricular hypertrophy because of the aortic obstruction.

Neonatal patients with preductal coarctation can exhibit differential cyanosis (differing oxygen saturations on the upper and lower parts of the body) because of unoxygenated blood shunting from the PA through the PDA to the aorta. Coarctations can also cause differential blood pressures based on the location of the coarctation in relation to the ductus (i.e., if the ductus is after the subclavian arteries, blood pressure will be higher in the arms than in the legs). Neonates with severe coarctation will present in shock with profound acidosis, caused by lack of blood flow to end organs (References 13, 89). Less severe forms can present with tachypnea, hepatomegaly, dyspnea, and tachycardia. Some patients with mild coarctation may never experience any symptomatology and may grow and develop normally. Collateral arteries may develop spontaneously in some patients to accommodate for the lack of blood flow through the aorta, and these collateral arteries can erode through the ribs (References 13, 89). A coarctation may be diagnosed in older patients who experience dyspnea on exertion or syncope. Echocardiography or magnetic resonance imaging can be used to confirm the diagnosis (References 13, 89).

Surgical correction is necessary to eliminate the coarctation. Two surgical methods are commonly employed: end-to-end anastomosis or patch repair. The end-to-end anastomosis does not involve cardiopulmonary bypass and can occur when the coarctation does not involve the carotid arteries. During this procedure, both ends of the coarctation are clamped, the narrowed section is dissected, and the aorta is then sutured together. The patch repair technique involves cardiopulmonary bypass, the coarctation is dissected, and the aorta is repaired with a prosthetic patch. Operative mortality is very low, reported at less than 2%, but it can be higher in neonates presenting in shock (Reference 13).

Preoperative pharmacotherapy is aimed at maintaining cardiac output in the presence of an obstruction. For preductal coarctations, PGE<sub>1</sub> may be used to maintain the PDA and deliver systemic blood flow postductus (Reference 117). Managing heart failure and decreasing afterload are also strategies for maintaining cardiac output before surgical intervention. In the immediate postoperative period, many patients

**Figure 8.** Coarctation of the aorta.

These diagrams represent two versions of coarctation of the aorta. A coarctation can occur before the ductus arteriosus (A) or after the ductus arteriosus (B). In addition, the preductal coarctations can occur further up the aortic arch and involve the carotid or subclavian arteries.

Reprinted with permission from: Lilly L. Pathophysiology of Heart Disease, 2nd ed. Baltimore: Lippincott Williams & Wilkins, 1998.

experience hypertension after coarctation repair (Reference 117). The etiology of this hypertension is not completely understood, but it should be managed appropriately to avoid rupturing aortic sutures. Many agents have been used, including esmolol, nitroprusside, labetalol, enalaprilat, and nicardipine (References 43, 120–127). Long-term management of hypertension is necessary for up to 6 months after the surgical procedure. Patients should be followed routinely because there is a potential for re-coarctation. The long-term survival rate for patients with coarctation repair is excellent.

### Hypoplastic Left Heart Syndrome

Patients with hypoplastic left heart syndrome (HLHS) have a small to nonexistent left ventricle and narrow (or atretic) aorta (Figure 9). Patients are unable to survive with HLHS without treatment because of insufficient blood flow from the left ventricle through the aorta to the systemic circulation. Hypoplastic left heart syndrome represents only about 1% of all congenital heart defects, but HLHS uses the largest amount of resources compared with other congenital cardiac defects (References 1, 2). Hypoplastic left heart syndrome is not compatible to life, but because of intracardiac shunting as a fetus, infants may not be given a diagnosis until they present postnatally in shock as the PDA begins to close.

This condition was uniformly fatal before the early 1980s, when Dr. William Norwood introduced the three-stage approach to surgical repair of HLHS (Reference 128). Before initial surgical intervention, patients may require a balloon atrial septostomy to create an ASD if the PFO has closed or is too small. The ASD allows shunting of oxygenated blood from the LA to the RA, which is necessary for survival. The first stage of the surgical palliation occurs within the first few days of life and includes the following procedures: combining the aorta and PAs into one “neo-aorta” (also called the Damus-Kaye-Stansel procedure), creating a large ASD, and placing an aortopulmonary shunt, also known as the BT shunt. These interventions allow oxygenated blood from the lungs to flow from the pulmonary veins to the LA, across the septum to the RA (where it mixes with deoxygenated blood from the inferior vena cava/superior vena cava), to the right ventricle. Blood then flows through the neo-aorta and then either to the lungs (by the BT shunt) or the systemic circulation by the aorta. Modifications of this initial stage have occurred with the Sano procedure, which replaces the BT shunt with a right ventricle to PA conduit (Reference 129). Hybrid procedures have been performed that involve stenting the PDA open to supply blood flow to the aorta from the PA, together with banding of the branch PAs,

which restricts pulmonary blood flow and prevents overcirculation (References 130–132). Because there is complete mixing of oxygenated and unoxygenated blood at the atrial level, oxygen saturations after the Norwood and associated procedures should be at about 70% to 80%. This represents an equal amount of blood flow to the pulmonary and systemic circulations (a  $Q_p/Q_s$  ratio of 1:1) (Reference 13).

The second stage of the palliation, the bidirectional Glenn procedure, occurs at 4–6 months of life and removes the BT shunt from the earlier Norwood procedure and attaches the superior vena cava to the PA (Reference 133). This delivers a greater amount of blood flow to the pulmonary vascular bed, and oxygen saturations generally increase to about 80% to 85% (Reference 13).

The Fontan procedure is the final stage of palliation, which consists of attaching the inferior vena cava, through a conduit, to the PA (Reference 134). This procedure occurs at about age 3 years and completely separates the pulmonary and systemic circulations. The separated circulations should allow oxygen saturations to return to normal (95% to 100%) with a single right ventricle pumping for both pulmonary and systemic circulations. A small fenestration is usually created between the conduit and the right atrium to relieve pressure in the conduit if the PVR becomes too high (Reference 13).

Preoperative pharmacotherapy for HLHS before the Norwood procedure consists of maintaining the PDA to ensure blood flow through the aorta to the systemic circulation with  $PGE_1$  administration, as well as managing the signs and symptoms of heart failure (References 135, 136). Prostaglandin E1 infusions are titrated to the lowest possible dose that will maintain ductal patency and minimize adverse events, such as hypotension or apnea. In the immediate postoperative period, treatment of LCOS and balancing of systemic and pulmonary blood flow are the goals of cardiovascular pharmacotherapy. Patients are often anticoagulated with a low-dose heparin infusion (6–10 units/kg/hour) until they are able to receive enteral medications; then, low-dose aspirin (1–5 mg/kg/day) is used as an antiplatelet agent for the prevention of BT shunt thrombosis (Reference 137). The ideal long-term, or inter-stage, management strategy for patients after a single ventricle palliation is unclear (References 138, 139). Sudden death during the inter-stage period can occur, and an exact etiology for this phenomenon is unknown (Reference 140). In addition, the lack of inter-stage weight gain has been noted for patients after single ventricle palliation, which has been thought to contribute to mortality (References 141–143). Pharmacotherapy has elicited few improvements in this area, with recent publications showing

Stage 2

Stage 3

**Figure 9.** Hypoplastic left heart syndrome and three-stage surgery.

This diagram represents the anatomy of unrepaired hypoplastic left heart syndrome (HLHS). Note the aortic atresia and small left ventricle. Stage 1 represents three options for the initial palliation of HLHS. (a) The classic Norwood procedure combines the aorta and pulmonary artery (also known as the Damus-Kaye-Stansel procedure), creation of an atrial septal defect, and placement of a Blalock-Taussig (BT) shunt. (b) The Sano procedure replaces the BT shunt with a right ventricle to pulmonary artery conduit. (c) A hybrid procedure involves stenting of the ductus arteriosus and banding of the branch pulmonary arteries. Stage 2 is the bidirectional Glenn procedure, in which the BT shunt or right ventricle to pulmonary artery conduit is taken down, and the superior vena cava is attached to the pulmonary artery. Stage 3 is the Fontan procedure, in which an extracardiac conduit is used to attach the inferior vena cava to the pulmonary artery, subsequently dividing pulmonary and systemic circulations.

the ineffectiveness of ACEIs and other medications in improving inter-stage weight gain (Reference 7). Current best practice appears to be close monitoring of weight and frequent follow-up before the bidirectional Glenn (References 141–143).

Little information exists for the pharmacotherapeutic management of the patient after the bidirectional Glenn procedure. Immediate postoperative management consists of maintaining cardiac output and preventing thrombus with a low-dose heparin infusion (6–10 units/kg/hour). Anecdotally, a nitroglycerin infusion has been used to help maintain the patency of the superior vena cava to PA anastomosis. Long-term pharmacotherapy in patients after the bidirectional Glenn is directed toward the prevention of heart failure and the maintenance of adequate cardiac output.

Immediate postoperative management of the patient after the Fontan procedure is focused on maintaining cardiac output and preventing LCOS. Patients are at risk of developing pleural or chylous effusions after the Fontan procedure. Literature has shown variable efficacy in restricted fat intake and the use of octreotide to decrease chylous effusions (References 144–146). Protein-losing enteropathy (PLE) can also occur in post-Fontan patients. Treatment of PLE has consisted of subcutaneous heparin injections, even though the mechanism for the benefit of this therapy is unclear (Reference 147). Recent literature has shown that the use of enteral budesonide or octreotide may be useful in the treatment of PLE after the Fontan procedure (References 148, 149).

One of the most controversial areas in pharmacotherapy for the Fontan patient is anticoagulation. Because of the physiology and hemodynamics of the Fontan circuit, the RA can become enlarged, with patients potentially developing atrial arrhythmias, such as atrial fibrillation or atrial flutter, leading to thrombus formation. Several studies have evaluated the risks and benefits of aspirin anticoagulation compared with warfarin anticoagulation in the Fontan patient without arrhythmias, finding that bleeding risk is increased with warfarin, but thrombus formation is increased with aspirin use (References 150–154). If a patient does develop atrial arrhythmias, warfarin is most likely indicated to prevent thrombus formation (References 114, 155). Currently, no consensus exists for the optimal anticoagulation regimen for a patient after the Fontan procedure.

Long-term pharmacotherapeutic management of the Fontan patient includes the prevention and management of heart failure. There is currently no consensus on the optimal management or prevention of heart failure in a patient with a single right ventricle, and practice varies widely (Reference 5). In addition, heart failure in this population differs significantly from

that in other adult populations because heart failure in the Fontan is caused by pressure/volume overload in a right ventricle. Enalapril and sildenafil have been studied in Fontan patients, but neither has been shown to improve symptoms or exercise tolerance (References 156–159).  $\beta$ -Blockers may show some benefit in failing Fontan, but large trials have not been performed (References 160, 161). Further research in this area is warranted to improve long-term outcomes.

Because the Fontan procedure is the terminal operation in the staged repair of HLHS, patients can develop several complications throughout their lifetime. Many patients undergo revisions of their original Fontan circuit because of decreased exercise tolerance or increasing cyanosis. Life expectancy and quality of life have improved with time. As surgical and medical management continues to improve, patients will live longer, and health care providers will require specialized training and knowledge to appropriately care for patients with a single ventricle.

## FUTURE DIRECTIONS

As surgical and medical management of congenital heart disease in children improves, patients are surviving into adulthood. The population of adult patients with congenital heart disease is growing by 5% per year, representing well over 1 million patients in the United States alone (References 162–164). Management of the adult patient with congenital heart disease is an area that requires clinicians to have specialized knowledge in both pediatric and adult cardiovascular diseases. Morbidity can be high in this patient subset, and currently, few centers are developed to care for this patient population (References 165, 166). The unique cardiac pathophysiologies and comorbidities in this patient population make application of pharmacotherapy challenging and ripe for research and evaluation (Reference 167). In addition, the neurologic complications that can be associated with cardiopulmonary bypass, chronic cyanosis, and low-flow states are undergoing evaluation. It is well known that patients with congenital heart disease can have lower levels of cognitive function, and future directions include research to eliminate this morbidity (References 168–172).

## CONCLUSIONS

The pharmacotherapeutic management of patients with congenital heart disease is complex and plagued by a lack of data compared with that for adult patients with cardiac pathophysiology. A comprehensive understanding of pathophysiology, hemodynamics, and pediatric pharmacology is necessary to optimize outcomes for this challenging patient population.

# CHAPTER 10

## PEDIATRIC ARRHYTHMIAS

*Brady S. Moffett, Pharm.D., MPH; and Scott L. Macicek, M.D.*

### LEARNING OBJECTIVES

1. Understand the epidemiology and pathophysiology of common pediatric arrhythmias.
2. List pharmacologic options for the acute and chronic treatment of common pediatric arrhythmias.
3. Identify monitoring parameters for therapeutic efficacy and toxicity for pharmacotherapy of common pediatric arrhythmias.

### ABBREVIATIONS IN THIS CHAPTER

AVNRT	Atrioventricular nodal reentrant tachycardia
AVRT	Atrioventricular reentrant tachycardia
ECG	Electrocardiogram/electrocardiographic/electrocardiography
LQTS	Long QT syndrome
PJRT	Permanent junctional reciprocating tachycardia
SVT	Supraventricular tachycardia
TdP	Torsades de pointes
VF	Ventricular fibrillation
VT	Ventricular tachycardia
WPW	Wolff-Parkinson-White (syndrome)

### INTRODUCTION

This chapter will focus on arrhythmias common to the pediatric population, divided into three major subsections: supraventricular tachyarrhythmias, ventricular tachyarrhythmias, and bradyarrhythmias. Our goal is to have these three sections encompass most management strategies for arrhythmias seen by a pediatric pharmacist evaluating drug therapy for pediatric patients. However, there will be exceptions to the strategies presented, particularly for those practicing in large, tertiary referral centers, and the reader will be given references for further investigation of uncommon arrhythmias.

Some assumptions were made when writing this chapter. Because this textbook focuses on the pediatric age group, only aspects of arrhythmia pathophysiology, medical care, or pharmacotherapy that are unique to the pediatric population will be discussed. Because of

space limitations and the availability of other excellent resources, basic cardiovascular anatomy and physiology (including an in-depth discussion of the mechanism of cardiac conduction) will not be covered in this chapter. Similarly, a basic understanding of electrocardiographic (ECG) interpretation will be assumed. If readers would like an update on these aspects of cardiovascular anatomy and physiology, they are directed to other sources (References 1, 2).

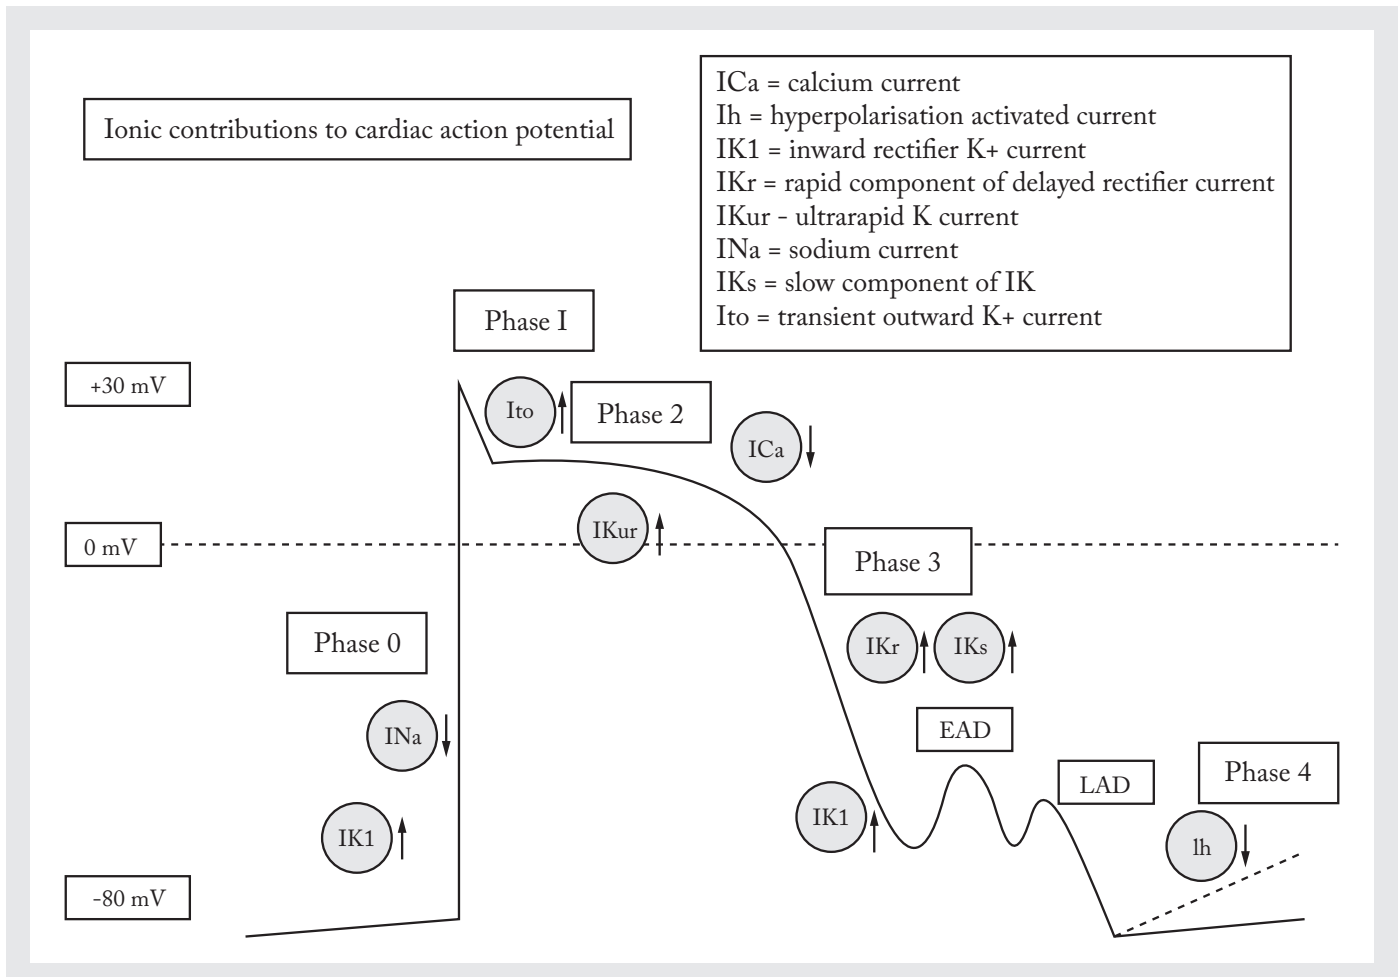

### NORMAL CONDUCTION

The cardiac conduction system consists of the sinoatrial (SA) node, the atrioventricular (AV) node, the bundle of His with the left and right bundle branches, and the Purkinje fibers. In a normal heart, electrical impulses are generated in the SA node and are subsequently transmitted through the atria to the AV node, bundle of His, and left and right bundle branches to the Purkinje fibers, which finally stimulate myocardial contraction.

The basis of electrical conduction begins with the shifting of ions into and out of cells, thus generating a change in polarization, also known as the action potential. The action potential involves four phases, with specific ions involved in each phase (Figure 1). Developmentally, changes in ion transport channels appear to occur with age, leading to increased expression of potassium and calcium channels with older age (Reference 3). In addition, the electrophysiologic characteristics of the AV node have been noted to change in pediatric patients as they age (Reference 4). Although the impact of this on the pharmacotherapy for pediatric arrhythmias is currently unknown, it may be elucidated in the future.

### ANTIARRHYTHMIC MEDICATIONS

Antiarrhythmic medications affect ion transport in myocardial cells. Three primary modes of electrical signal transduction and generation are affected: (1) automaticity (the rate of action potential generation), (2) conduction velocity (the speed of action potential movement through the myocardium), and (3) refractory period (the time to repolarize). All antiarrhythmic medications are classified by Vaughan-Williams categories on the basis of their primary mechanism of action (Table 1). The dosing and monitoring of these agents is often individualized on the basis of the arrhythmia being treated and other patient comorbidities

**Figure 1.** Action potential.

This figure describes the action potential of the Purkinje fibers and the associated ion shifts. Phase 0 consists of Na<sup>+</sup> influx into the cell, resulting in a positive charge. At phase 1, K<sup>+</sup> effluxes from the cell, followed by Ca<sup>++</sup> ions. K<sup>+</sup> ions efflux from the cell in phase 2. Phase 3 includes more K<sup>+</sup> efflux from the cell, to decrease the action potential threshold. Phase 4 spontaneous depolarization occurs only in pacemaker cells. Early afterdepolarizations (EAD) and late afterdepolarizations (LAD) represent “extra” depolarizations that can occur in patients with prolonged phase 2 and phase 3 (K<sup>+</sup> channel) repolarizations, potentially resulting in arrhythmias. Republished with permission from Chakrabarti A, Stuart AG. Understanding cardiac arrhythmias. Arch Dis Child 2005;90:1086–90.

(Reference 5). In addition, the effect of each of these medications on electrophysiologic and hemodynamic parameters has been summarized. Each of these drugs will be evaluated in depth regarding their effect on various arrhythmias in the upcoming sections.

### SUPRAVENTRICULAR TACHYARRHYTHMIAS

Supraventricular tachyarrhythmias are the most common arrhythmia in childhood, occurring in about 1 in every 250 children. A higher prevalence has been reported in patients who have undergone cardiac surgery or have congenital heart disease (Reference 6). However, most patients with supraventricular tachyarrhythmias have structurally normal hearts, and patients are not uncommonly given a diagnosis on routine office visits (Reference 7). Most supraventricular

tachyarrhythmias are paroxysmal (lasting 30 seconds or less), but they can be incessant, resulting in significant hemodynamic compromise and heart failure in as little as 24–48 hours (Reference 8). Patients can become symptomatic, exhibiting signs of heart failure such as poor feeding, sweating, and tachypnea in infants and fatigue, tachypnea, and peripheral edema in older patients (Reference 8). Although overall mortality from supraventricular arrhythmias is low, rapid diagnosis and appropriate treatment are essential to minimize patient morbidity (Reference 9).

Overall, supraventricular tachyarrhythmias have been traditionally defined as an abnormally rapid heart rhythm originating above the bundle of His (Reference 10). Within this broad heading, there are many different pathophysiologic mechanisms of arrhythmias, including those with focal atrial tachycardias (FATs),

**Table 1. Summary of Antiarrhythmic Medication Dosing in Pediatric Patients (Reference 5)**

<b>Drug</b>	<b>Dosage</b>	<b>Notes on Pharmacotherapy</b>
<b>Class Ia (Na<sup>+</sup> channel blockade – moderate)</b>		
Quinidine sulfate	Oral: 30 mg/kg/day or 900 mg/m <sup>2</sup> /day given in five daily doses Range: 15–60 mg/kg/day in four or five divided doses IV: 2–10 mg/kg/dose every 3–6 hours as needed (IV not routinely recommended)	Two forms available (sulfate and gluconate). Drug level monitoring typically not performed
Procainamide	IV: Loading dose: 3–6 mg/kg/dose; max 100 mg/dose. May be repeated to a total max of 15 mg/kg IV: Continuous infusion: 20–80 mcg/kg/minute	Procainamide and NAPA concentrations used to guide therapy
Disopyramide	Oral: • < 1 year: 10–30 mg/kg/day in four divided doses • 1–4 years: 10–20 mg/kg/day in four divided doses • 4–12 years: 10–15 mg/kg/day in four divided doses • 12–18 years: 6–15 mg/kg/day in four divided doses	Drug level monitoring typically not performed
<b>Class Ib (Na<sup>+</sup> channel blockade – mild)</b>		
Lidocaine	IV: Bolus: 1 mg/kg/dose IV: Continuous infusion: 20–50 mcg/kg/minute	Drug level monitoring useful for guiding therapy
Mexiletine	Oral: 1.4–5 mg/kg/dose every 8 hours	
<b>Class Ic (Na<sup>+</sup> channel blockade – strong)</b>		
Flecainide	Oral: Starting dose: 1–3 mg/kg/day or 50–100 mg/m <sup>2</sup> /day divided three times/day. Max: 8 mg/kg/day or 200 mg/m <sup>2</sup> /day. Average effective dose: 4 mg/kg/day or 140 mg/m <sup>2</sup> /day	Drug level monitoring useful for guiding therapy
Propafenone	Oral: 200–300 mg/m <sup>2</sup> /day divided three or four times/day. Max: 600 mg/m <sup>2</sup> /day divided three or four times/day	Drug levels not typically performed
<b>Class II (β-blockade)</b>		
Propranolol	Oral: Neonates: 0.25 mg/kg/dose every 6 hours. Max: 5 mg/kg/day Oral: Infants and children: 0.5–1 mg/kg/day in divided doses every 6–8 hours Usual dose: 2–4 mg/kg/day. Max: 60 mg/day	
Esmolol	IV: Bolus: 100–500 mcg/kg/dose IV: Continuous infusion: 300–1000 mcg/kg/minute	
Atenolol	Oral: 0.5–1 mg/kg/day given one or two times/day. Max: 2 mg/kg/day or 100 mg/day	
Metoprolol	Oral: Children 1–17 years: 1–2 mg/kg/day given twice daily. Max: 6 mg/kg/day or 200 mg/day	Extended-release tablets given once daily
Nadolol	0.5–1 mg/kg/day given daily. Max: 2.5 mg/kg/day	
<b>Class III (K<sup>+</sup> channel blockade)</b>		
Sotalol	Oral: Children ≤ 2 years: 30 mg/m <sup>2</sup> /dose every 8 hours adjusted per age nomogram OR 2 mg/kg/day divided every 8 hours OR 80–200 mg/m <sup>2</sup> /day divided every 8 hours Oral: Children > 2 years: 80–200 mg/m <sup>2</sup> /dose divided every 8 hours	Institutional practices for dosing sotalol can vary. ECG monitoring is important for QT-interval prolongation.
Amiodarone	IV: Bolus: 5 mg/kg/dose up to 15 mg/kg. Max dose will vary on the basis of indication. IV: Continuous infusion: 10–20 mg/kg/day or 5–15 mcg/kg/minute Oral: 10–20 mg/kg/day or 600–800 mg/m <sup>2</sup> /day one or two times/day	Patients may be loaded for 1–2 weeks at the beginning of therapy because of the long half-life of amiodarone. Reduction to the most effective dose can occur after loading.

Class IV (Ca <sup>++</sup> channel blockade)		
Verapamil	IV: Children 1–15 years: 0.1–0.3 mg/kg/dose. Max: 5 mg/dose Oral: 4–8 mg/kg/day in three divided doses OR 1–5 years: 40–80 mg every 8 hours > 5 years: 80 mg every 6–8 hours	IV use is not recommended in patients < 1 year.
Diltiazem	Oral: Children: 1.5–2 mg/kg/day in three or four divided doses. Max: 8 mg/kg/day	Extended-release formulations can be given once daily.
Digoxin	Oral and IV: Loading doses and maintenance doses have considerable variation depending on age, and dosing information cannot be summarized in the space provided. Historically, oral maintenance doses have ranged from 5 mcg/kg/day to 10 mcg/kg/day divided one or two times/day.	Drug level monitoring usually useful only in assessment of toxicity
Adenosine	IV: 0.1 mg/kg/dose; subsequent doses 0.2 mg/kg/dose, up to 0.3 mg/kg/dose	Administer by rapid push with a rapid flush through intravenous access closest to the heart.

IV = intravenous; max = maximal; NAPA = *N*-acetyl procainamide.

reentrant mechanisms mediated by an accessory pathway outside the AV node (Wolff-Parkinson-White syndrome [WPW] and concealed pathways, permanent junctional reciprocating tachycardia), a reentrant mechanism within the AV node (atrioventricular nodal reentrant tachycardia [AVNRT]), or junctional ectopic tachycardias (JETs). More than 90% of the supraventricular arrhythmias diagnosed in children have a reentrant mechanism, and these will be addressed in the most detail (Reference 11). Typically, the definition of supraventricular tachyarrhythmias excludes atrial fibrillation and atrial flutter, but for completeness, both will be addressed in this section as arrhythmias that are generated above the ventricles.

### Initial Management of Supraventricular Arrhythmias

Initial management of supraventricular arrhythmias, before definitive diagnosis, has standard approaches. Vagal maneuvers, such as ice to the face or carotid massage, have been performed for initial management in hemodynamically stable patients with limited success (Reference 12). Initial pharmacologic management often consists of adenosine as a diagnostic and therapeutic tool, causing temporary AV block, depending on the mode of tachycardia (References 13, 14). Despite the widespread use of adenosine for initial management and therapy for supraventricular arrhythmias, proarrhythmic effects have occurred, and defibrillation equipment should be readily available when adenosine is administered (Reference 15).

### Focal Atrial Tachycardias

Focal atrial tachycardias, consisting primarily of automatic atrial ectopic tachycardias, account for 4% to 14% of all supraventricular arrhythmias in children and are typically refractory to pharmacologic management (References 16, 17). Although most forms of supraventricular tachyarrhythmias are reentrant in nature, FATs consist of a site within the myocardium that exhibits pacemaker cell characteristics, generating action potentials from areas other than the SA or AV node. Various other forms of FATs can occur, including microreentrant atrial tachycardia, chaotic atrial tachycardia, or multifocal atrial tachycardia (References 11, 18). Patients who have undergone cardiac surgery are often the most likely patient subset for FATs, though some FATs are caused by other disease states or are idiopathic (Reference 16). Patients with FATs will present with an elevated heart rate, typically greater than 200 beats/minute for infants and children. The ECG findings for FATs can be difficult to identify, particularly in patients with heart failure or in neonates (Reference 19). Electrocardiographic readings will show an elevated heart rate with normal QRS and an extended R-P interval, although it may be difficult to see P waves in this type of tachycardia (References 16, 19). The clinical course of FATs can vary depending on age (References 16, 20, 21). Ventricular dysfunction and heart failure can ensue if FATs are not corrected in a timely manner (Reference 22). Catheter ablation may be necessary as a nonpharmacologic intervention for incessant FATs refractory to medical therapy (Reference 23).

The goals of pharmacotherapy for FATs are to decrease the automaticity of the ectopic focus, potentially decrease the conduction velocity of the impulse through the Purkinje fibers, and slow the ventricular rate. Pharmacologic management of FATs, after diagnosis, is based primarily on case-series data, and approaches to treatment vary widely (References 16, 20, 21). Historically, digoxin and class Ia and class IV antiarrhythmic agents have been employed to control FATs, with little effectiveness (References 16, 23, 24).  $\beta$ -Blockers are the most common first-line antiarrhythmic agent. The use of  $\beta$ -blockers such as propranolol or atenolol, with or without digoxin, has had varying results on the effectiveness of control, with some reports showing resolution of arrhythmia, but others showing lack of effect (References 16, 24, 25). Oral propafenone, a class Ic antiarrhythmic, has shown promise for the treatment of FATs, with reported arrhythmia resolution rates from 33% to 89%, although it is not often used at most pediatric centers (References 26–29). It has been hypothesized that patients younger than 1 year without structural heart disease have a better response to propafenone for control of FATs (Reference 30). Another class Ic antiarrhythmic, flecainide, has also been shown to be effective for the treatment of patients with FATs and is more commonly used than propafenone, but it is contraindicated in patients with congenital heart disease (References 31, 32). It has been reported that pharmacotherapy is often more effective in patients younger than 3 years compared with patients older than 3 years (Reference 21). Amiodarone has been used to treat FATs in infants and children, with high success rates of up to 100% (References 16, 33, 34). However, the adverse effect profile of amiodarone, compared with that of other agents, can be much higher (Reference 34). In a comparison study of infants treated with procainamide or amiodarone for supraventricular arrhythmias (excluding JET), continuous-infusion procainamide was shown to have a higher incidence of control without any greater incidence of adverse effects (Reference 35). Finally, sotalol has recently been used to treat patients with FATs with high rates of success (References 36–38). It appears that the best efficacy with sotalol occurs in younger patients who receive higher doses (Reference 30). The combination of flecainide and sotalol has been used to treat FATs and other arrhythmias with high success rates in patients who have been refractory to single-agent therapy (Reference 39).

Nevertheless, despite advances in antiarrhythmic therapy,  $\beta$ -blockers remain the most common first-line agent for the treatment of FATs.

### Atrioventricular Nodal Reentrant Tachycardia

The first reentrant mechanism for supraventricular arrhythmias to be discussed is AVNRT. Of the two primary reentrant mechanisms, AVNRT is more common in older children, seldom occurring before 2 years of age

(References 11, 40, 41). To have a reentrant rhythm, two separate pathways capable of conducting an action potential must be present. The pathophysiology of AVNRT consists of these two pathways within the AV node (termed *dual AV nodal physiology*), a slow pathway and a fast pathway, allowing a reentrant circuit (Reference 42) (Figure 2). In typical AVNRT, an ectopic beat must conduct down the slow pathway and then turn around and go back up the fast pathway to set up a circuit of rapid tachycardia (Reference 43). Most patients have the above typical AVNRT, with a few patients having atypical AVNRT consisting of conduction down the fast pathway and up the slow pathway (Reference 42, 44–47). Patients with AVNRT typically present with a rapid heart rate and, occasionally, chest pain, shortness of breath, and light-headedness. Those in prolonged tachycardia can present with signs and symptoms of heart failure. Neonates and infants will present with poor feeding, sweating while feeding, cough, cyanosis, and pallor with a marked decrease in activity (Reference 48). Typically, patients with AVNRT will present with a rapid heart rate and narrow QRS on ECG, with a P wave occurring immediately after the QRS (termed *short RP tachycardia*), but often, there are few differentiating characteristics from other supraventricular tachyarrhythmias (References 49, 50). Ablation of the slow pathway is often undertaken in the cardiac catheterization laboratory, with initial success rates greater than 95% in experienced centers and recurrence rates after ablation of less than 10% (References 45, 47, 51).

The goal of pharmacotherapy is to block the reentrant cycle within the AV node. Using antiarrhythmic medications to increase the refractory period, decrease automaticity, and/or decrease conduction velocity, the cycle can be broken. Initial management consists of vagal maneuvers and adenosine. The pharmacotherapy for AVNRT is highly varied, and many modalities have been used. Medications that decrease AV nodal conduction (digoxin,  $\beta$ -blockers, verapamil) are typically initiated as first-line oral agents and have a high rate of efficacy (References 46, 52). Propranolol is usually the first-line choice for a  $\beta$ -blocker in infants (Reference 53). Atenolol and nadolol have also been used in the treatment of AVNRT in older children (Reference 54). The percentage of breakthrough in patients receiving  $\beta$ -blockers is not insignificant, even if tachycardia is initially well controlled (Reference 41). Flecainide and propafenone have also been used for arrhythmias recalcitrant to initial therapies. Of the class Ic agents, flecainide has the largest experience in the treatment of refractory AVNRT, with up to 100% resolution of arrhythmias in one report and 81% success in another, but flecainide is contraindicated in the presence of congenital heart disease (References 31, 55). Few data exist for the use of amiodarone in AVNRT, potentially because of the high resolution rates with other antiarrhythmic

**Figure 2.** Atrioventricular nodal reentrant tachycardia.

This figure shows the dual pathways that can occur in an atrioventricular node. The fast pathway typically conducts before the slow pathway and is refractory when the slow pathway reaches it, thus causing the slow pathway conduction to stop. However, a premature atrial beat may cause extra conduction down the slow pathway, which then conducts retrograde up the fast pathway, resulting in a reentrant circuit (sometimes referred to as “circus motion”). This is termed atrioventricular nodal reentrant tachycardia (AVNRT).

agents. Amiodarone appears to be a suitable last-line agent for arrhythmias refractory to all other agents on the basis of reports of effectiveness when treating other arrhythmias (References 56, 57). Similarly, sotalol has few data describing its use in AVNRT, although initial data are favorable as treatment of refractory AVNRT (References 58, 59).

In conclusion, the greatest body of evidence suggests that first-line therapy for AVNRT is a  $\beta$ -blocker or digoxin. In general, medical therapy is used in very young patients who may be at higher risk of complications during a catheter-based ablation procedure. Recalcitrant arrhythmias should be treated with flecainide, sotalol, or amiodarone.

### Accessory Pathway–Mediated Reentrant Tachycardias

The second mechanism for reentrant arrhythmia uses an accessory pathway as an essential component of the tachycardia circuit. These are known as atrioventricular reentrant tachycardias (AVRTs) and are composed of

two major subsets: WPW syndrome and concealed accessory pathways including permanent junctional reciprocating tachycardia (PJRT).

To have an accessory pathway–mediated tachycardia, four components are necessary: the atrium, the AV node, the ventricle, and the accessory pathway. Most commonly, an ectopic beat travels down the AV node and activates the ventricle, resulting in retrograde conduction up the accessory pathway to the atrium and back down the AV node (orthodromic tachycardia) (Figure 3). Although many accessory tracts have been identified, the most common is the Kent bundle, a residual fiber along the AV valve annulus, allowing electrical conduction between the atrium and the ventricle. Accessory pathway–mediated tachycardias can be distinguished by the direction of the impulse through the accessory tract during tachycardia: antidromic (from the atria to the ventricles) or orthodromic (from the ventricles to the atria) (Reference 60). Evidence of an accessory pathway can sometimes be seen on the surface ECG, with findings of a short PR interval, a slurred QRS upstroke (delta wave), and a wide QRS complex, and is considered the classic definition of the WPW pattern of ventricular preexcitation (Reference 60).

Wolff-Parkinson-White syndrome is diagnosed by the presence of preexcitation on an ECG and evidence of a supraventricular tachycardia (SVT). Accessory pathways with only retrograde conduction cannot be seen on a surface ECG and are termed *concealed accessory pathways*, which can still create a circuit for AVRT (Reference 60).

Orthodromic tachycardia, the most common form of AVRT, usually appears as a narrow QRS tachycardia (which is often difficult to distinguish from AVNRT on ECG) (Reference 60). This is because the ventricles are depolarized by the normal conduction system, and the accessory tract is conducting retrograde in tachycardia. Antidromic AVRT occurs less often, is marked by ventricular preexcitation, and is more often a wide QRS complex because of more rapid ventricular activation through the accessory pathway (Reference 60).

Most patients with SVT presenting at younger than 1 year will have some form of accessory pathway–mediated tachycardia. More than 90% will spontaneously resolve by 1 year of age (Reference 7). However, a recurrence rate of about 30% has been reported after initial resolution (Reference 61). An increased incidence of

supraventricular arrhythmias occurs in infancy and then again later in childhood, with a final peak in adolescence (Reference 61). The long-term prognosis for patients with WPW is excellent for those with structurally normal hearts, in the absence of other comorbidities (References 9, 43). However, asymptomatic pediatric patients with WPW left untreated have about a 55% chance of becoming symptomatic by age 40 (Reference 62). Evaluation of all patients with WPW is necessary to prevent long-term morbidity, including risk of atrial fibrillation and risk of developing cardiomyopathy.

Initial treatment of AVRT is similar to treatment of other supraventricular arrhythmias (vagal maneuvers and adenosine). Long-term management of AVRT often includes ablation of the accessory tract, which has been shown to be very successful and is considered the standard of care by many (References 43, 63–68).

The goals of pharmacotherapy are to break the reentrant cycle by decreasing the automaticity of the pacemaker cells, decreasing the conduction velocity, and/or increasing the refractory period. As previously described, adenosine is often used as initial pharmacologic therapy before a definitive diagnosis.

Digoxin was a mainstay of treatment in patients with AVRT and WPW for decades, and some practitioners still use it (References 69–72). Digoxin can

decrease the refractory period of the accessory pathway in WPW, and it can increase the signal transmission from the atria to the ventricles, potentially resulting in rapid ventricular conduction in patients with atrial fibrillation (Reference 73). However, some consider this primarily a risk to patients younger than 1 year because accessory pathway refractory periods are much shorter in children than in adults (Reference 71). Even though digoxin has been used effectively in pediatric patients with WPW and SVT, other agents have shown similar efficacy without the risk of ventricular arrhythmias (Reference 7).

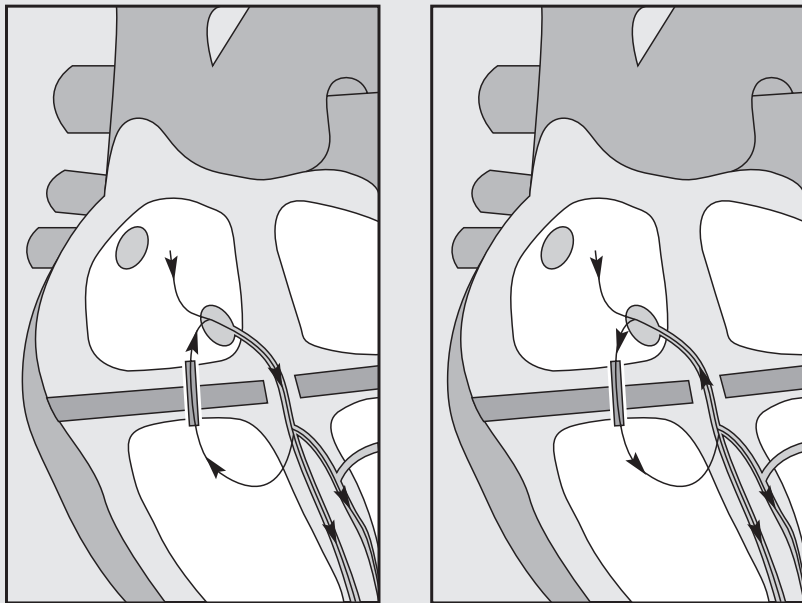

As with digoxin, verapamil use has been discouraged in the treatment of AVRT because it also decreases the refractory period of accessory pathways and can result in rapidly conducted ventricular arrhythmias (References 7, 74–77). Verapamil, particularly the intravenous formulation, is contraindicated in neonates and infants because of the risk of cardiovascular collapse.

$\beta$ -Blockers are most often considered the first-line agent for patients with AVRT (References 7, 58). Propranolol, atenolol, and nadolol have all been used with high efficacy and low adverse event profiles in pediatric patients (References 7, 53, 54, 78–80). In patients with a need for intravenous medication, such as postoperative patients, intravenous esmolol has been used

to treat supraventricular arrhythmias (References 81–87).

Traditionally, the use of class Ia agents (quinidine or, more commonly, procainamide) is a next step in patients who are not controlled with  $\beta$ -blockade (References 7, 8, 41). The intravenous form has been used in infants and neonates, but with few data on efficacy for refractory AVRT (References 72, 89, 90).

A substantial body of literature is associated with the use of class Ic agents in patients with WPW. Propafenone was initially a drug of choice for patients whose previous therapies had failed (References 27–29, 91, 92). Now, oral flecainide represents an effective option for patients with supraventricular arrhythmias and WPW because of the large body of experience with the agent (References 31, 39, 55, 93–100). Clinicians, however, are hesitant to use flecainide in patients with structural heart disease (i.e., congenital heart disease) because of the increased mortality risk identified in adult and pediatric data (References 101–103).

**Figure 3.** Accessory pathway reentrant arrhythmias.

This diagram represents orthodromic (left) and antidromic (right) reentrant tachycardia through a Kent bundle. The reentrant circuit is started when an ectopic beat conducts through the atrioventricular node.

Republished with permission from Esberger D, Jones S, Morris F. ABC of clinical electrocardiography. Junctional tachycardias. *BMJ* 2002;324:662–5.

The class III agents are often reserved for the treatment of refractory AVRT, but they can be very effective. Amiodarone has been used with high rates of success (60% to 100% complete resolution), but it has also been reported to have a high incidence of adverse events, including hypotension, QT prolongation, and proarrhythmia (References 34, 88, 104–106). Sotalol has also been used for refractory WPW with good success, but the published experience to date has been much smaller than with other agents (References 37, 38, 59, 107–109). In addition, the risk of ventricular proarrhythmia, caused by QT-interval prolongation and development of torsades de pointes (TdP), and hypotension are concerns with sotalol.

In summary, oral  $\beta$ -blockers are the typical first-line agents for the treatment of supraventricular arrhythmias in patients with WPW. Patients with refractory arrhythmias may benefit from the addition of a second agent before progressing therapy to a class III agent. Depending on the patient's age, ability to take oral medications, and underlying pathophysiology, intravenous procainamide or oral flecainide is a reasonable next step. Finally, before multiagent therapy, oral or intravenous amiodarone or sotalol may be used.

### Permanent Junctional Reciprocating Tachycardia

Although a large portion of supraventricular arrhythmias are caused by reentrant mechanisms, PJRT as a subset is relatively rare. Permanent junctional reciprocating tachycardia differs from the other reentrant tachycardias because it is characterized by an accessory pathway that exhibits only slow decremental retrograde conduction from the ventricles to the atria (Reference 60). This results in an ECG pattern of long RP tachycardia with inverted P waves in the inferior leads. Permanent junctional reciprocating tachycardia is often incessant and, if left untreated, can result in cardiomyopathy and heart failure (References 60, 110, 111). Although PJRT can spontaneously resolve, it has a high degree of morbidity caused by incessant tachycardia, which often forces practitioners to treat it (References 110–112). Depending on age, the refractory nature of the tachycardia, and ventricular function, use of ablation is often considered the standard of care for older children with PJRT (rarely in infants) (References 110, 111).

Pharmacotherapy for PJRT consists of case reports or case series because of the relative infrequency of the arrhythmia. Drugs used have included propranolol, flecainide, propafenone, sotalol, and amiodarone (References 27, 31, 59, 105, 112).  $\beta$ -Blockers alone are often ineffective. Propafenone has been used with limited success (References 26, 27). Early experience with treatment of PJRT showed success with flecainide, in which six of seven patients were successfully treated (Reference 31). Amiodarone was also used early with

limited success (about 50% resolution) (Reference 105). Multidrug therapy has also been used to treat PJRT, using flecainide and propranolol, flecainide and sotalol, or amiodarone and propranolol (Reference 112). The largest study of PJRT reported that most patients (79%) did not respond to first-line therapy and that as many as nine different pharmacotherapeutic strategies had to be tried before control was gained. The highest rate of complete or partial effectiveness (84% to 94%) occurred with either amiodarone or verapamil (alone or in combination with digoxin) (Reference 110).

Permanent junctional reciprocating tachycardia is a difficult arrhythmia to treat with antiarrhythmic medications, and few data are available to guide therapy.  $\beta$ -Blockers remain first-line therapy. However, escalation of therapy to class I, class III, class IV, or multidrug regimens is likely.

### Atrial Flutter, Atrial Fibrillation, and Intra-atrial Reentrant Tachycardia

The last three supraventricular arrhythmias are addressed together because of their shared characteristics and relative infrequency in the pediatric population. These arrhythmias are often considered “macro-reentrant” tachycardias because the entire atrium often consists of one large reentrant circuit (References 6, 113–116). Atrial flutter and atrial fibrillation are rare in neonates, infants, and children and are often found in patients with concomitant heart disease and in patients who have undergone surgical correction of congenital heart disease (References 6, 113–118). Presentation of atrial flutter in neonates typically occurs within the first 48 hours of life (Reference 116). Atrial flutter appears as a “saw-tooth” pattern on ECG, whereas atrial fibrillation is described as “irregularly irregular” (Reference 119). Intra-atrial reentrant tachycardia (IART) has also been termed *scar flutter* because it is seen in patients with a history of heart surgery. Direct current cardioversion is often used to convert patients to normal sinus rhythm (with anticoagulation possibly indicated before cardioversion) (References 6, 113–116). First-line therapy for IART is pharmacologic, but patients often require catheter ablation, placement of implantable pacemakers or cardioverters-defibrillators, or surgery (Reference 120). The use of transesophageal pacing for conversion of atrial flutter and atrial fibrillation in neonates and infants has shown success, but direct current cardioversion remains the mainstay of therapy (Reference 118). However, for older children, the presence of atrial fibrillation or IART, particularly in conjunction with congenital heart disease, is often treated with pharmacotherapy before cardioversion or in conjunction with cardioversion, depending on a patient's hemodynamic state (Reference 121).

Many agents have been used in the treatment of atrial flutter. Atrial flutter in neonates may not require pharmacotherapy, because rates of spontaneous conversion, or use of cardioversion, can resolve the arrhythmia with a low incidence of recurrence (References 113, 116, 122–124). Neonates with atrial flutter have historically been treated with digoxin, despite the low rates of success (less than 50%), and most clinicians would not treat a patient for longer than 1 year after diagnosis if there were no signs of recurrence (References 113, 116, 122, 124).  $\beta$ -Blockers, including propranolol, have often been used as a first-line agent for the treatment of neonatal atrial flutter after cardioversion (References 123, 125, 126). Other agents such as amiodarone, procainamide, quinidine, and sotalol have also been used for the treatment of neonatal atrial flutter (References 38, 113, 127–131). Treatment of atrial flutter in older infants and children has shown efficacy with the use of propafenone but poor results with the use of flecainide (References 27, 31, 32, 92). Amiodarone may be the most effective agent for the treatment of atrial flutter in infants and children, showing a 94% resolution rate (Reference 121). Sotalol has also been used, however, with lower rates of conversion than with amiodarone (References 108, 128). Overall treatment recommendations for neonates with atrial flutter include a  $\beta$ -blocker as a first-line therapy, but progression to other agents may be necessary for intractable arrhythmias. Infants and older children with atrial flutter may benefit from amiodarone, but the adverse events that can be associated with it must be weighed against the benefit gained.

Atrial fibrillation pharmacotherapy has primarily been extrapolated from adult data, because atrial fibrillation is extremely rare in children but common in adults. Digoxin has been used to slow ventricular response in atrial fibrillation with the addition of procainamide or quinidine if therapy initially fails (References 117, 132, 133). Often, progression of pharmacotherapy to sotalol or amiodarone becomes necessary (References 109, 128). Currently, the data for treatment of atrial fibrillation are sparse and likely subject to institutional bias; thus, treatment decisions should be considered on a case-by-case basis.

### Junctional Ectopic Tachycardia

Although JET is a rare supraventricular arrhythmia, the mortality and morbidity associated with JET can be as high as 35% to 40% (References 6, 22, 134–145). Junctional ectopic tachycardia is most often associated with postoperative cardiac surgical patients and patients with myocarditis (pJET) (References 6, 22, 134–142). The ECG pattern of JET can have a wide or narrow QRS complex depending on the presence of underlying bundle branch block. It classically has a QRS morphology similar to that of sinus rhythm for that particular

patient (Reference 22). Early recognition and treatment of JET is important because the tachycardia can result in profound decreases in cardiac output and lead to cardiovascular collapse, particularly in the postoperative patient (Reference 146). Patients with JET will often present in severe heart failure (Reference 147). Junctional ectopic tachycardia can be particularly difficult to treat because the tachycardia-associated decrease in cardiac output can result in increased adrenergic tone, which can subsequently further increase the junctional rate (Reference 22). Nonpharmacologic interventions for the treatment of pJET include cooling of the patient to reduce automaticity, sedation, decrease in environmental stimuli, reduction in inotropic agents, overdrive pacing, or His bundle ablation (References 22, 143–145, 148, 149). Congenital JET (cJET) typically is not as life threatening as pJET, but unlike pJET, which can resolve in 48–72 hours, cJET often requires chronic treatment (References 22, 135, 138, 142). In addition, 50% of patients with cJET have a family history of JET (Reference 22).

For pJET, intravenous amiodarone should be considered a first-line agent after nonpharmacologic intervention (References 34, 150–152). Other agents such as digoxin or propafenone have been previously used with much lower success rates (References 92, 153). Before cardiac surgery, the supplementation of magnesium and use of propranolol have both been shown to decrease the incidence of pJET (References 149, 154). The treatment of cJET with amiodarone has also shown good results, whereas the use of a  $\beta$ -blocker with or without digoxin has been fairly unsuccessful (Reference 142). Oral propafenone has shown variable results in treating cJET, yet it can still be considered an agent for initial therapy (References 28, 155, 156). Finally, sotalol has also been used for the treatment of cJET in some patients (References 107, 137). The most effective agent for the treatment of pJET or cJET at this time appears to be amiodarone.

## VENTRICULAR TACHYARRHYTHMIAS

Ventricular tachycardia (VT) and ventricular fibrillation (VF) are of great concern, particularly because of their association with sudden cardiac death in children and adolescents. This section will focus on VT and the subsequent potential progression to VF in pediatric patients.

### VT and Fibrillation

The etiologies of VT in pediatric patients are varied, and they differ considerably from typical adult etiologies. Patients with congenital heart disease, particularly patients with tetralogy of Fallot, have been noted to have a higher incidence of VT than the general pediatric

population (Reference 157). In addition, patients with cardiomyopathies, such as hypertrophic cardiomyopathy or left ventricular noncompaction syndrome, are at a very high risk of sudden death because of VT leading to VF (Reference 158). Other etiologies of VT include surgery for congenital heart disease, genetic disorders (Brugada syndrome, long QT syndrome [LQTS]), catecholamine-sensitive polymorphic tachycardia, arrhythmogenic right ventricular dysplasia, myocarditis, and electrolyte disturbances (References 6, 159, 160). Many drugs have been implicated in the development of VT, primarily caused by QT-interval prolongation and TdP, which will be addressed in a separate section. Despite the many identified pathologies for VT, the etiology is often idiopathic. The incidence of spontaneous VT has been reported to be as high as 3% in patients with no preexisting cardiac disease (References 161, 162).

Pediatric patients with VT can present with chest pain, syncope with exertion, or cardiac arrest (Reference 163). Ventricular tachycardia is defined as three or more consecutive beats originating in the ventricles, and it appears as a wide QRS complex tachycardia on ECG (References 163, 164). Long-term prognosis of pediatric patients with VT is variable and dependent on many factors. These include the etiology of VT, severity of cardiovascular compromise with VT, and patient comorbidities (Reference 165).

Treatment of patients with VT requires that their hemodynamic status be considered before therapy initiation. Patients with hemodynamic compromise caused by VT/VF are emergently treated according to Pediatric Advanced Life Support (PALS) guidelines (Reference 166). For in-depth summaries of acute pharmacologic management of VT/VF, the PALS algorithms should be consulted (Reference 166).

Patients with chronic episodes of hemodynamically stable VT are managed differently, with the focus on prevention of VT/VF by medical or pharmacologic interventions. First-line therapy for chronic management of nonsustained VT in pediatric patients is often  $\beta$ -blockers, but this has been extrapolated from adult data (Reference 167). Atenolol, metoprolol, or nadolol have been used for treatment of VT and LQTS in children, whereas propranolol has been used in infants (References 168, 169). Mexiletine has also been used for the treatment of ventricular arrhythmias in pediatric patients with congenital heart disease (References 115, 170). Pharmacotherapy for the prevention of VT/VF often depends on the underlying substrate for VT; therefore, first-line therapies should be employed on the basis of patient-specific pathophysiology. Primary therapies that have been evaluated include  $\beta$ -blockers or amiodarone (Reference 165). Disopyramide can also

be considered for patients with VT and hypertrophic obstructive cardiomyopathy as an adjunct to  $\beta$ -blockers (Reference 171).

### Torsades de Pointes

Torsades de pointes is a form of polymorphic VT that is associated with a prolonged QT interval, which was previously discussed. Torsades de pointes occurs because of prolongation of the QT interval, which can occur with various disease states, including congenital LQTS, drug-induced long QT, and other forms of acquired long QT (Reference 172). Patients with a QT interval of 450 milliseconds or greater if they are males or 460 milliseconds for females on ECG are considered to have prolonged QT interval and therefore are at risk of TdP or other ventricular arrhythmias (References 172, 173). These numbers, however, are not absolute, and a patient's entire clinical scenario should be evaluated when determining QT-interval prolongation. Electrocardiographic findings for TdP are reflective of its name: the peaks of the QRS complexes appear to "twist"—thus, the name torsades de pointes, or "twisting of the points" (Reference 164). Many medications have been implicated in causing TdP, with prolongation of the QT interval as the most common reason for the removal of medications from the market in the United States (Reference 174). A table with selected medications that cause QT-interval prolongation and that may be used in pediatric patients has been provided (Table 2).

Management strategies are 2-fold: prevention of TdP and treatment of patients with TdP. Prevention of TdP focuses on the management of congenital LQTS, maintenance of electrolyte homeostasis, and minimization of exposure to medications that can potentially prolong the QT interval. It is beyond the scope of this chapter to summarize all the information associated with congenital LQTS because the various mutations often dictate pharmacotherapy (References 175, 176). In general,  $\beta$ -blocker therapy is indicated as first-line pharmacologic therapy in patients with high-risk LQTS mutations. If the mutations for LQTS affect sodium channels, mexiletine and flecainide have shown some initial benefit in adult patients (Reference 177). Patients may occasionally require a pacemaker or an implantable cardioverter defibrillator.

Acute management of TdP requires the use of intravenous magnesium sulfate for treatment (25–50 mg/kg/dose) and subsequent removal of any medications that may be prolonging the QT interval (References 178, 179).

### BRADYARRHYTHMIAS

Two primary forms of bradyarrhythmias are most commonly seen in pediatric patients: sinus bradycardia and AV nodal block.

**Table 2.** Select Medications Responsible for QT Prolongation That May Be Used in Pediatric Patients<sup>a</sup>

Class	Medications
<p>Class 1 (highest risk)</p> <p>These drugs will prolong the QT interval and may put patients at risk of proarrhythmia, including TdP.</p>	<p>Amiodarone Chlorpromazine Clarithromycin Disopyramide Erythromycin Haloperidol Methadone Pentamidine Procainamide Quinidine Sotalol</p>
<p>Class 2 (moderate risk)</p> <p>These drugs have some reports regarding QT-interval prolongation and may induce proarrhythmia in patients, but they do not currently have sufficient evidence for causing TdP. Patients may be at risk of TdP if these medications are used with other risk factors for the development of TdP.</p>	<p>Amantadine Azithromycin Chloral hydrate Dolasetron Escitalopram Flecainide Foscarnet Fosphenytoin Granisetron Levofloxacin Nicardipine Octreotide Ondansetron Quetiapine Risperidone Tacrolimus Venlafaxine Voriconazole</p>
<p>Class 3 (low risk)</p> <p>Drugs that have weak evidence for the development of TdP and that would be unlikely to cause arrhythmia when used in normal doses in patients without other risk factors</p>	<p>Amitriptyline Ciprofloxacin Citalopram Diphenhydramine Fluconazole Fluoxetine Imipramine Itraconazole Paroxetine Ritonavir Sertraline Trazodone Trimethoprim/ sulfamethoxazole</p>

<sup>a</sup>Medications and classifications are constantly modified according to the most recent literature. For complete listings and classifications of medications, see [www.qt4drugs.org](http://www.qt4drugs.org).

TdP = torsades de pointes.

Adapted from Reference 218.

## Sinus Bradycardia

Sinus bradycardia is defined as a heart rate less than the lower limit of normal values, and it can occur in a wide variety of patient subsets, from preterm infants to well-trained athletes (References 180–187). Rarely is sinus bradycardia a cause for medical treatment unless hemodynamic instability occurs, such as in cardiogenic shock or if the patient has notable symptoms related to bradycardia. Patient presentation for bradycardia can vary on the basis of age and can include poor feeding and lack of weight gain (in neonates and infants), fatigue, exercise intolerance, and, in severe bradycardia, cardiogenic shock or seizures (Reference 185). Sinus node dysfunction, or “sick sinus syndrome,” is a common cause of sinus bradycardia. Etiologies of sinus node dysfunction include medications, excessive vagal tone, electrolyte imbalances, elevated intracranial pressure, and congenital heart disease (particularly after repair of a congenital heart lesion) (Reference 183). A genetic component to sinus node dysfunction has been identified that is associated with LQTSs (References 188, 189). Cardiac pacing is an option because pharmacotherapy for sinus bradycardia is not currently indicated. Limitation or removal of agents that can cause sinus bradycardia, or correction of preexisting patient pathophysiologies that can lead to bradycardia, is warranted (Reference 183).

## AV Nodal Block

Atrioventricular nodal block, defined as a delay in signal conduction from the atria to the ventricles, primarily involves the AV node and/or the bundles of His (Reference 183). Atrioventricular block is classified according to the degree of PR-interval prolongation and the association of P waves with QRS complexes. First-degree AV block, or PR-interval prolongation in adults, is defined as a PR interval greater than 0.2 millisecond while maintaining a 1:1 atria-to-ventricle conduction ratio. Second- and third-degree (or complete) AV block are characterized by increasing the degree of AV dissociation (Reference 183). Complete AV block has no associated conduction between atria and ventricles, and it is characterized by an atrial rate that is higher than the ventricular rate (Reference 183).

Primary modalities for treatment of higher-grade or symptomatic AV block include pacemaker insertion and correction of the underlying pathophysiology that is leading to AV block (Reference 190). Removal of offending agents, such as medications, is indicated for the treatment of AV block. Pharmacotherapy is rarely beneficial as primary treatment.

## ANTIARRHYTHMIC AGENT SELECTION

As shown throughout this chapter, many different agents can be used to treat similar arrhythmias, and single agents can be used in a wide variety of indications.

The basic pharmacology of each class will be reviewed, and salient points will be addressed regarding each of the antiarrhythmic agents discussed in the chapter that may affect decision-making when initiating pharmacotherapy. Specifically, this section will focus on dosing, drug concentration monitoring, dosage forms, and adverse events. Dosing information has been summarized (Table 1). For other information regarding antiarrhythmic drug properties, such as pharmacokinetic parameters, the reader is urged to consult a comprehensive drug reference (Reference 5).

## CLASS IA

The class Ia agents block sodium channel uptake in the fast sodium channels. In relation to other class I agents, the blockade would be considered moderate, and the resultant effects of decrease in automaticity, increase in refractory period, and decrease in conduction velocity would also be considered moderate. The QT interval can be moderately prolonged, with little to no effect on QRS duration or PR interval. Left ventricular dysfunction and hypotension with therapy have been noted (References 30, 58).

### Quinidine

Quinidine has been used to treat children with rare arrhythmias, such as the Brugada syndrome (Reference 191). Pharmacokinetic studies highlighting doses with quinidine have been performed (Reference 192). Clearance of quinidine is inversely proportional with age in pediatric patients; therefore, younger patients may require higher doses (Reference 193). A trough serum concentration of 2–7 mcg/mL is considered therapeutic for the treatment of arrhythmias (Reference 5).

However, quinidine is not used often because of the high rate of adverse events, proarrhythmia (TdP), central nervous system toxicity, and hypotension with the intravenous form (Reference 194). Quinidine is available in two different forms (gluconate and sulfate), with dosing differences between them, and requires special attention to minimize medication errors. Careful consideration should occur before the use of quinidine regarding the risk-benefit ratio. There is a formulation for an extemporaneous preparation of a suspension (Reference 195).

### Procainamide

There is a paucity of data for the dosing of procainamide in neonates, infants, and children. The dosing and monitoring strategies have been primarily extrapolated from adult literature. Intravenous dosing consists of a loading dose followed by a continuous infusion of 20–80 mcg/kg/minute, with doses to achieve therapeutic concentrations on the lower end for neonates and preterm

neonates, likely because of decreased clearance (References 90, 196). Patients with renal dysfunction or receiving renal replacement therapy have reduced clearance of procainamide and metabolites and require dosage adjustments (Reference 90).

Drug level monitoring is indicated for intravenous procainamide. Concentrations of procainamide and its active metabolite, *N*-acetyl procainamide (NAPA), are drawn after an intravenous bolus and every 12 hours during continuous-infusion therapy (Reference 5). Goal concentrations have been reported at 4–10 mcg/mL for procainamide, but they can vary depending on institutional practices (Reference 5). Procainamide therapy is usually not titrated to NAPA concentrations, but these concentrations are useful to determine whether the patient is a “fast acetylator” (a NAPA/procainamide ratio of 1:1 or greater) and will therefore need higher doses (Reference 90).

The most common adverse events associated with procainamide are hypotension, primarily with continuous-infusion administration, and proarrhythmia, such as heart block. Recent reports have documented that procainamide is associated with fewer adverse events than amiodarone, with similar efficacy in certain situations (Reference 35).

### Disopyramide

Minimal data are available for disopyramide use in pediatric patients because newer agents have been shown to be more effective at controlling arrhythmias or have fewer adverse events (Reference 171). Disopyramide dosing should be adjusted in patients with renal dysfunction (Reference 5). Serum concentrations of disopyramide can be measured, though there is no correlation with drug efficacy in pediatric patients (Reference 5). Adverse events with therapy include proarrhythmia (Reference 5). There is a formulation for an extemporaneous preparation of a suspension (Reference 5).

## CLASS IB

Medications in class Ib are considered to have the least potent sodium channel blockade, affecting the fast sodium channels in the phase 0 upstroke of the action potential. Class Ib agents decrease both automaticity and conduction velocity and increase the refractory period, but all effects are to a lesser extent compared with the other class I antiarrhythmics. There is little effect on the QRS duration, PR interval, QT interval, or left ventricular function.

### Lidocaine

Lidocaine can be given as an intravenous bolus or as continuous infusion for acute ventricular arrhythmias (Reference 5). Pharmacokinetic parameters have been described in pediatric patients with congenital heart

disease (Reference 197). Serum lidocaine concentrations can be monitored at steady state to prevent toxicity, with goal ranges reported from 1.5 to 5 mcg/mL (Reference 5). Hypotension, central nervous system toxicity, and proarrhythmia have been noted as adverse events upon bolus intravenous injection or continuous intravenous infusion (Reference 5).

### Mexiletine

A paucity of data exists for the use of mexiletine in pediatric patients for treating ventricular arrhythmias and certain types of LQTS (References 170, 198). Mexiletine is structurally similar to lidocaine, but orally active. Serum mexiletine concentrations can be monitored as trough concentrations to minimize toxicity (Reference 5). Potential adverse events include proarrhythmia and ataxia (Reference 5). There is a formulation for an extemporaneous preparation of a suspension (Reference 199).

## CLASS Ic

The phase 0 upstroke involving sodium ion channel blockade is blocked to the greatest degree by class Ic agents. Similarly, decreases in automaticity and conduction velocity and increases in refractory period are the most pronounced of all the class I agents. The PR interval, QT interval, and QRS duration are all prolonged.

### Flecainide

Dosing is controversial regarding whether dosing per kilogram or by body surface area should be used to achieve therapeutic concentrations (References 5, 31, 55). Flecainide interacts with milk; therefore, concentrations can be lower (or doses will need to be higher) in patients who are breastfeeding or receiving milk and concentrations may change when the patient's diet changes if not immediately given around a feed (References 5, 55). Sex, race, and cytochrome (CYP) P450 2D6 enzyme expression have been shown to affect flecainide disposition (References 200, 201). Flecainide is contraindicated in patients with congenital heart disease because of reports of increased mortality (Reference 101).

Flecainide concentrations can be monitored when initiating therapy and on a regular basis thereafter. Therapeutic range for treatment of arrhythmia is 0.2–1 mcg/mL drawn as a trough, but the utility of flecainide concentration monitoring on patient outcomes is unknown (Reference 5). Concentrations may not need to be measured if using low doses because the effectiveness of therapy can be monitored by QRS widening. In-hospital initiation of flecainide is usually required.

Adverse events are relatively uncommon, primarily consisting of neurologic changes and proarrhythmia (less than 1%), and they are rare when concentrations are within therapeutic ranges (References 5, 55). There is a formulation for an extemporaneous preparation of a flecainide suspension (Reference 5).

### Propafenone

Propafenone dosing is controversial regarding whether milligram-per-kilogram dosing or body surface area should be used (References 5, 27, 91). Patients who received the lower range of dosing had decreased effectiveness when undergoing treatment of WPW compared with patients who received higher doses (300–380 mg/m<sup>2</sup>/day) (Reference 58). Level monitoring is not typically used for propafenone because levels do not correlate well with ECG parameters (Reference 202). There is a formulation for an extemporaneous preparation of a suspension (Reference 203).

## CLASS II

The  $\beta$ -blockers make up the class II agents and exhibit their actions primarily on the pacemaker cell action potentials by limiting catecholamine stimulation. These effects primarily result in decreased automaticity, and they subsequently increase the effective refractory period of the Purkinje fibers. Use of  $\beta$ -blockers can acutely decrease left ventricular function and will prolong the PR interval. There is usually no effect on the QT interval or QRS duration.

### Propranolol

Standard dosing regimens for propranolol have been established, and most centers commonly use a maximum of 4 mg/kg/day (References 5, 8). Drug level monitoring for propranolol is not currently indicated.

Reported adverse events with propranolol include hypotension, bradycardia, and hypoglycemia. Caution should be used when a  $\beta$ -blocker is administered in a patient with reactive airway disease (Reference 5). Propranolol is currently available in two different concentrations of a commercially available solution: 4 mg/mL and 8 mg/mL for enteral use (Reference 5). Intravenous propranolol is also available, but with limited experience (Reference 5).

### Esmolol

Esmolol can be used as a continuous infusion for treatment of supraventricular arrhythmias or ventricular arrhythmias (Reference 5). Pharmacokinetic and dosing studies have been performed in children, and esmolol is often used when a quick onset and short

half-life of  $\beta$ -receptor blockade are beneficial (References 81, 204). Adverse events are similar to those of other  $\beta$ -blockers and consist of bradycardia and hypotension (Reference 5).

### Atenolol

Atenolol has been used for arrhythmias in children, but with less experience than other  $\beta$ -blockers such as propranolol (References 54, 168). Pharmacokinetic and pharmacodynamic studies have been performed with atenolol in children, and drug level monitoring is not currently indicated (References 54, 80, 205). Common adverse events associated with atenolol include bradycardia and hypotension (Reference 5). There is a formulation for an extemporaneous preparation of an atenolol suspension (Reference 5).

### Metoprolol

Metoprolol has not typically been used for the treatment or prevention of arrhythmias in pediatric patients; thus, there are few data to guide therapy (References 169, 206). Metoprolol is more cardio-specific in its  $\beta$ -blockade than other  $\beta$ -blockers and may have a lower incidence of bronchospasm (Reference 5). Care should be taken that patients receive the correct formulation of tablet: metoprolol tartrate or metoprolol succinate (extended release). There is a formulation for an extemporaneous preparation of a suspension (Reference 207).

### Nadolol

Pharmacokinetic studies have been performed for nadolol in children, and the authors of the study warn of using nadolol in children younger than 2 years because of wide variations in pharmacokinetic parameters (Reference 208). Common adverse events for nadolol include bradycardia and hypotension (Reference 5). No formulation for a suspension is currently available.

## CLASS III

The class III agents exhibit their antiarrhythmic effects primarily through potassium channel blockade, extending phase 4 of the action potential and increasing the refractory period. However, agents in this class often have several mechanisms of action. Sotalol has nonselective  $\beta$ -blockade effects in addition to potassium channel blocking effects. Amiodarone has sodium channel blocking effects,  $\beta$ -blocking effects, and calcium channel blocking effects. Electrocardiographic findings in patients receiving class III antiarrhythmics include prolonged PR and QT intervals and increased QRS duration. The prolongation of the QT intervals places patients at risk of TdP. Hypotension can occur, particularly with intravenous amiodarone.

### Sotalol

Sotalol dosing for neonates, infants, and children has been controversial. Currently, three dosing methods have been suggested for patients younger than 2 years (Reference 5). A dosing nomogram for patients younger than 2 years has been proposed, with reductions in dose for younger patients on the basis of body surface area (Reference 5). Other pharmacokinetic studies have been performed showing that lower doses of sotalol are effective in patients younger than 2 years but that sotalol should be dosed on a milligram-per-kilogram basis (References 209, 210). Recent data have supported dosing on body surface area, with no reduction in dose for age or renal function, with good outcomes (Reference 211). Younger patients may be more tolerant of higher doses of sotalol than older patients (Reference 30). The ideal method for dosing sotalol in this age subset is unclear. Monitoring of ECG for QT-interval prolongation is necessary when initiating or titrating therapy.

Primary adverse events associated with sotalol are arrhythmia related. Bradycardia and TdP can occur with sotalol use, and females are more likely to have TdP with sotalol compared with males (References 5, 194). Maintenance of electrolyte homeostasis (i.e., potassium) is important for preventing TdP, and frequent ECG monitoring is indicated. In-hospital initiation of sotalol is usually required.

Sotalol is available as a tablet, and there is a formulation for an extemporaneous preparation of a suspension (Reference 5). Intravenous sotalol has recently become available, though there is no pediatric experience to date with intravenous sotalol.

### Amiodarone

Amiodarone can be dosed either on body surface area or per body weight for continuous-infusion or chronic therapy (Reference 5). In the acute setting, body weight dosing is primarily used for intravenous bolus (Reference 5). Amiodarone serum concentrations can be drawn, but few data are available to interpret concentrations or their effect on antiarrhythmic efficacy (References 212, 213).

Many adverse events are associated with amiodarone therapy. Pulmonary fibrosis, thyroid toxicity, corneal deposits, hepatotoxicity, decreased growth, developmental delay, dermatologic hypersensitivity, and proarrhythmia (i.e., TdP) have all been reported with amiodarone therapy, and a baseline evaluation for potentially affected organ system function is warranted (References 214–217). Hypotension is a common adverse event after the intravenous administration of amiodarone (References 218, 219). Some centers may precede an infusion of amiodarone with an infusion of calcium to prevent hypotension. Drug interactions with amiodarone are also significant because it affects CYP enzymes and P-glycoprotein drug transport mechanisms (Reference 5).

Although an intravenous formulation of amiodarone is available, it is only compatible with a 5% dextrose solution (Reference 5). In addition, amiodarone intravenous solutions must be given through tubing that does not have bis(2-ethylhexyl)phthalate (DEHP) in the formulation because a solubility component of intravenous amiodarone (Tween 80) has been noted to leach DEHP from the tubing, potentially causing sterility in male patients (Reference 5). There is a formulation for an extemporaneous preparation of a suspension (Reference 220). Because amiodarone is highly lipid soluble, special care must be taken when preparing a suspension.

## CLASS IV

The class IV agents include the nondihydropyridine calcium channel blockers. As opposed to dihydropyridine calcium channel blockers (i.e., nifedipine), the class IV agents more specifically act on the myocardium, and pacemaker cell action potential, by blocking slow L-type calcium channels. Calcium channel blockade decreases phase 4 depolarization by increasing the refractory period of the pacemaker cell and decreasing conduction velocity in the AV node. Electrocardiographic findings include an increased PR interval. These agents can decrease left ventricular function and cause hypotension; they are not recommended for children younger than 1 year.

### Verapamil

Dosing for treatment or prevention of arrhythmias is not well established in pediatric patients, with limited pharmacokinetic studies performed to date (References 221, 222). In general, the use of verapamil in patients younger than 1 year is discouraged, despite some reports of successful use (References 223–225). Intravenous verapamil therapy for the treatment of arrhythmias in neonates and infants is discouraged because of instances of proarrhythmia, including AV block and cardiovascular collapse after administration (References 74, 77, 226). Different strategies to avoid the cardiovascular adverse effects have been tried, including administering intravenous calcium with verapamil and using slow infusion rates (Reference 227).

Verapamil is available in different extended-release formulations. Therefore, attention to dosage forms is important to minimize errors. There is a formulation for an extemporaneous preparation of a suspension (Reference 207).

### Diltiazem

Few data are available for the use of diltiazem to treat or prevent arrhythmias in pediatric patients (Reference 228). Proarrhythmic effects, including AV block and hypotension, are two primary concerns for adverse

events (Reference 5). Diltiazem is available as immediate- and extended-release formulations, and there is a formulation for an extemporaneous preparation of a suspension (Reference 229).

### Digoxin

Digoxin acts by blocking the sodium/potassium ATPase pump in the myocardium, which results in decreased conduction velocity (by decreasing the rate of transmission through the AV node) and increased refractory period. Sinus bradycardia and AV block can occur, particularly when serum digoxin concentrations are elevated.

Digoxin use in pediatric patients for the treatment of arrhythmias has a large body of literature because it has historically been first-line therapy for many types of arrhythmias (References 30, 58). Pharmacokinetic studies of children have been performed to delineate dosing (Reference 230). Digoxin toxicity can occur in patients with renal dysfunction, electrolyte imbalances, or drug interactions (Reference 231). Serum digoxin concentrations are not indicated for routine therapy because concentrations do not correlate with efficacy, but they may be useful in the assessment of digoxin toxicity (Reference 232). In addition, neonates may have false-positive results for elevated digoxin concentrations because of digoxin-like interacting substances in the blood (Reference 233). Digoxin toxicity manifests as bradycardia (including AV block), nausea and vomiting, and visual disturbances (Reference 231). Digoxin-immune Fab is used to treat symptomatic digoxin toxicity (Reference 231). Digoxin should be avoided in patients with WPW.

Precautions should be taken when administering digoxin because dosing is in micrograms, and errors have occurred when using a commercially available digoxin solution (Reference 234).

### Adenosine

Adenosine is an endogenous nucleoside that directly affects potassium currents, which depresses AV nodal function. The ECG often shows no conduction after the administration of adenosine (in reentrant arrhythmias), or depressed nodal activity, which lasts a few seconds.

Published experience with adenosine in pediatric patients is extensive (References 14, 235–240). Patients may require several doses of adenosine to achieve the desired effect. Adenosine, which has a short half-life (6–10 seconds), should be administered as a rapid intravenous push, followed by a rapid flush, through intravenous access that is closest to the heart, to ensure adequate delivery of the drug to the myocardium before metabolism (Reference 5).

Despite extensive experience with adenosine, adverse effects have been noted, including the generation of wide complex tachyarrhythmias (References 15, 241). Caution should be exercised when using

adenosine in patients with asthma because bronchospasm can occur. Only experienced personnel should administer adenosine in a setting where life-support equipment is available.

## CONCLUSIONS

The pharmacotherapy for pediatric arrhythmias can be complex and highly variable. A comprehensive knowledge of arrhythmia pathophysiology and antiarrhythmic pharmacology and the impact of pediatric growth and development is essential to ensure optimal outcomes. Future efforts to refine the pharmacotherapy for pediatric arrhythmias are warranted to minimize morbidity and maximize efficacy.

# CHAPTER 11

## PEDIATRIC HYPERTENSION

Christopher A. Thomas, Pharm.D.

### LEARNING OBJECTIVES

1. Outline the history, incidence, and epidemiology of pediatric hypertension.
2. Review the pathophysiology, including neurohormonal and humoral pathways, of pediatric hypertension.
3. Describe the clinical presentation, criteria for diagnosis, blood pressure measurement methodology, and approach to management of pediatric hypertension and hypertensive emergencies.
4. Explain the pharmacology and pediatric implications for each drug class used in the treatment of pediatric hypertension and hypertensive emergencies.

### ABBREVIATIONS IN THIS CHAPTER

ABPM	Ambulatory blood pressure measurement
ACE	Angiotensin-converting enzyme
AHA	American Heart Association
ARB	Angiotensin receptor blocker
AT	Angiotensin
BP	Blood pressure
CCB	Calcium channel blocker
DBP	Diastolic blood pressure
ESH	European Society of Hypertension
4th Report	The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents
JNC VII	The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure
RAAS	Renin-angiotensin-aldosterone system
SBP	Systolic blood pressure
SVR	Systemic vascular resistance

### INTRODUCTION

Ancient works have referred to hypertension as “hard pulse disease,” but modern medicine most simply defines it as the persistence of elevated arterial blood pressure (BP) (Reference 1). Although the incidence of pediatric hypertension is relatively low, its damaging effects may be experienced throughout all age groups. Hypertension has been linked to increased morbidity and mortality in pediatric patients since the 1960s (References 2, 3). Yet not until the late 1960s were reference BP ranges for children developed. In the past 40 years, much research has focused on the identification, definition, and treatment of hypertension in the pediatric patient (Reference 4).

Research leading to a subsequent increase in pediatric hypertension literature has afforded clinicians more evidence-based resources to manage this disease state (Reference 4). In contrast to the available adult literature, the amount of quality pediatric data is limited. Also unlike existing adult data, robust clinical trials evaluating the treatment of pediatric hypertension are scant. Many studies suggest that pediatric hypertension “tracks” into adulthood; however, data showing that the treatment of pediatric hypertension reduces or prevents this tracking phenomenon are nonexistent (References 5–9). The most recent evidence-based efforts to aid pediatric clinicians in the management of hypertension were produced by the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents in the United States in 2004 and the European Society of Hypertension (ESH) in 2009 (References 10, 11). This chapter will review pertinent aspects of these guidelines, including pathologic mechanisms, pharmacotherapy, and relevant recently published clinical literature regarding the treatment of pediatric hypertension and hypertensive emergencies.

### History

Although the adverse effects of hypertension have been known in adult arenas since 2600 BC, pediatric medicine was late to recognize or even consider childhood hypertension without suggestive signs and symptoms until the late 1960s (References 1, 12). Established pediatric BP norms were unavailable in this era because normal values for pediatric hypertension were typically borrowed from adult literature. With the simultaneous contributions of the investigators of the Muscatine

and Bogalusa Heart Studies, which began in 1971 and 1972, respectively, interest and research in pediatric hypertension and cardiovascular disease began to gain momentum (References 13, 14). These studies helped pave the way for hypertension research in children and established the importance of evaluating pediatric BP on the basis of age, sex, and height.

## EPIDEMIOLOGY

The incidence of hypertension in children and adolescents is about 1%–5% of the normal pediatric population (Reference 15). This is relatively low compared with a 28% incidence of hypertension in adults reported in 2006 (Reference 16). With evidence suggesting that youths with high BP are more likely to be hypertensive adults, diagnostic screening, preventive measures, and pharmacologic treatment of hypertension in children with the goal of minimizing potential long-term deleterious effects have been deemed of great importance by many expert clinicians (References 5–10).

## Pathophysiology of Pediatric Hypertension

Cardiovascular function is regulated by a complex cascade of neurohormonal mechanisms that influence hemodynamics. Neural mechanisms include sympathetic tone, the baroreflex system, and cardiopulmonary reflex. Humoral regulation occurs through the renin-angiotensin-aldosterone system (RAAS), endothelial vasoactive factors, glucocorticoids, arginine vasopressin, and natriuretic peptides (References 17–21). Although many pathways exist, not one has proved to be the sole cause of essential pediatric hypertension. For this reason, many pharmacologic agents have been developed to address potential underlying imbalances in hemodynamic regulation mechanisms.

## Neural Regulation

The central nervous system (CNS) plays an essential role in the regulation of BP by allocating autonomic tone to various areas of the cardiovascular system through receptors that detect pressure changes in the vasculature and changes in the chemical composition of the blood. These  $\alpha$ - and  $\beta$ -receptors reside on the pre- and postsynaptic surfaces of sympathetic terminals and regulate norepinephrine release (References 18, 19, 22). Stimulation of central  $\alpha_2$ -receptors inhibits the release of norepinephrine, whereas activation of central  $\beta$ -receptors has the opposite effect (References 18, 19, 22). The response seen on arterioles and venules because of peripheral  $\alpha_1$ -receptor activation is vasoconstriction (References 18, 19).  $\beta_1$ -Receptors are very densely dispersed within the heart, and  $\beta_2$ -receptors are present in

abundance within the lungs as well as the arterioles and venules.  $\beta_1$ -Activation produces an increase in heart rate and contractility, and  $\beta_2$ -activation causes vasodilation (References 18, 19).

The negative feedback mechanism regulating sympathetic tone and ultimately short-term BP control is called the baroreflex system (Reference 19). Receptors designed to detect changes in arterial BP are mainly located in the aorta and carotid arteries (References 18, 19). Other baroreceptors are located in the afferent arterioles of the kidneys, but their main role is involved in renin release (Reference 20). Increased baroreceptor activity occurs because of an acute intravascular pressure elevation that results in decreased heart rate and contractility in addition to peripheral vasodilation (References 18, 19). This effect is illustrated by the use of carotid massage to treat supraventricular tachycardia. By manually palpating the carotid artery, this nonpharmacologic intervention attempts to increase vagal tone by mimicking increased arterial pressure. An acute BP decrease has the opposite baroreceptor effect, causing vasoconstriction and an increase in heart rate and contractile force because of decreased baroreceptor activity. As children age, their physiologic normal BP increases with increasing body size (Reference 17). Baroreceptors subsequently adjust to changing BP norms as children age to help maintain safe hemodynamic control (Reference 17).

## Humoral Regulation

Together with neural regulation, many humoral mechanisms contribute to the maintenance of cardiovascular function and homeostasis. Alterations in any or all of these mechanisms may lead to the pathologic development of hemodynamic abnormalities.

The RAAS is primarily regulated by the kidney's effect on electrolyte and fluid balance, sympathetic tone, vascular smooth muscle tone, and BP. In humans, angiotensin-converting enzyme (ACE) activity leads to increased production of angiotensin (AT) II, decreased bradykinin concentrations, sympathetic norepinephrine release, and aldosterone release. Inhibition of this pathway by ACE inhibitors such as captopril causes vasodilation, decreased afterload, increased cardiac output, and mild diuresis (References 20, 21, 23). In the first months of life, it is crucial to consider the differences existing in the RAAS. Plasma renin activity and subsequent AT II concentrations in newborns and infants are very high (Reference 23). This difference may cause significant hypotension in neonates if caution is not observed in dose initiation and titration of ACE inhibitors.

Other pharmacologic RAAS targets for antihypertensive effects in pediatric patients include AT-receptors (Reference 24). The pediatric AT<sub>1</sub>-receptor regulates the function of the cardiovascular system, but the AT<sub>2</sub>-receptor has no important role in cardiovascular homeostasis (Reference 24). Because the activation of AT<sub>1</sub>-receptors produces direct arterial vasoconstriction, increased sympathetic tone, and aldosterone release, angiotensin receptor blockers (ARBs) are also used in children to combat hypertension.

## ASSESSMENT OF PEDIATRIC BP

Together with a thorough knowledge of the physiologic mechanisms behind hemodynamic homeostasis in children, it is important to understand how to assess BP in pediatric patients. In this section, the differences between primary and secondary hypertension will be reviewed, together with appropriate pediatric BP measurement techniques, diagnostic criteria for pediatric hypertension, and normal physiologic BP ranges in infants, children, and adolescents.

### BP Measurement

The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents (4th Report) has recommended a methodology for measuring BP in children, which is listed in Box 1 (Reference 10). The 4th Report urges clinicians to begin routine BP measurements at 3 years of age because of the difficulty measuring BP in younger children. Neonates, infants, and toddlers can certainly develop hypertension, so care should be taken to routinely evaluate BP in children younger than 3 years if they have certain comorbid diseases as defined in the 4th Report (Reference 10). Examples include neonatal complications requiring intensive care, congenital heart disease, and kidney disease (Reference 10). For

all patients, special consideration should be focused on investigating the presence of preexisting circumstances that may cause BP elevation at measurement. For example, an infant who is crying during measurement may have a falsely elevated BP compared with BP at rest. To aid the clinician in recognizing the pharmacologic causes of hypertension, a brief list highlighting common childhood and adolescent prescriptions, over-the-counter drugs, food, and supplements that can elevate BP are listed in Table 1 (References 25–27).

Blood pressure in pediatric patients should be measured by placing the stethoscope over the brachial artery (proximal and medial to the antecubital fossa) and just below the bottom edge of the BP cuff (References 28, 29). For pediatric patients, special attention should be placed on selecting the appropriate cuff size (References 28, 29). The American Heart Association (AHA) recommends selecting a cuff with a bladder that will cover 80% to 100% of the patient's arm circumference (References 28, 29). Children with large arms are recommended to use small, standard, or large adult cuffs and, if necessary, a thigh cuff (Reference 29). The importance of using the appropriate-sized cuff when measuring pediatric BP is paramount because using an incorrect size may provide false readings (Reference 29). Smaller cuffs tend to yield falsely high measurements, whereas larger cuffs underestimate BP (References 30, 31). It is recommended that infants and neonates (or patients with faint Korotkoff sounds) have an indirect BP measurement with an ultrasonic flow detector (Reference 32).

### Diagnosis of Pediatric Hypertension

The 4th Report defines normal and abnormal pediatric BP values in percentiles with reference to age, sex, and height (Reference 10). The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII) does not refer to specific patient characteristics,

#### Box 1. Methodology for pediatric BP measurement.

- Measure BP in patients > 3 years at each health care visit, < 3 years if certain conditions met.
- Auscultation preferred (normal BP values based on auscultation)
- Choose appropriate cuff size.
- Avoid stimulants (drugs or food) before measurement.
- Rest quietly for at least 5 minutes before measurement.
- Use right arm, seated position, back supported, feet resting on floor (supine position for infants).
- High blood pressure must be remeasured and confirmed on repeat visits to diagnose hypertension.
- BP > 90th percentile as measured by oscillometric technique must be confirmed by auscultation method.

Information from References 10 and 11.  
BP = blood pressure.

but simply defines hypertension in adults as 140/90 mm Hg or greater (Reference 33). The JNC VII adult definitions of hypertension are based on known risk factors for cardiovascular disease (Reference 33). The strategy of using static systolic blood pressure (SBP) and diastolic blood pressure (DBP) measurements, as with adults, is inappropriate in children for two reasons. First, pediatric evidence linking hypertension to increased risk of cardiovascular disease is lacking. Second, because normal BP values change as children grow, clinicians must rely on data that compare pediatric BP values with those of their pediatric peers (References 10, 34). Population-based normal BP values (represented in percentiles) for children 1 year of age or older, grouped by age, sex, and height, have been published previously in the 4th Report and by the ESH (References 10, 11). These guidelines should be reviewed by any clinician involved in the diagnosis, evaluation, and treatment of childhood hypertension (References 10, 11). The ESH embraces the same principles regarding BP norms based on patient demographics, but of note, the normal values listed by the 4th Report are slightly lower than the European values across each demographic category (References 10, 11). Thus, it is recommended that U.S. clinicians follow the 4th Report BP values when diagnosing and treating hypertension, whereas Europeans should follow the ESH report. Guidelines for normal BP values in newborns and infants can be found in the Report of the Second Task Force on Blood Pressure

Control in Children (Reference 34). Definitions of varying severities of hypertension in children and adolescents based on percentiles for age, sex, and height are listed in Table 2 (Reference 10).

### Ambulatory Blood Pressure Measurement

Ambulatory blood pressure measurement (ABPM) recently gained acceptance in the essential diagnosis and treatment of hypertension in pediatric patients (Reference 11). It is most simply defined as the repeated measurement of BP in the outpatient setting while the patient is participating in normal daily living activities, including sleep (Reference 35). Pediatric patients may have dramatically different BP readings in a physician's office compared with BP readings in everyday ambulatory settings. Such patients meet the defining criteria for white-coat hypertension. However, pediatric patients who are normotensive in the office and hypertensive outside are considered to have masked hypertension. Techniques such as ABPM may reveal the presence of either diagnosis (Reference 11). According to the ESH and the AHA, ABPM is effective in detecting white-coat hypertension, masked hypertension, and differences in nocturnal BP as well as in differentiating between primary and secondary hypertension in pediatric patients (References 11, 35). The ESH recommends 24-hour ABPM to confirm or disprove suspected hypertension in patients with certain comorbidities such as diabetes, renal disease, or solid-organ

**Table 2.** Classification of Hypertension in Children and Adolescents, with Measurement Frequency and Therapy Recommendations

Classification	SBP or DBP Percentile*	Frequency of BP Measurement	Therapeutic Lifestyle Changes	Pharmacologic Therapy
Normal	<90 <sup>th</sup>	Recheck at next scheduled physical examination	Encourage healthy diet, sleep, and physical activity	—
Prehypertension	90 <sup>th</sup> to <95 <sup>th</sup> or if BP exceeds 120/80 even if <90 <sup>th</sup> percentile up to <95 <sup>th</sup> percentile**	Recheck in 6 months	Weight-management counseling if overweight; introduce physical activity and diet management***	None unless compelling indications such as chronic kidney disease, diabetes mellitus, heart failure, or left ventricular hypertrophy exist
Stage I Hypertension	95 <sup>th</sup> -99 <sup>th</sup> percentile plus 5 mmHg	Recheck in 1–2 weeks or sooner if the patient is symptomatic; if persistently elevated on two additional occasions, evaluate or refer to source of care within 1 month	Weight-management counseling if overweight; introduce physical activity and diet management***	Initiate therapy based on clinical indications or other compelling indications (as shown above) exist
Stage II Hypertension	>99 <sup>th</sup> percentile plus 5 mmHg	Evaluate or refer to source of care within 1 week or immediately if the patient is symptomatic	Weight-management counseling if overweight; introduce physical activity and diet management***	Initiate therapy****

\*For sex, age, and height measured on at least three separate occasions; if systolic and diastolic categories are different, categorize by the higher value.

\*\*This occurs typically at 12 years old for SBP and at 16 years old for DBP.

\*\*\*Parents and children trying to modify the eating plan to the Dietary Approaches to Stop Hypertension Study eating plan could benefit from consultation with a registered or licensed nutritionist to get them started.

\*\*\*\*More than one drug may be required.

BP = blood pressure; DBP = diastolic blood pressure; SBP = systolic blood pressure.

transplantation and in patients undergoing treatment of refractory hypertension (Reference 11). Complementary to the ESH recommendations, the AHA recently released an official scientific statement regarding the use of ABPM in pediatric patients to guide the diagnosis and treatment of hypertension (Reference 35). In addition, the AHA has published recommended indications for ABPM use in pediatric patients (Box 2), together with normal pediatric ABPM values for girls and boys stratified by age (5–16 years only) and height (120–175 cm only) (Reference 35).

**Box 2.** Indications for ambulatory blood pressure measurement.

- Confirm the diagnosis of hypertension.
- Assess blood pressure variability.
- Evaluate pharmacologic therapy effectiveness.
- More accurately evaluate blood pressure in chronic disease states.

## Clinical Presentation

Children with hypertension may have varying underlying etiologies upon presentation, categorized as primary (essential) or secondary hypertension. Primary hypertension is defined as hypertension without a known cause, whereas secondary hypertension can be directly linked to a known underlying disorder (e.g., coarctation of the aorta) (Reference 10). Although primary hypertension is the most common form of hypertension in adults, the incidence of secondary hypertension in pediatric patients highly outweighs that of primary hypertension (Reference 10). The differences between primary and secondary hypertension in pediatric patients will be described in this section.

## Primary Hypertension

Although primary hypertension is relatively uncommon with respect to the distribution of hypertension in pediatric patients as a whole, more attention has been drawn to primary hypertension in children and adolescents because pediatric hypertension may track into adulthood (References 5–9). The concept of tracking when referring to hypertension is illustrated by the likelihood that children who develop hypertension are more likely to be hypertensive in their adult years, thus potentially increasing future risks of individually developing serious cardiovascular disease (References 5–10). The incidence of primary hypertension has been recognized as being on the rise in children, which explains the 4th Report's recommendation for clinicians to increase the frequency of BP screening early in life (Reference 10). Because essential hypertension does not present with obvious clinical signs and symptoms, the disease has the potential to be undiagnosed for months to years and is known as a "silent killer."

## Secondary Hypertension

Unlike primary hypertension, elevated BP in children is typically associated with a directly related underlying disorder. The most common etiologies of childhood hypertension occur secondary to renal/urological diseases or coarctation of the aorta (Reference 36). An underlying etiology should be ruled out for every hypertensive patient, especially when very young children, youths with stage II hypertension, or children with severe hypertension and clinical signs of end-organ damage (hypertensive emergencies) present with a confirmed diagnosis of hypertension (Reference 10). A comprehensive list of etiologies of pediatric hypertension is shown in Table 3 (Reference 37).

When ruling out secondary hypertension in children, the 4th Report recommends checking BP in both arms as well as one leg (Reference 10). The rationale is to confirm previously measured hypertensive states and potentially detect vascular abnormalities such as

coarctation of the aorta (Reference 38). Children with coarctation will have decreased lower extremity BP, compared with arm measurements, because of impaired blood flow to the legs (Reference 38). In addition to impaired lower extremity blood flow, the BP measured in the left arm may be lower than that in the right arm if the coarctation is proximal to the left subclavian artery (Reference 39). Although expert recommendations guide clinicians to measure two upper extremity BPs followed by one measurement in the legs, many clinicians recommend one upper extremity reading and one lower measurement, especially in younger children, to prevent falsely high measurements caused by discomfort and agitation from repeated BP measurements.

## MANAGEMENT OF PEDIATRIC HYPERTENSION

### Therapeutic Goals

The goals of therapeutic management are highly dependent on the clinical presentation and severity of hypertension. For example, BP reduction is needed much more urgently in a patient who presents with hypertensive crisis compared with a patient with stage I essential hypertension. This section will review goals of antihypertensive therapies as well as appropriate management strategies of pediatric hypertension, including lifestyle modifications and pharmacologic therapy.

### Lifestyle Modifications

Lifestyle modifications to treat pediatric hypertension include exercise, weight loss, and stress reduction. The goal of using such lifestyle modifications to treat pediatric hypertension is to lower BP within an acceptable range without the use of medications. When lifestyle modifications do not achieve this goal or when medication is required as a first-line treatment option, lifestyle modifications should be combined with pharmacotherapy. Exercise is a recommended nonpharmacologic therapy for children and adolescents with essential hypertension and may be used as primary or adjunctive treatment (Reference 10). The AHA currently recommends that children 2 years or older participate in at least 60 minutes of developmentally appropriate, moderate-intensity physical activity each day of the week (Reference 40). Many studies have shown that exercise programs lower both SBP and DBP in children (References 41–45). The common factor shown to reduce BP is aerobic exercise, whereas resistance training alone has not had a therapeutic effect (References 41–45). The discontinuation of aerobic activity results in the return of BP to pre-exercise values, so continued commitment to an exercise routine is recommended (References 41–44).

**Table 3. Common Causes of Pediatric Hypertension**

Neonates (0–30 days)	Infant to 6 Years	6–10 Years	10 Years to Adolescence

Information from Reference 37, with permission.

In addition to exercise, weight loss is an essential life-style modification to use when obesity and hypertension coexist (Reference 46). Not only does weight reduction have a BP-lowering effect, but it also minimizes other cardiovascular risk factors such as dyslipidemia and insulin resistance (Reference 10). Diet is an essential part of an adequate weight-loss program, especially in hypertensive patients (References 10, 47). Salt restriction and other healthy eating habits are recommended for hypertensive adults and children alike (Reference 47). Because excess sodium intake is directly related to hypertension, the AHA has developed maximum daily sodium intake

recommendations (Table 4) for pediatric patients to curb sodium overindulgence (Reference 48).

Together with exercise and weight loss, stress reduction may be a key nonpharmacologic intervention to help reduce BP because it has been identified as an environmental factor that may lead to the development of essential hypertension (Reference 37). Although concrete recommendations do not exist regarding the modality in which stress should be reduced in children to prevent or reduce high BP, stress reduction is still thought of as an important potential intervention in pediatric patients (Reference 10).

## Approach to Pharmacologic Therapy

Because of the potential cardiovascular consequences of prolonged hypertension and the tracking phenomenon of BP into adulthood, BP reduction in children with hypertension is now regarded as an important therapeutic goal to prevent complications associated with the disease (Reference 10). The 4th Report clearly defines the indications for pharmacologic treatment of hypertension in children as the following clinical cases: symptomatic hypertension, secondary hypertension, hypertensive target-organ damage, failure of non-pharmacologic BP reduction measures, and type 1 and 2 diabetes mellitus (Reference 10). The goals of pharmacologic therapy differ depending on the severity of hypertension and the coexistence of other risk factors and comorbidities. The 4th Report defines BP reduction goals with specific indications, listed in Table 5 (Reference 10). Although adult studies typically aim to reveal differences in morbidity and mortality between treatment groups through long-term follow-up studies, similar high-quality treatment data are unavailable in pediatric patients. Because clinical trials linking improved outcomes to specific antihypertensive agents are nonexistent in pediatric patients, adult data may be extrapolated to this patient population to guide treatment.

Initiation of an antihypertensive agent in a pediatric patient typically follows a stepwise pattern. The recommended strategy for treating pediatric hypertension is to start with low doses and titrate upward slowly on the basis of achieved goal BP (Table 5) and tolerability of the drug (Reference 10). Drug titration should be halted or another agent should be considered for primary or adjunct therapy when the highest recommended dose is reached (Reference 10). When adverse effects develop, medication doses may need to be reduced or discontinued altogether, and another agent may need to be considered (Reference 10). Table 6 provides a comprehensive list of medication doses, including typical pediatric dosing ranges and considerations for antihypertensive agents.

## Pharmacologic Therapy

Antihypertensive drug classes used in children consist of ACE inhibitors, ARBs, calcium channel blockers (CCBs), diuretics (loop, thiazide, and potassium-sparing diuretics),  $\beta$ -adrenergic receptor antagonists, centrally acting sympatholytic agents, peripheral adrenergic antagonists, and direct-acting vasodilators. Although adult prescribing patterns typically aim to lower morbidity and mortality by following evidence-based guidelines, such data are unavailable to guide therapy in children. Therefore, the treatment goal for hypertension in children is simply to lower BP within the range of BP norms for age, sex, and height while limiting adverse events.

**Table 4.** Maximum Daily Recommended Sodium Intake

Age (years)	Sodium (mg)
1–3	1500
4–8	1900
9–13	2200
14–18	2300

**Table 5.** Blood Pressure Treatment Goals

Comorbidities	Blood Pressure Reduction Goal
Uncomplicated, primary, no target organ damage	< 95th percentile
Chronic renal disease, diabetes, or hypertensive target organ damage	< 90th percentile

Information from Reference 10.

## ACE Inhibitors

### Mechanism/Use

The therapeutic effect of ACE inhibitors in children is achieved by inhibiting the conversion of AT I to AT II, a potent vasoconstrictor (Reference 49). Because AT II facilitates sympathetic activity, ACE inhibitors reduce BP by decreasing systemic vascular resistance (SVR) (Reference 49). In addition, because AT II promotes aldosterone and antidiuretic hormone release while causing vasoconstriction of the efferent arterioles of the kidney, ACE inhibitors decrease intravascular volume by promoting diuresis and natriuresis (Reference 49). Angiotensin-converting enzyme inhibitors also prolong the half-life of the vasodilator bradykinin by inhibiting its metabolism (Reference 49). Although ACE inhibitors have been shown to prevent the cardiac and vascular remodeling associated with chronic hypertension and heart failure in adults, their use for this purpose currently can only be extrapolated to children because pediatric clinical data are unavailable.

### Pediatric Pharmacokinetics

Captopril is probably one of the most widely used ACE inhibitors in children because of its short half-life, making it an easily titratable drug. This property also enhances safety to the patient and security to the clinician when initiating the drug because its BP-lowering effects will be short-lived if hypotension occurs. This is important to consider in children, especially infants and neonates, because ACE inhibitor-induced hypotension is more likely to be seen in this age group (Reference 37). Risks of hypotension in this patient population must be respected; thus, low initial doses and slow upward

**Table 6.** Medications Used in Pediatric Hypertension<sup>a</sup>

Class	Drug	Dose	Interval	Liquid Preparation Available?	Adverse Effects	Removed by Dialysis?	Adjustment for Organ Dysfunction	Notes
ACE inhibitor	Captopril	Initial: Preterm neonates: 0.01 mg/kg/dose < 6 months: 0.1 mg/kg/dose ≥ 6 months: 0.3–0.5 mg/kg/dose Max: 6 mg/kg/day	TID	Yes	Angioedema Cough Dysgeusia Hyperkalemia	C - Yes HPD - Likely PD - No	Renal	Neonates and infants may need lower initial doses and require slow titration. <sup>b</sup> Contraindicated in pregnancy <sup>b</sup>
	Enalapril	Initial: 0.08 mg/kg/day up to 5 mg Max: 0.6 mg/kg/day up to 40 mg	Daily– BID	Yes	Neutropenia Orthostatic hypotension Rash	C - Yes HPD - Likely PD - Yes	Renal	Avoid in patients with bilateral renal artery stenosis. <sup>b</sup> Monitor serum potassium and creatinine periodically. <sup>b</sup>
	Lisinopril	Initial: 0.07 mg/kg/day up to 5 mg Max: 0.6 mg/kg/day up to 40 mg	Daily	Yes		C - Yes HPD - Likely PD - ND	Renal	Incidence of cough is very low in pediatric patients. <sup>b</sup>
ARB	Irbesartan	6–12 years: 75–150 mg/day ≥ 13 years: 150–300 mg/day	Daily	No	Cough Hyperkalemia Orthostatic hypotension	C - No HPD - ND PD - ND	No - Caution in renal impairment	Monitor serum potassium and creatinine periodically. <sup>b</sup> Contraindicated in pregnancy <sup>b</sup>
	Losartan	Initial: 0.7 mg/kg/day up to 50 mg Max: 1.4 mg/kg/day up to 100 mg	Daily	Yes		C - No HPD - No PD - No	Not recommended in severe renal or hepatic impairment	Incidence of cough is very low in pediatric patients. <sup>b</sup> Use close blood pressure monitoring to guide adjustment for renal or hepatic dysfunction. Not recommended in children if creatinine clearance is ≤ 30 mL/minute <sup>b</sup>
	Olmesartan	1–5 years and ≥ 5 kg: 0.3 mg/kg/day Max: 0.6 mg/kg/day 20 to < 35 kg: 10 mg/day up to 20 mg ≥ 35 kg: 20 mg/day up to 40 mg	Daily	Yes		C - No HPD - No PD - Unlikely	No	Use of valsartan in children younger than 6 years is not recommended. <sup>b</sup>
	Valsartan	6–16 years: 1.3 mg/kg/day up to 40 mg/day Max: 2.7 mg/kg/day up to 160 mg/day	Daily	Yes		C - No HPD - ND PD - Unlikely	Renal Use caution in hepatic impairment.	Valsartan oral suspension has increased bioavailability compared with tablet formulation. <sup>b</sup>
α- and β-antagonists	Labetalol	Initial: 1–3 mg/kg/day Max: 10–12 mg/kg/day up to 1,200 mg	BID	Yes	Bradycardia Bronchospasm Hyperkalemia	C - No HPD - ND PD - No	Potential reduction needed in hepatic impairment	

(Continued)

**Table 6.** Medications Used in Pediatric Hypertension<sup>a</sup> (Continued)

Class	Drug	Dose	Interval	Liquid Preparation Available?	Adverse Effects	Removed by Dialysis?	Adjustment for Organ Dysfunction	Notes
β-Antagonist	Atenolol	Initial: 0.5–1 mg/kg/day Max: 2 mg/kg/day up to 100 mg	Daily– BID	Yes	Bradycardia Bronchospasm Drowsiness	C - Yes HPD - Likely PD - No	Renal	Use caution in children with diabetes because β-blockers prevent signs and symptoms of hypoglycemia. <sup>b</sup>
	Metoprolol	Initial: 1–2 mg/kg/day Max: 6 mg/kg/day up to 200 mg	BID	Yes	Exercise intolerance Fatigue Heart block Hypoglycemia	C - Yes HPD - Likely PD - ND	Potential reduction needed in hepatic impairment	Hypoglycemia caused by β <sub>1</sub> -blockade, which inhibits glycogenolysis in the liver and glucagon release from the pancreas. <sup>b</sup>
	Propranolol	Initial: 0.5–2 mg/kg/day Max: 4 mg/kg/day up to 640 mg	BID– four times/ day	Yes <sup>c</sup>	Lethargy	C - No HPD - Unlikely PD - No	Potential reduction needed in hepatic impairment	Use caution in children with asthma with nonselective agents, although not an absolute contraindication. <sup>b</sup>
CCBs	Amlodipine	1–5 years: 0.05–0.1 mg/kg/day 6–17 years: 2.5–5 mg/day	Daily– BID	Yes	Constipation Dizziness Flushing Palpitations	C - No HPD - Unlikely PD - No	No - Monitor closely in hepatic impairment.	Propranolol is the most lipophilic and has the highest propensity to cause CNS-related adverse effects. <sup>b</sup>
	Felodipine	Initial: 2.5 mg/day Max: 10 mg/day	Daily	No	Tachycardia	C - No HPD - Unlikely PD - Unlikely	No - Monitor closely in hepatic impairment.	Felodipine and nifedipine (extended release only) cannot be crushed or chewed. <sup>b</sup>
	Isradipine	Initial: 0.15–0.2 mg/kg/day Max: 0.8 mg/kg/day up to 20 mg/day	TID– four times/ day	Yes		C - No HPD - Unlikely PD - No	No - Monitor closely in hepatic or renal impairment.	
	Nifedipine (extended release)	Initial: 0.25–0.5 mg/kg/day Max: 3 mg/kg/day up to 180 mg/day	Daily– BID	No		C - No HPD - Unlikely PD - No	Potential reduction needed in hepatic impairment	

Class	Drug	Dose	Interval	Liquid Preparation Available?	Adverse Effects	Removed by Dialysis?	Adjustment for Organ Dysfunction	Notes
Central $\alpha$ -agonist	Clonidine	Initial: 5–10 mcg/kg/day Max: 25 mcg/kg/day OR 0.9 mg/day	BID–TID	Yes	Bradycardia Constipation Drowsiness	C - No HPD - ND PD - No	Renal	Transdermal dose is equivalent to total daily oral dose. Patches should not be cut. <sup>b</sup>
	Guanfacine	$\geq 12$ years: 1 mg Max: 2 mg	QHS		Dry mouth Orthostatic hypotension Rebound hypertension Sedation	C - No HPD - ND PD - No	Use with caution in renal or hepatic impairment.  Renal	Should not be abruptly discontinued because of risks of rebound hypertension. <sup>b</sup>
	Methyl dopa	Initial: 2.5 mg/kg/dose Max: 65 mg/kg/day OR 3 g/day	BID–four times/day	Yes		C - Yes HPD - Likely PD - Yes		
Direct renin inhibitor	Aliskiren	Initial: 1.7–2 mg/kg/day Max: 4–4.2 mg/kg/day up to 300 mg	Daily	No	Angioedema Diarrhea Dizziness Headache Hyperkalemia	C - ND HPD - ND PD - ND	No - Use with caution in renal impairment.	Contraindicated in pregnancy <sup>b</sup> Contraindicated in adult patients with diabetes or moderate to severe renal impairment while taking ACE inhibitors or ARBs <sup>b</sup>
								Reported only in a case series of four patients with chronic kidney disease and in a survey of 10 patients aged 4–17 years. <sup>b</sup> Studies are currently enrolling patients, but safety and efficacy data are not known. Use caution when using in pediatric patients. <sup>b</sup>
<b>Diuretics</b>								
Loop	Furosemide	Initial: 0.5–2 mg/kg/dose Max: 6 mg/kg/dose	Daily–four times/day	Yes <sup>c</sup>	Hypocalcemia Hypochloremic metabolic alkalosis Hypokalemia Hypomagnesemia Hypovolemia Orototoxicity	C - No HPD - Unlikely PD - Unlikely	No	Risk and severity of ototoxicity are directly related to high doses. <sup>b</sup>
	HCTZ	Initial: 1 mg/kg/day Max: 3 mg/kg/day up to 50 mg	Daily	Yes	Dyslipidemia Hypochloremic metabolic alkalosis Hypokalemia Hypomagnesemia Hyponatremia Hypovolemia Hyperuricemia	C - No HPD - ND PD - Unlikely	No	Mechanism behind dyslipidemia and hyperglycemia remains unclear. <sup>b</sup> May be ineffective in patients with poor renal function. <sup>b</sup>

**Table 6.** Medications Used in Pediatric Hypertension<sup>a</sup> (Continued)

Class	Drug	Dose	Interval	Liquid Preparation Available?	Adverse Effects	Removed by Dialysis?	Adjustment for Organ Dysfunction	Notes
K <sup>+</sup> sparing	Amloride	Initial: 0.4–0.625 mg/kg/day up to 20 mg	Daily	Yes	Gynecomastia (only spironolactone) Hyperkalemia	C - ND HPD - ND PD - ND	Renal	Avoid use in patients with severe renal dysfunction. <sup>b</sup>
	Spironolactone	Initial: 1 mg/kg/day Max: 3.3 mg/kg/day up to 100 mg	Daily– BID	Yes	Metabolic acidosis	C - Unlikely HPD - ND PD - Unlikely	Renal	
	Triamterene	Initial: 1–2 mg/kg/day Max: 3–4 mg/kg/day up to 300 mg	BID	No		C - ND HPD - ND PD - ND	Renal	
Peripheral α-antagonist	Doxazosin	Initial: 1 mg/day Max: 4 mg/day	Daily	No	Dizziness Drowsiness Fatigue	C - No HPD - ND PD - No	Use with caution in hepatic impairment.	Usually not first-line agents — usually used in resistant hypertension <sup>b</sup>
	Prazosin	Initial: 0.05–0.1 mg/kg/day Max: 0.5 mg/kg/day	TID	Yes	Headache Muscle weakness Orthostatic hypotension	C - No HPD - Unlikely PD - No	No	
	Terazosin	Initial: 1 mg/day Max: 20 mg/day	Daily	No		C - No HPD - Unlikely PD - No	No	
	Hydralazine	Initial: 0.75 mg/kg/day Max: 7.5 mg/kg/day up to 200 mg	Four times/day	Yes	Dizziness Hypertrichosis (minoxidil only)	C - No HPD - ND PD - No	Renal	Usually not first-line agents — usually used in resistant hypertension or in hypertensive crisis <sup>b</sup>
Vasodilator	Minoxidil	Initial: 0.04–0.07 mg/kg/dose Max: 50–100 mg/dose	Daily– TID	Yes	Orthostatic hypotension Sodium and water retention RAAS activation Reflex tachycardia Vivid dreams	C - Yes HPD - Likely PD - Yes	No	Hydralazine may cause rebound hypertension by RAAS activation. <sup>b</sup>

<sup>a</sup>All agents may cause hypotension.

<sup>b</sup>Information from References 10, 37, 49–59, 65, 68, 69, 75, 79–95, 111–119.

<sup>c</sup>Compound is commercially available.

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; BID = twice daily; C = conventional hemodialysis (KUf ≤ 8 mL/hour/mm Hg); CCB = calcium channel blocker; CNS = central nervous system; HCTZ = hydrochlorothiazide; HPD = high permeability dialysis (KUf > 8 mL/hour/mm Hg); Max = maximum; ND = no data available; PD = peritoneal dialysis; QHS = every night; RAAS = renin-angiotensin-aldosterone system; TID = three times/day.

titration are recommended to avoid these risks, particularly in neonates and infants. For unknown reasons, neonates and infants have an increased sensitivity to ACE inhibitors. Proposed mechanisms include, but are not limited to, higher renin concentrations, developing kidneys, and decreased hepatic drug metabolism in this age group (Reference 37). Angiotensin-converting enzyme inhibitors with longer half-lives, such as enalapril and lisinopril, are also used in children (Reference 37). Advantages include increased adherence and improved quality of life with once- or twice-daily administration.

Both captopril and enalapril are extensively metabolized and excreted into the urine (Reference 49). Enalapril, which is actually a prodrug, must be metabolized by the liver to its active form, enalaprilat, before it exhibits antihypertensive effects (Reference 49). Lisinopril is not hepatically metabolized and is primarily excreted in the urine as unchanged drug (Reference 49).

#### *Adverse Effects*

Angiotensin-converting enzyme inhibitors are generally well tolerated in children, making them an attractive therapeutic option. Many adverse effects caused by ACE inhibitors, particularly ACE inhibitor-induced cough, occur rarely in children compared with the rate of occurrence in adults (References 50–52).

#### ***AT II Receptor Antagonists***

##### *Mechanism/Use*

Because AT II is generated by other pathways in addition to the ACE, ARBs were developed to block the final step in this neurohormonal pathway—the binding of AT II to AT<sub>1</sub>-receptors (Reference 24). By antagonizing this receptor, ARBs cause vasodilation, aldosterone antagonism, reduction in sympathetic activity, and renal efferent arteriole relaxation (Reference 24). Unlike ACE inhibition, ARBs do not affect the metabolism of bradykinin (Reference 24). Because elevated bradykinin concentrations cause vasodilation, however, this may be a drawback to ARB therapy.

##### *Pediatric Pharmacokinetics*

Many ARBs have been reported to be used in pediatric patients, with several studies recently published at the time of this writing (References 53–58). Pharmacokinetic properties of ARBs in pediatric patients vary depending on the agent used (References 54, 56–58). Onset of action typically occurs within 1–2 hours. Most ARBs are metabolized from an inactive form to an active metabolite, with olmesartan metabolism occurring in the gut (References 54, 56, 58). Angiotensin receptor blockers are eliminated primarily through the fecal route as well as the urine (References 54, 56, 58). The half-lives of ARBs

are prolonged (6–15 hours), allowing once-daily dosing (References 54, 56, 58). Data in young children (younger than 6 years) are relatively scant, with most available data representing the use of valsartan (References 53, 54).

#### *Adverse Effects*

In pediatric randomized controlled trials, ARBs have a pediatric adverse effect profile similar to placebo (References 53, 57, 58). The reported adverse effects are similar to those of ACE inhibitors, and the class of ARBs as a whole has been reported to be well tolerated in children, causing minimal episodes of hypotension (References 53–58).

#### ***Direct Renin Inhibitors***

##### *Mechanism/Use*

Renin inhibition is not currently an attractive therapeutic option for pediatric hypertension. Aliskiren, the only U.S. Food and Drug Administration–approved direct renin inhibitor, prevents the production of AT I and therefore reduces AT II concentrations, causing vasodilation. As of this writing, the use of aliskiren had only been reported in four pediatric patients with chronic kidney disease, indicating the paucity of important clinical data to guide prescribers on safe and effective use (Reference 59). Hope is on the horizon, however, because a pharmacokinetic study of children aged 6–17 years is already complete (not yet published). In addition, a follow-up study evaluating safety and efficacy is enrolling patients (References 60, 61).

##### *Pediatric Pharmacokinetics*

Very little is known about the pharmacokinetics of aliskiren in pediatric patients because of the lack of available literature (Reference 59).

#### ***Calcium Channel Antagonists***

##### *Mechanism/Use*

Calcium channel antagonists are being used in the treatment of pediatric hypertension, despite the paucity of clinical data establishing the safety and efficacy of their use (Reference 62). The classification of CCBs, which identifies drugs in this class as dihydropyridines and non-dihydropyridines, is based on relative cardiac/vascular activity. Cardiac and vascular smooth muscle both rely on intracellular calcium for contraction. By blocking the influx of extracellular calcium, CCBs help decrease SVR and cardiac conduction. At therapeutic doses, the dihydropyridines are relatively safe to use in all age ranges and are the most useful class in the treatment of pediatric hypertension (Reference 62). Their high affinity for vascular calcium channels results in a reduction in BP by decreasing SVR through vasodilation (Reference 62). Non-dihydropyridine CCBs are generally recommended to be avoided in patients

younger than 1 year because the inhibition of AV node conduction may cause potent negative inotropic effects and thus can be fatal in young children (References 10, 62–64). Although JNC VII does not recommend the use of a CCB as a single agent for adult hypertension, the 4th Report includes CCBs as an acceptable first-line option in pediatric patients (References 10, 33).

#### *Pediatric Pharmacokinetics*

Amlodipine has seldom been studied in children; however, case reports suggest those younger than 6 years require higher doses per kilogram and even twice-daily dosing (Reference 65). Nifedipine is used for pediatric hypertension, but most of the available literature discusses its use for hypertensive urgencies, which will be discussed later (Reference 65). All CCBs are hepatically metabolized and do not require adjustment in the presence of renal dysfunction. Amlodipine is the dihydropyridine with the highest vascular selectivity, greatest oral bioavailability, and longest half-life, allowing once-daily dosing for chronic hypertension.

#### ***β-Adrenergic Receptor Antagonists***

##### *Mechanism/Use*

Blood pressure reduction with β-adrenergic antagonists (β-blockers) is achieved by reducing cardiac output through negative inotropic and chronotropic effects (References 66, 67). The receptor specificity and relative cardioselectivity vary between β-blockers. Atenolol and metoprolol are very cardioselective (except at high doses), antagonizing only β<sub>1</sub>-receptors, whereas propranolol blocks β<sub>1</sub> and β<sub>2</sub>. This additional β<sub>2</sub>-blockade may result in pulmonary cross-reactivity leading to bronchoconstriction and asthma exacerbations; however, the incidence in pediatric patients is minimal (Reference 66). In addition to β<sub>1</sub>- and β<sub>2</sub>-blockade, carvedilol possesses α<sub>1</sub>-receptor activity, causing a reduction in SVR.

#### *Pediatric Pharmacokinetics*

The pharmacokinetics as well as receptor specificity vary widely between β-blockers. All are lipophilic enough to cross the blood-brain barrier and thus have the ability to cause drowsiness and fatigue (References 66, 67). Propranolol shows the most rapid onset of action (1–2 hours) and has the shortest half-life (4.5 hours), whereas atenolol and metoprolol typically take longer to take effect (3 hours) and have a longer elimination half-life (8 hours). Metoprolol and propranolol are both hepatically metabolized and therefore need not be adjusted in renal dysfunction (Reference 67). Atenolol, however,

undergoes minimal hepatic metabolism and is highly eliminated through the urine, leaving patients with renal dysfunction at a higher risk of drug accumulation and accompanying adverse effects (Reference 67).

#### ***Diuretics***

The 4th Report includes diuretics as an option for first-line antihypertensive therapy in children (Reference 10). In contrast to JNC VII, which recommends a thiazide diuretic as first-line therapy for most adult patients, the 4th Report does not single out a specific drug or drug class for clinicians to target as first-line therapy in children and adolescents (References 10, 33). By reducing intravascular volume and peripheral vascular resistance, diuretics have been shown to decrease BP (Reference 37). They may be particularly useful in patients who require several drugs to control hypertension or who have considerable sodium and water retention.

##### *Mechanism/Use*

###### LOOP DIURETICS

Loop diuretics are the most powerful diuretics that may also have effects on hemodynamics. After reaching the tubular lumen of the nephron, their inhibition of the Na<sup>+</sup>/K<sup>+</sup>/2Cl<sup>-</sup> cotransporter in the thick ascending loop of Henle causes increased sodium concentrations in the distal tubule, thus promoting diuresis and natriuresis (Reference 70). Loop diuretics also potentiate the production of prostaglandins in the kidneys, leading to enhanced renal blood flow. As a whole, loop diuretics have no significant effect on hemodynamics, and they are generally not considered potent antihypertensive agents in children (Reference 70). Furosemide is the most commonly used loop diuretic in children. Other loop diuretics, such as torsemide and bumetanide, are not routinely used in the management of hypertension in children (References 10, 71–74).

###### THIAZIDE/THIAZIDE-LIKE DIURETICS

Thiazide diuretics are recommended by JNC VII as a first-line antihypertensive agent in most adults, and they are used in children as well (Reference 33). By inhibiting the Na<sup>+</sup>/Cl<sup>-</sup> transporter in the distal tubule, thiazide and thiazide-like diuretics produce mild diuresis and natriuresis by inhibiting about 5% of total sodium reabsorption, showing about one-fifth the diuretic capability of loop diuretics (Reference 75). Although their diuretic actions are mild, the proposed mechanism behind their hemodynamic effects is a reduction in SVR by direct vasodilation caused by vascular potassium channel activation (References 75–77). Commonly prescribed thiazide diuretics in children include chlorothiazide and hydrochlorothiazide, whereas thiazide-like diuretics include chlorthalidone and metolazone.

## POTASSIUM-SPARING DIURETICS

Potassium-sparing diuretics all work to promote diuresis while conserving potassium depletion; however, spironolactone shows slight mechanistic differences compared with amiloride and triamterene. Spironolactone antagonizes aldosterone by competing for binding sites at the distal segment of the distal tubule, causing increased  $\text{Na}^+$  and  $\text{H}_2\text{O}$  excretion into the urine. Its potassium-sparing effects are produced by the inhibition of aldosterone-sensitive sodium reabsorption (Reference 78). By inhibiting this mechanism, fewer potassium and hydrogen ions are excreted in the urine (Reference 78). Amiloride and triamterene, however, directly inhibit sodium channels in the distal convoluted tubule and the collecting duct, thus reducing the activity of the sodium/potassium transporter in the distal renal tubule to produce potassium-sparing diuresis independently of aldosterone (Reference 78).

### *Centrally Acting Sympatholytic Agents*

#### *Mechanism/Use*

$\alpha_2$ -Adrenergic receptor activation in the brain decreases BP through sympathetic tone reduction (Reference 86). Drugs that show this pharmacologic activity include clonidine, guanabenz, guanfacine, and methyldopa (Reference 86). Clonidine is the most commonly prescribed  $\alpha_2$ -agonist for the treatment of pediatric hypertension. Guanfacine and methyldopa are also used, but less often (Reference 86). Guanfacine and clonidine are also used for other indications such as attention-deficit/hyperactivity disorder (References 87, 88). Clonidine has shown utility in adjunctive analgesia and prevention of withdrawal symptoms associated with opioid weans as well (References 89, 90).

$\alpha_2$ -Adrenergic receptor agonists are typically not considered first-line therapy for hypertension in adults because of the lack of long-term morbidity and mortality data. Use in pediatric patients is low for the same reasons and may be avoided because of the incidence of adverse effects and subsequent reduction in quality of life. For these reasons,  $\alpha_2$ -adrenergic agonists are typically reserved as adjunctive agents to be used in refractory hypertension or single-dose agents for hypertensive emergencies while intravenous agents are being prepared (Reference 86).

#### *Pediatric Pharmacokinetics*

The onset of action for guanfacine and methyldopa are 1.5–4 hours and 2 hours, respectively (Reference 86). Their duration of action, however, varies widely, with guanfacine showing a half-life of about 17 hours (allowing once-daily dosing), compared with 1.7 hours (up to four times/day dosing) for methyldopa (Reference 86). Both drugs are eliminated primarily by the kidneys (Reference 86). The pharmacokinetic profile of clonidine will be reviewed in detail in the hypertensive crisis section later in the chapter.

## *Peripheral Adrenergic Antagonists and Direct Vasodilators*

#### *Mechanism/Use*

These agents are typically used as adjunctive medications for refractory hypertension and are not often selected as first-line agents. Selective  $\alpha_1$ -receptor blockade causes peripheral vasodilation and a subsequent reduction in BP. Doxazosin, prazosin, and terazosin make up the  $\alpha_1$ -receptor blocker drug class. Minoxidil and hydralazine are direct vasodilators that are also used in the treatment of hypertensive urgencies (References 37, 91–95).

The prescribing of both drug classes for childhood hypertension has dwindled and is associated with the potential for adverse effects (Reference 37). In addition, adult data showing a reduction in morbidity and mortality with their use are nonexistent and have been linked to increases in cardiovascular morbidity, thus preventing pediatric extrapolation and halting subsequent increases in prescribing patterns (Reference 96).

#### *Pediatric Pharmacokinetics*

The pediatric pharmacokinetic profile of minoxidil and hydralazine will be reviewed in the hypertensive crisis section later in the chapter.

### **Monitoring Therapeutic Outcomes**

The frequency and intensity of monitoring in patients with pediatric hypertension are highly reliant on the severity of illness at presentation and the presence of underlying disease states. Table 2 highlights the recommended frequency of BP measurement according to severity of hypertension (Reference 10).

## **HYPERTENSIVE CRISES**

Pediatric hypertensive crises markedly increase the risks of morbidity and mortality, prompting immediate clinical attention and necessitating emergency treatment (References 37, 91). Despite many years of available therapeutic treatment options, a paucity of robust pediatric clinical literature exists. Randomized controlled trials enrolling patients with pediatric hypertensive emergencies are nonexistent. This forces clinicians to make empiric clinical decisions forged from extrapolated adult data and small pediatric observational studies. A sound knowledge base of pediatric pharmacology and pathophysiology is needed in conjunction with a thorough understanding of the adult and pediatric clinical literature to guide clinical decision-making.

## **DEFINITIONS AND CLINICAL PRESENTATION**

Both hypertensive emergencies and urgencies are considered types of hypertensive crises. Hypertensive urgency is defined as severely elevated BP without signs

and symptoms of end-organ dysfunction (Reference 10). A hypertensive emergency, however, is severely elevated BP presenting with end-organ damage (Reference 10). An example of the difference between the two diagnoses includes a patient with severely elevated BP and corresponding seizures (hypertensive emergency) compared with a patient with an equivalently elevated BP and less severe symptoms, such as a severe headache (hypertensive urgency) (References 97, 98).

Pediatric hypertensive crises present in a variety of ways, but by definition, all cases have severely elevated BP. Exceeding stage II hypertension in severity, both hypertensive urgencies and emergencies require immediate pharmacologic intervention to reduce BP, even though their clinical presentation differs. Debate is ongoing regarding the necessity to differentiate between the two definitions because each diagnosis equally requires prompt medical intervention with the same pharmacologic agents and treatment strategies (Reference 91). Even more important than being able to differentiate between the definitions of hypertensive urgency and emergency on clinical presentation is the ability to grasp the concept that a failure to rapidly treat patients with hypertensive crisis leads to end-organ dysfunction that might eventually cause irreversible damage or death (References 37, 99). Signs and symptoms of end-organ damage may manifest as encephalopathy, seizures, intracerebral hemorrhage, facial palsy, retinopathy, acute renal failure, hematuria, congestive heart failure, and arrhythmias (References 10, 37, 91, 99–103).

### Pathogenesis

As discussed at the beginning of this chapter regarding the pathogenesis of primary and secondary hypertension, hypertensive crises are also a result of the dysfunction of complex neurohormonal and hemodynamic pathways causing dangerous elevations in systemic BP (References 91, 99). Activation of the RAAS, oxidative and mechanical damage to the microvasculature, fluid overload, severe renal dysfunction, coarctation of the aorta, sympathetic overstimulation, and endothelial dysfunction all may contribute to the pathology of hypertensive crises (References 91, 99).

## PHARMACOLOGIC THERAPY FOR HYPERTENSIVE CRISIS

### Therapeutic Goals

Pediatric guidelines for the treatment of high BP call for controlled antihypertensive therapy in patients with hypertensive crisis (Reference 10). Goals for controlled antihypertensive therapy include a gradual BP decrease of 25% or less within the first 8 hours, followed by a deliberate and gradual lowering of BP throughout the next 40 hours (Reference 10). Final goals to aim for should include BP at the 90th percentile or less for sex,

age, and height if patients present with end-organ damage or have underlying comorbidities such as diabetes or chronic renal dysfunction (Reference 10). All other patients should have their BP decreased to the 95th percentile or less (Reference 10).

Oral agents may be used for hypertensive crises in pediatric patients, but unlike medications used as rapidly titratable continuous infusions, their utility is generally limited to less severe cases such as hypertensive urgencies (References 10, 91, 94, 95, 97–110). Easily titratable continuous infusions are typically preferred because of their superior ability to tightly control BP descent, which allows a rapid reduction in BP while avoiding dangerously fast decreases (Reference 91). Table 7 highlights common intravenous agents, including pediatric dosing ranges and considerations for hypertensive crisis.

### *Sodium Nitroprusside*

#### *Mechanism/Use*

Sodium nitroprusside (SNP) is rapidly metabolized to cyanide and nitric oxide within red blood cells, which directly vasodilate arterial and venous smooth muscle, and is considered a first-line therapeutic agent for hypertensive crises (References 66, 120). With its initial pediatric data reported in the 1970s, SNP is historically one of the most frequently used agents for hypertensive crisis in children, despite the absence of a single randomized controlled trial (Reference 121).

#### *Pediatric Pharmacokinetics*

Pharmacologic assets of SNP include a rapid onset of action (less than 60 seconds) and a short elimination half-life, allowing rapid titration of continuous infusions (Reference 66). Another benefit includes its ability to lower BP by decreasing SVR without increasing preload or causing negative inotropic effects (Reference 122).

Drawbacks of SNP administration include potential cyanide and thiocyanate toxicity in addition to tachyphylaxis associated with prolonged therapy (Reference 122). Cyanide toxicity results from enzymatic breakdown of SNP within red blood cells (References 122, 123). Humans are normally able to attenuate cyanide accumulation by forming the renally eliminated thiocyanate molecule. This is accomplished by the enzyme rhodanese in the presence of thiosulfate.

High doses, prolonged infusions, or the presence of hepatic dysfunction causes depletion of endogenous thiosulfate stores, which increases the risk of cyanide toxicity, whereas prolonged infusions and renal dysfunction may cause thiocyanate accumulation and subsequent toxicity (Reference 124). Signs and symptoms of cyanide toxicity include the following: vomiting, headache, hypotension, delirium, psychosis, weakness, muscle spasms, tachypnea, tachycardia, tinnitus, metabolic acidosis, coma, and death (References 122, 123).

**Table 7. Common Intravenous Agents Used in Pediatric Hypertensive Crisis<sup>a,b</sup>**

Drug	Mechanism of action	Initial dose	Maximal dose	Adverse effects	Adjustment for organ dysfunction	Notes
Esmolol	$\beta_1$ -Antagonist	<b>B:</b> 100–500 mcg/kg <b>C:</b> 50–500 mcg/kg/hour	<b>B:</b> 500 mcg/kg <b>C:</b> 1000 mcg/kg/hour	Bradycardia Bronchospasm (potential at high doses) Hypoglycemia	No	<ul style="list-style-type: none"> <li>▪ Loses <math>\beta_1</math>-selectivity at higher doses, although the dose at which it loses cardioselectivity is unknown</li> <li>▪ Bolus doses as high as 1000 mcg/kg and continuous-infusion rates up to 1000 mcg/kg/minute have been reported.</li> </ul>
Hydralazine	Direct vasodilator (arterial)	0.1–0.2 mg/kg/dose every 4–6 hours	0.6 mg/kg/dose OR 20 mg	Dizziness Headache Palpitations Reflex tachycardia Rebound hypertension	Renal	<ul style="list-style-type: none"> <li>▪ May be given IV or IM</li> <li>▪ May be given orally as well (0.25 mg/kg/dose every 6 hours, max: 25 mg)</li> <li>▪ Activates RAAS</li> <li>▪ Prolonged half-life</li> <li>▪ Often used as a single dose to control hypertension while continuous agents are being prepared</li> </ul>
Labetalol	$\alpha_1, \beta_1, \beta_2$ -antagonist	<b>B:</b> 0.2–1 mg/kg <b>C:</b> 0.25–1 mg/kg/hour	<b>B:</b> 20 mg <b>C:</b> 3 mg/kg/hour	Bradycardia Bronchospasm Hyperkalemia Hypoglycemia	Potential reduction needed in hepatic impairment	<ul style="list-style-type: none"> <li>▪ Does not cause reflex tachycardia</li> <li>▪ Longer half-life compared with other agents</li> <li>▪ Young children may require lower doses (~0.6 mg/kg/hour) to achieve a desired antihypertensive effect.</li> <li>▪ Bronchospasm has been reported infrequently in pediatric patients.</li> </ul>
Nicardipine	Calcium channel antagonist (selective for arterial $Ca^{2+}$ channels)	0.2–0.5 mcg/kg/min	3 mcg/kg/minute	Flushing Headache Reflex tachycardia	Renal Potential reduction needed in hepatic impairment	<ul style="list-style-type: none"> <li>▪ Selective for arterial <math>Ca^{2+}</math> channels with minimal activity on myocardium</li> <li>▪ Doses higher than 3 mcg/kg/minute have been reported with lack of additional benefit in BP reduction.</li> </ul>
Sodium Nitroprusside	Direct vasodilator (venules and arterioles)	0.3–1 mcg/kg/minute	10 mcg/kg/minute	Cyanide toxicity Tachyphylaxis Thiocyanate toxicity	Renal Hepatic	<ul style="list-style-type: none"> <li>▪ The typical maximal dose is 4 mcg/kg/minute, although doses as high as 10 mcg/kg/minute have been reported.</li> <li>▪ May administer sodium thiosulfate to prevent or treat cyanide toxicity</li> <li>▪ Tachyphylaxis may develop after prolonged treatment.</li> </ul>

<sup>a</sup>Information from References 10, 37, 62, 66, 86, 91, 95, 97, 98, 103–105, 120–152, 154–161.

<sup>b</sup>All agents may cause hypotension.

B = bolus; BP = blood pressure; C = continuous infusion; IM = intramuscularly; IV = intravenously; Max = maximum; RAAS = renin-angiotensin-aldosterone system.

Clinical literature indicates that patients who receive a continuous infusion of 2 mcg/kg/minute or greater for at least 24 hours or those with renal or hepatic dysfunction are at increased risk; however, present evidence has failed to establish reference ranges for cyanide concentrations that correlate to toxicity in pediatric patients (References 123, 125–130). Focused on combating SNP-induced cyanide toxicity, some institutions add sodium thiosulfate to nitroprusside infusions to take advantage of its ability to reduce serum cyanide concentrations by replacing exhausted thiosulfate reserves (References 131–133). Of note, clinical literature describing the safety and efficacy of the prolonged co-administration of the two drugs is lacking.

### **Nicardipine**

#### *Mechanism/Use*

Nicardipine is an intravenous CCB that has recently been studied with more frequency compared with other agents used for hypertensive emergencies in pediatric patients (References 134–141). Like SNP, it is considered a first-line treatment option for pediatric hypertensive crises (Reference 10). Its mechanism of action involves peripheral arterial vasodilation with minimal effects on the myocardium (Reference 10). Its relatively high affinity for vascular calcium channels and lack of activity on myocardial calcium channels causes SVR reduction with a potential to produce reflex tachycardia (References 134–136).

#### *Pediatric Pharmacokinetics*

Much like SNP, nicardipine has a pharmacokinetic profile that includes a rapid onset of action (1–2 minutes) and can be rapidly titrated (Reference 135). Drug elimination is highly driven by hepatic metabolism through cytochrome P450 (CYP) enzymes. Although a smaller percentage of the drug is excreted in urine and feces, no adjustments for renal dysfunction are required. Unlike SNP, its metabolism does not produce toxic metabolites, so it can safely be infused for a prolonged period (e.g., greater than 10 days) without risks of toxicity (Reference 135).

### **Labetalol**

#### *Mechanism/Use*

Labetalol is yet another agent with limited pediatric data that is considered a first-line antihypertensive agent for pediatric hypertensive emergencies and urgencies (References 91, 120). Unlike nicardipine and nitroprusside, intravenous labetalol reduces BP without causing reflex tachycardia. This is because of its mechanism of antagonizing both  $\alpha_1$ - and  $\beta$ -adrenergic receptors in a 1:7 ratio (Reference 142).

#### *Pediatric Pharmacokinetics*

Labetalol's onset of action occurs after only 5 minutes, and it can be titrated every 10 minutes (Reference 103). Compared with other continuously infused agents for pediatric hypertensive crisis, labetalol has a relatively long half-life of around 5.5–8 hours (Reference 142). Labetalol is hepatically metabolized by glucuronidation pathways and is unaffected by renal insufficiency (References 142–144).

### **Esmolol**

#### *Mechanism/Use*

As previously stated, esmolol is a cardioselective  $\beta_1$ -adrenergic antagonist. Although esmolol may be used in hypertensive emergencies, most pediatric data are specific to use in children with supraventricular tachycardia and hypertension control after repair of aortic coarctation (References 145–151).

#### *Pediatric Pharmacokinetics*

One of the properties that makes esmolol an attractive agent for this indication is its immediate onset of action (less than 1 minute) and unique drug metabolism by red blood cell esterases, resulting in a half-life of 3–9 minutes in pediatric patients (References 145–147, 149–152). Neonates and infants have been reported to metabolize esmolol more rapidly than older children, adolescents, and adults; however, data are conflicting, with a reported maximum half-life difference of about 6 minutes, which is most likely clinically insignificant (References 145–147, 150–152).

### **Hydralazine**

#### *Mechanism/Use*

Although hydralazine can be used in the treatment of pediatric hypertension, its primary utility resides in the treatment of acute hypertension and hypertensive emergencies (References 37, 91). A direct vasodilator, hydralazine causes a reduction in SVR by inhibiting calcium-dependent ATPase (adenosine triphosphate) and phosphorylation in arteriolar smooth muscle (References 92, 93, 122, 153). Recent reports describe the mechanism in more detail as stimulation of the HIF (hypoxia-inducible factor)-1- $\alpha$  protein by inhibiting PHD (prolyl hydroxylase domain) enzymes. This mechanism results in the induction of VEGF (vascular endothelial growth factor), endothelin-1, adrenomedullin, and heme oxygenase 1, all of which cause the intracellular accumulation of cGMP (cyclic guanosine monophosphate). This results in the clinical response of smooth muscle relaxation and arteriolar vasodilation (Reference 153).

### *Pediatric Pharmacokinetics*

Typical onset of action for hydralazine occurs between 20 and 40 minutes after an oral dose (not as useful in hypertensive emergencies) and between 5 and 20 minutes after intravenous/intramuscular dosing (Reference 154). Not much is known about the specific pediatric pharmacokinetics of hydralazine aside from methods of drug elimination and onset of action. Hydralazine is highly removed from the body through the first-pass effect. It is mainly metabolized by acetylation in the liver and partly eliminated by the kidneys (References 10, 91, 122). Patients with severe renal dysfunction may exhibit a longer hydralazine half-life and may require less frequent dosing, depending on their underlying hepatic metabolism rate.

### **Clonidine**

#### *Mechanism/Use*

Oral central  $\alpha$ -agonists such as clonidine are also used to treat hypertensive urgencies. Their main effects cause vasodilation through  $\alpha_2$ -stimulation and a subsequent reduction in sympathetic tone, which leads to a reduction in SVR and BP.

#### *Pediatric Pharmacokinetics*

With its rapid onset of action (15–30 minutes after oral ingestion), clonidine is an ideal oral agent for urgent treatment (Reference 86). Clinicians should exercise caution when using it for this indication because its 6- to 8-hour half-life (in adults) could result in a prolonged, dangerous decline in BP (References 86, 105). The pediatric pharmacokinetics and pharmacodynamics of orally administered clonidine are poorly understood. Rectal and nasal administration of clonidine in infants and children for anesthetic purposes have shown a half-life of 5–20 hours, possibly indicating prolonged activity in young children (References 156, 157).

### **Oral Calcium Channel Antagonists**

#### *Mechanism/Use*

Oral calcium channel antagonists show differences in specificity for cardiac myocytes and vascular smooth muscle. The use of non-dihydropyridine CCBs (verapamil and diltiazem) has been reported in pediatric patients (Reference 62). The 4th Report does not include non-dihydropyridines or nifedipine as desirable agents for use in hypertensive crisis (Reference 10). Verapamil and diltiazem use is limited because of their negative inotropic and chronotropic activity through blockade of cardiac electrical conduction. The use of short-acting nifedipine, which has been well documented, is controversial (References 62, 97, 98, 158–160). Many authors

do not recommend its use because of its overtly potent antihypertensive effects, which may cause significant morbidity and mortality related to a rapid and dangerous decline in BP (References 62, 97, 98, 158–160).

Unlike diltiazem and verapamil, dihydropyridines (excluding nifedipine) such as isradipine are more commonly used in children for hypertensive urgencies. Without disturbing myocardial electrical conduction, isradipine produces vasodilation and decreases SVR by exhibiting its primary actions on L-type calcium channels (Reference 158). Pediatric data are available on the use of isradipine for the treatment of acute hypertension; however, information on its use for hypertensive crisis in children is limited (References 106–109).

#### *Pediatric Pharmacokinetics*

Like those of other oral agents used for hypertensive urgencies, isradipine's pharmacokinetic profile includes a rapid onset of action (30–60 minutes), with peak effects occurring after 2–3 hours (Reference 91). It is metabolized by hepatic enzymes CYP3A3 and CYP3A4 with a half-life of about 3–8 hours (Reference 108). Because amlodipine does not have a rapid onset of action but has a long half-life, it is not used in hypertensive emergencies because of the inability to rapidly titrate its effects on hemodynamics.

### **Minoxidil**

#### *Mechanism/Use*

Minoxidil is a direct arteriolar vasodilator, thus making it a potentially useful agent in the treatment of hypertensive urgencies and emergencies (References 91, 95). Its use, however, is usually reserved as a single dose to control hypertension while continuous-infusion agents are being prepared or when hypertension is resistant to several drug therapies (Reference 10).

#### *Pediatric Pharmacokinetics*

Peak drug activity occurs within 60 minutes of ingestion, and a half-life of 4 hours ensures rapid drug clearance (Reference 161). Drug elimination primarily occurs through hepatic glucuronidation with secondary renal elimination.

### **Monitoring Therapeutic Outcomes**

Because hypertensive emergencies have a high propensity to cause marked acute morbidity and mortality, hypertensive emergencies should be monitored very closely in an institutional setting (e.g., in an intensive care unit), whereas the treatment of less severe forms of hypertension can be followed in an outpatient setting. When patients with hypertension are discharged

from the hospital, close follow-up should be scheduled to ensure continued adequate BP control, treatment of any underlying disease states, and limitation of adverse drug effects (Table 2) (Reference 10).

## CONCLUSIONS

Although pediatric hypertension and hypertensive crises are relatively rare compared with the incidence in adults, they are both important public health concerns because of their ever-increasing incidence as well as their potential to cause damaging effects on the human body. Knowledge of pediatric hypertension guidelines, potential lifestyle modifications, and pediatric pharmacology of antihypertensive agents is essential to providing high-quality care that is safe and effective for pediatric patients.

# CHAPTER 12

## NEONATAL RESPIRATORY DISTRESS SYNDROME AND BRONCHOPULMONARY DYSPLASIA

Kimberly Le Dinh, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. Explain the pathophysiology and clinical presentation of respiratory distress syndrome (RDS) and bronchopulmonary dysplasia (BPD).
2. Identify nonpharmacologic approaches to the prevention and treatment of RDS and BPD.
3. Discuss the pharmacologic agents for the prevention and treatment of RDS and BPD.
4. Evaluate the risks and benefits of treatment modalities aimed at improving the clinical symptoms of infants with RDS and BPD.

### ABBREVIATIONS IN THIS CHAPTER

BPD	Bronchopulmonary dysplasia
F <sub>IO<sub>2</sub></sub>	Fraction of inspired oxygen
iNO	Inhaled nitric oxide
RDS	Respiratory distress syndrome

### INTRODUCTION

Premature newborns commonly have complications with respiratory development and function. Respiratory distress syndrome (RDS) is a respiratory disorder caused by surfactant deficiency. Pulmonary surfactant prevents alveolar collapse to facilitate optimal gas exchange and prevent respiratory failure. Infants with RDS have lung immaturity that often requires oxygen supplementation and mechanical ventilation, both of which are risk factors for the development of bronchopulmonary dysplasia (BPD), a chronic lung disease of infancy in which the infant lung is characterized by inflammation and fibrosis. Recent treatment options and supportive therapies for RDS and BPD have significantly improved neonatal outcomes and survival.

### RESPIRATORY DISTRESS SYNDROME

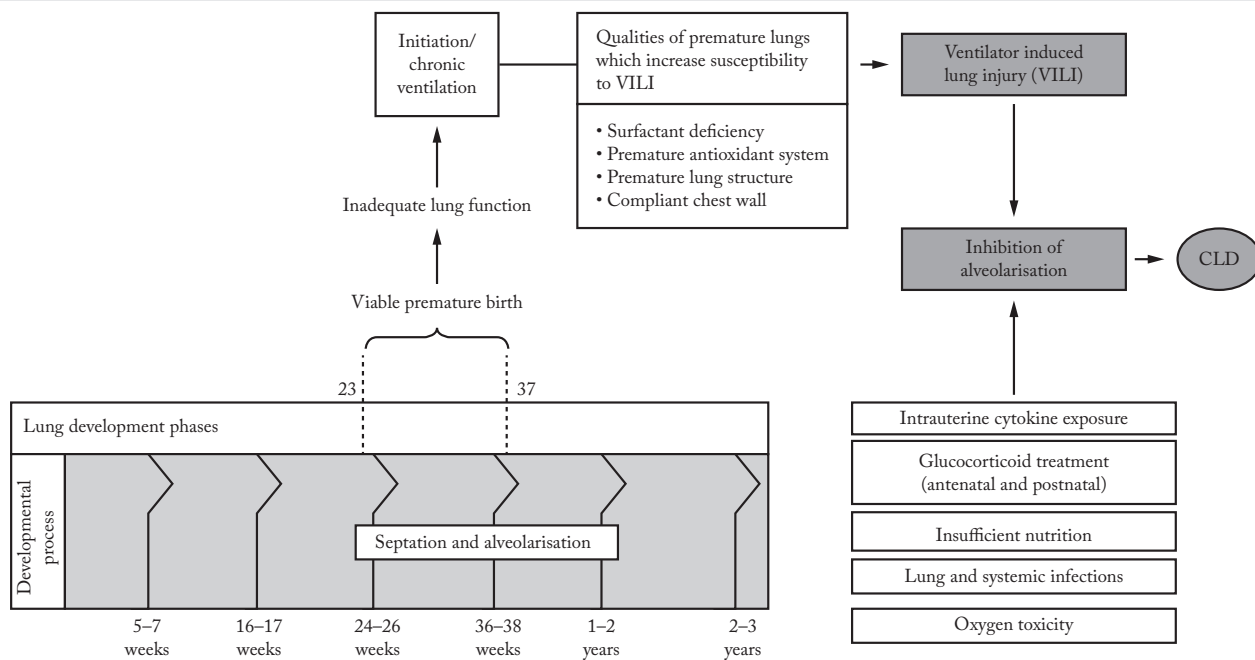

Respiratory distress syndrome, historically known as hyaline membrane disease, is a lung condition of prematurity. It was a common cause of neonatal morbidity and mortality before the discovery of exogenous pulmonary surfactant several decades ago. Because RDS is considered a developmental disorder, the risk of RDS

increases dramatically with decreasing gestational age and birth weight. Maternal steroid use before delivery promotes the maturation of the neonatal surfactant system to decrease the severity and incidence of RDS by 40% to 50% (Reference 1). Even with antenatal interventions, about 50% of infants born before 30 weeks' gestational age and 25% of infants born after 30 weeks' gestational age will develop RDS (Reference 2). Furthermore, surfactant therapy has significantly reduced the incidence of death and BPD in premature infants with RDS.

### Pathophysiology

Surfactant acts to lower surface tension at the air-liquid interface in the alveoli to prevent alveolar collapse. A sufficient amount of surfactant to sustain normal lung function is not acquired until the end of the saccular phase (Figure 1) of lung development, which occurs around 36 weeks' gestational age (Reference 4). An inadequate production or impaired release of pulmonary surfactant because of prematurity will result in RDS at birth. For comparison, premature infants have one-tenth of the surfactant pool compared with term neonates (10 mg/kg vs. 100 mg/kg) (Reference 5). Consequently, inadequate surfactant production leads to atelectasis, a complete or partial collapse of the lung, and impaired gas exchange.

Surfactant consists of highly organized lipid and surfactant proteins in the following concentrations: saturated phosphatidylcholine (50%), unsaturated phosphatidylcholine (20%), natural lipids (8%), phosphatidylglycerol (8%), other phospholipids (6%), and surfactant proteins (8%) (Reference 5). Although each surfactant protein has a unique function (Table 1), the critical components required for normal respiratory function are phosphatidylcholine, surfactant protein B, and surfactant protein C. An immature lung has lower percentages of these components, hindering the premature infant from adequately lowering the surface tension to allow adequate gas exchange within the alveoli. The severity of RDS is dictated by the extent of lung injury as a result of progressive atelectasis and ventilation-perfusion mismatch. The pathogenesis of lung damage may be further complicated by a structurally immature lung, pulmonary edema, and impaired alveolar ventilation.

**Figure 1.** The pulmonary development phases and the impact of ventilator-induced lung injury and other factors that contribute to BPD or CLD.

BPD = bronchopulmonary dysplasia; CLD = chronic lung disease.

## Clinical Presentation

Neonates with RDS usually present soon after birth with signs of respiratory distress such as tachypnea, grunting, retractions, and cyanosis (Reference 6). Physical findings may include the use of accessory breathing muscles, nasal flaring, tachycardia, and increasing oxygen requirements. A characteristic chest radiograph shows diffuse reticular-granular opacification with defined large airways. Other neonatal disorders that could present similarly to RDS include early-onset sepsis, transient tachypnea of the newborn, and spontaneous pneumothorax (Reference 6). The diagnosis of RDS is based on the infant's clinical presentation at birth and supported by findings on the chest radiograph consistent with surfactant deficiency. Infants who are younger than 30 weeks' gestational age or who did not receive antenatal steroids have the highest risk of RDS.

The clinical course is dictated by the severity of RDS, birth weight, gestational age, and extent of lung injury. In uncomplicated cases, RDS is transient, and recovery is expected within several days. However, RDS may be complicated by other common neonatal comorbidities (e.g., patent ductus arteriosus, infection). The infant may require supplemental oxygen or prolonged mechanical ventilation, resulting in extensive lung injury with eventual progression to BPD.

## Treatment

### Therapeutic Goals

The goal of RDS treatment is aimed at rapidly replacing pulmonary surfactant and minimizing the pathologic sequelae of acute pulmonary injury. The initial management of RDS immediately after birth includes early surfactant administration and establishment of adequate ventilation and oxygenation. The desired outcome is limiting the severity of lung injury and reducing the duration of supplemental oxygen or mechanical ventilation with continued efforts to prevent the development of BPD.

### Nonpharmacologic Therapy

It is critical to establish ventilation and oxygenation promptly after birth to prevent pulmonary vasoconstriction and subsequent atelectasis. Infants usually require supplemental oxygen, continuous positive airway pressure, or mechanical ventilation at any time during the clinical course of RDS. In general, continuous positive airway pressure is adequate for mild or moderate RDS and may reduce the need for additional surfactant doses. Supplemental oxygen or mechanical ventilation should be discontinued as soon as tolerated to minimize the risk of BPD.

**Table 1.** Functions of Surfactant Proteins

Surfactant Proteins	Function
A	Hydrophilic protein that regulates the turnover of pulmonary surfactant, formation of tubular myelin, and immunity
B	Hydrophobic protein that is involved in the formation of tubular myelin and that facilitates improvement in surfactant surface activity
C	Improves spreadability and surfactant surface activity
D	Involved in bacterial opsonization

### Pharmacologic Therapy

#### Surfactant Replacement Therapy

Surfactant therapy is the standard of care for the prophylaxis and treatment of RDS. Systematic reviews have confirmed the many benefits of surfactant replacement, which include decreased ventilation requirements and a reduced incidence in mortality, pneumothorax, and pulmonary interstitial emphysema. Infants younger than 30 weeks' gestational age or with a birth weight of less than 1250 g have the greatest reduction in mortality rates with surfactant therapy (Reference 7). However, the occurrence of other neonatal comorbidities (e.g., intraventricular hemorrhage, necrotizing enterocolitis, nosocomial infections, retinopathy of prematurity, and patent ductus arteriosus) has not changed with the introduction of surfactant (References 6, 8, 9).

#### Types of Surfactant

The two types of exogenous surfactants are synthetic and natural. Synthetic surfactants contain phospholipids without surfactant proteins and are currently not approved for use in the United States (Reference

2). Natural, also known as animal-derived, surfactants are modified or purified from bovine or porcine lungs. Systematic reviews show better clinical outcomes and improved survival with animal-derived compared with synthetic surfactants in the prophylaxis and treatment of RDS (References 2, 10).

Infants receiving animal-derived surfactant have shown significant reductions in ventilator requirement and the incidence of pneumothoraces and mortality, with only marginal increases in low-grade intraventricular hemorrhage (Reference 10). Adverse immunologic or infectious complications with natural surfactant have not been recognized. Animal-derived surfactant is considered the mainstay treatment of RDS in clinical practice (Reference 10).

Beractant, calfactant, and poractant alfa are the commercially available animal-derived surfactants in the United States. These products have varying amounts of phospholipids and surfactant proteins B and C. They also differ in viscosity and administration volume (Table 2). All commercially available natural surfactant products are effective for the prevention and treatment of RDS. There are no randomized controlled trials to support the superiority of one preparation over the other (References 2, 11). However, treatment with poractant alfa allowed for a quicker weaning of oxygen and ventilatory pressures (References 11). Additionally, a recent meta-analysis showed a significant decrease in mortality with high-dose poractant alfa (200 mg/kg/dose) compared with beractant (100 mg/kg/dose), with the poractant alfa group also requiring fewer total doses (Reference 12).

#### Mechanism of Action

Exogenous surfactant replaces deficient or dysfunctional pulmonary surfactant in infants with RDS or premature infants at risk of developing RDS. Surfactant deficiency increases surface tension at the air and alveolar surfaces leading to alveolar collapse. Because of unopposed

**Table 2.** A Comparison of the Source, Composition, and Dose of Animal-Derived Surfactants Available in the United States

Surfactant	Animal Source	Phospholipid Concentration (mg of phospholipids/kg)	Initial Dose (mg of phospholipids/kg)	Subsequent Doses (mg of phospholipids/kg)	Dosing Interval (hours)	Maximum Total Doses
Beractant	Bovine	25	100 mg/kg (4 mL/kg)	100 mg/kg (4 mL/kg)	6	4
Calfactant	Bovine	35	105 mg/kg (3 mL/kg)	105 mg/kg (3 mL/kg)	12	4
Poractant alfa	Porcine	80	200 mg/kg (2.5 mL/kg)	100 mg/kg (1.25 mL/kg)	12	3

surface tension forces, an increase in the work of breathing is required to reinflate the alveoli (Reference 13). Surfactant acts to lower the surface tension at the air-liquid interface to stabilize the alveoli. Once surfactant is instilled and evenly distributed to the distal lung, an acute response occurs within minutes. The exogenous surfactant will decrease the surface tension to allow the lung to inflate at a lower pressure and a greater volume, resulting in a rapid oxygenation response. The result is a reduction in the work of breathing, an increase in lung compliance, the resolution of RDS symptoms, and a subsequent reduction in lung injury.

#### *Prophylaxis and Rescue Therapy*

Prophylactic surfactant therapy is surfactant administration within 30 minutes of birth to neonates at high risk of having RDS before the diagnosis of RDS is confirmed. Meanwhile, rescue surfactant therapy is administered to neonates with established RDS within 12 hours of birth. Early rescue therapy is surfactant administration within 1–2 hours of birth, whereas late rescue therapy is administration after 2 hours (Reference 14).

Prophylactic surfactant replacement has the advantage of replacing surfactant before the onset of respiratory symptoms and lung injury. Prophylaxis in premature neonates improves significant clinical outcomes such as death, pneumothorax, and pulmonary interstitial emphysema (Reference 15). However, the impact of prophylactic surfactant administration on the risk of BPD is unclear (Reference 14). A prophylactic approach should be considered in neonates who are at extremely high risk of RDS, such as those who were born at or earlier than 30 weeks' gestation or who were not exposed to antenatal steroids (Reference 14). Although these infants will also benefit from rescue surfactant therapy, the prophylactic approach decreases the severity and complications of RDS (Reference 14). Possible clinical risks of a prophylactic approach are unnecessary drug exposure and intubation in infants with respiratory disorders other than RDS (e.g., pulmonary hypoplasia, lung injury).

Few studies have compared prophylactic surfactant therapy with early or late rescue therapy. The limited data show better outcomes with prophylactic administration, but these therapies were mostly studied in infants who were not exposed to antenatal steroids (Reference 14). Surfactant replacement, either prophylactic or rescue, should occur before or soon after the presentation of RDS to optimize the clinical benefits of drug therapy.

#### *Repeated Surfactant Doses*

Surfactant doses may be repeated up to the recommended maximum number of treatments determined by the surfactant product (Table 2) if persistent respiratory distress

is observed 6–12 hours after the initial dose. Infants with lung injury from mechanical ventilation or supplemental oxygen are most likely to benefit from more than a single dose of surfactant because pulmonary edema or inflammation will inhibit surfactant function (Reference 5). A second dose of surfactant may be necessary if the infant continues to need mechanical ventilation with an oxygen requirement ( $F_{I}O_2$  [fraction of inspired oxygen]) of greater than 30% or 40% (Reference 16).

Several studies have shown better outcomes with multiple doses as opposed to a single dose of surfactant in premature infants with RDS (References 7, 17). A meta-analysis of two trials comparing single versus several doses of surfactant showed a reduction in the incidence of pneumothorax with a trend toward decreased mortality when more than one dose of surfactant was administered (Reference 17). No complications from multiple surfactant doses were observed in these trials. There is a paucity of data distinguishing the differences in the outcomes of two doses compared with three or four doses of surfactant. Criteria for multiple dosing of surfactant need to be further defined to limit unnecessary treatment. The infant should be evaluated after each surfactant administration for signs of clinical improvement, as evidenced by a reduction in oxygen requirement or ventilator support. In general, repeated doses are not indicated if the infant had a favorable improvement in oxygenation and has no significant respiratory distress.

#### *Administration*

Surfactant is administered by instilling the solution through a catheter into the endotracheal tube. The volume of medication and number of aliquots depend on the specific surfactant product (Table 1). The neonate may be placed in several positions to facilitate surfactant distribution, which varies according to the manufacturer's guideline for the individual products. For example, each dose of beractant is administered in four 1-mL/kg aliquots with the infant in four different positions: (1) inclined slightly downward with the head turned right, (2) inclined slightly downward with the head turned left, (3) inclined slightly upward with the head turned right, and (4) inclined slightly upward with the head turned left. This administration technique ensures a uniform and rapid distribution of surfactant in the lungs. Complications can occur with transient airway obstruction or inappropriate instillation into the right mainstem bronchus or esophagus, so administration should be performed with the guidance of a trained clinical expert (e.g., respiratory therapist).

#### *Monitoring Parameters and Adverse Effects*

Improvements in lung volume and compliance occur rapidly after surfactant administration. Close observation is critical because the infant may require prompt

mechanical ventilation changes to prevent further lung injury and pneumothorax. Although considered a well-tolerated therapy, surfactant may cause adverse effects such as apnea, bradycardia, and oxygen desaturation. An infrequent complication of surfactant therapy is pulmonary hemorrhage with extremely low-birth-weight infants at the highest risk (References 14, 17). Future research should focus on optimizing surfactant preparations, minimizing acute lung injury, and exploring noninvasive administration techniques to reduce short- and long-term complications of RDS, such as the development of BPD.

## BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia is often the pulmonary sequelae of RDS and the most common cause of morbidity in surviving premature infants in the United States (References 18–21). Also referred to as chronic lung disease of infancy, BPD begins with any neonatal disorder that causes postnatal respiratory failure requiring long-term mechanical ventilatory or supplemental oxygen support. Both the underlying condition and the treatment interventions for neonatal respiratory failure contribute to airway inflammation, leading to chronic airflow obstruction and hyperreactivity in the infant with BPD (Reference 22). Infants younger than 30 weeks' gestational age or weighing less than 1500 g have the highest risk of BPD. Of the infants born under 1500 g—about 1.5% of all newborns in the United States—20% will develop BPD (Reference 23).

### Pathophysiology

The premature lung is most susceptible to lung injury during the saccular stage of lung development between 24 and 36 weeks' gestation. At this stage, lung structure and function are immature, increasing the likelihood of lung injury and disruption of alveolarization (Reference 24). Mechanical ventilation is the primary cause of acute lung injury because of an overdistention of the immature airspaces. This cellular and interstitial lung injury triggers the release of proinflammatory cytokines, resulting in increased alveolar permeability and leakage of protein and water. In addition, high concentrations of oxygen produce free radicals and subsequent damage to the lung parenchyma in the underdeveloped respiratory epithelium and antioxidant defense system (Reference 25). Airway hyperactivity, smooth muscle hypertrophy, and bronchoconstriction are characteristic of the acute stage of BPD. This period occurs during the first few weeks of life after early lung injury, generally around 28–36 weeks' postmenstrual age. The progression to chronic BPD, which occurs after 36 weeks' postmenstrual age, is marked by pulmonary fibrosis and muscularization, leading to a

reduction in lung compliance and impairment of gas exchange (References 26, 27). Other factors that may contribute to the pathophysiology of BPD include infection, steroids, and surfactant deficiency (Figure 1). Unfortunately, there is very limited knowledge regarding the time to complete resolution of BPD, which may last several months to years (Reference 26).

### Clinical Presentation

Infants with BPD often present with chronic respiratory signs such as tachypnea, shallow breathing, and retractions. Coarse rhonchi, diffuse rales, and wheezes are heard on auscultation. Chest radiograph often reveals diffuse haziness and lung hypoinflation (Reference 28). The severity of BPD is related to the degree of injury to the airways and distal lung. Infants with moderate to severe BPD may have acute episodes of pulmonary decompensation, bronchoconstriction, or reversible bronchospasm triggered by worsening pulmonary function. Acute exacerbations are described as a combination of an increased work of breathing or oxygen requirement and the presence of apnea or bradycardia. These episodes may be related to infections, severe airway reactivity, increased pulmonary edema, or the development of tracheobronchomalacia. Bronchopulmonary dysplasia may be accompanied by cardiovascular abnormalities (e.g., cardiomegaly), emphysema, pulmonary fibrosis, or lung hyperexpansion (Reference 1). Although BPD is primarily a respiratory disease, short- and long-term complications could involve many systems, including pulmonary hypertension, cardiac dysfunction (e.g., cor pulmonale), poor neurodevelopment, and poor growth in severe cases (Reference 29).

A diagnosis of BPD is made if the infant continues to require supplemental oxygen or respiratory support at 28 days of life and/or 36 weeks' postmenstrual age (Reference 1). The National Institute of Child Health and Human Development, the National Heart, Lung and Blood Institute, and the Office of Rare Diseases further categorize the disease into mild, moderate, or severe BPD on the basis of gestational age (younger than 32 weeks or 32 weeks or older), oxygen requirement ( $F_{IO_2}$  of less than 30% or  $F_{IO_2}$  of 30% or greater), or need for positive-pressure ventilation (Reference 30). The greatest risk factors for BPD are prematurity, chronic exposure to mechanical ventilation, and prolonged oxygen supplementation (Reference 31).

### Treatment

#### *Therapeutic Goals*

Infants often present in acute exacerbation with tachypnea, retractions, or wheezing. The therapeutic goal is an overall improvement in clinical symptoms by

minimizing further lung injury and complications, decreasing oxygen requirements, and achieving optimal nutrition for adequate lung growth.

### ***Nonpharmacologic Therapy***

#### *Mechanical Ventilation and Supplemental Oxygen*

Infants with severe BPD often require prolonged ventilator support. Although mechanical ventilation contributes greatly to lung injury, the infant may require respiratory support in the acute phase of BPD during the first several weeks after preterm birth (Reference 32). Ventilator adjustments should be made accordingly to avoid hyperventilation while maintaining appropriate oxygen saturations and adequate gas exchange (Reference 33).

Continuous positive airway pressure ventilation is the preferred ventilatory support technique because it does not require intubation and mechanical ventilation (Reference 34). Infants can be weaned off continuous positive airway pressure to supplemental oxygen alone as pulmonary function improves. In the chronic phase and more severe form of BPD, weaning ventilator settings is usually not possible until the infant shows good growth and a steady weight gain. If the infant can maintain oxygen saturations above 90% during periods of sleep, feedings, and activity, a trial off supplemental oxygen can be considered. Eventually, adequate oxygenation can be maintained with room air as BPD improves or resolves.

#### *Fluid Restriction*

Pulmonary edema decreases lung compliance and increases the need for mechanical ventilatory support. High fluid intake or inadequate urine output places the premature infant at a greater risk of pulmonary edema (Reference 35). Restricting fluid volume from medications or nutrition could help counteract the pulmonary lung injury and capillary leak seen in BPD. In a randomized study of infants weighing less than 1751 g, the investigators compared the control group having a fluid intake of 200 mL/kg/day with a restricted group having a fluid intake of 150 mL/kg/day after the first week of life. A significant difference in mortality and BPD, defined by imaging findings, clinical symptoms, and oxygen requirement at 1 month of life, was observed with the group receiving fluid at 150 mL/kg/day (Reference 36). One argument is that the study was quite liberal with the fluid restriction because 150 mL/kg/day could be considered the standard maintenance fluid intake, not a restricted amount in neonates (Reference 1). Although it is uncertain whether fluid restriction less than 150 mL/kg/day provides additional benefit, fluid intake should be kept at the minimum required for optimal growth and adequate urine output to avoid pulmonary edema (References 36, 37).

### ***Pharmacologic Therapy***

Most treatment modalities are aimed at improving the clinical symptoms of infants with BPD. Multidrug therapy typically includes diuretics, bronchodilators, and corticosteroids. However, the exact mechanism and safety of these drug therapies are not well studied and have not been shown to reverse pulmonary injury in the BPD population. Currently, there is no optimal agent or regimen for the prevention and treatment of BPD, and an evidence-based treatment guideline does not exist. In addition to the patient's disease severity, the risks of treatment and potential adverse events must be considered before initiating pharmacologic therapy.

#### *Diuretics*

Diuretics are often used in infants with BPD to improve pulmonary function (Reference 38). They increase pulmonary compliance by decreasing pulmonary resistance and interstitial lung fluid (Reference 1). A transient improvement in gas exchange and reduction in oxygen requirement are observed when diuretics are administered to an infant with BPD (Reference 38). Diuretics are usually considered when the infant with BPD cannot be weaned off aggressive respiratory support or has cardiac failure (Reference 23). They are also useful when fluid restriction causes nutritional compromise and inadequate delivery of calories to promote lung growth. The common classes of diuretics used in BPD are loop and thiazide diuretics (Reference 39).

The loop diuretic used most frequently in neonates is furosemide, a potent diuretic that acts in the ascending loop of Henle and distal tubule (Reference 40). Around 25% of the filtered sodium is reabsorbed to cause significant diuresis (Figure 2). Furosemide is thought to be effective in BPD by increasing plasma oncotic pressure and lymphatic flow while decreasing interstitial edema and pulmonary vascular resistance. A single dose of intravenous furosemide (1 mg/kg/dose) acutely improved pulmonary mechanics compared with placebo in a study of 10 infants with chronic BPD who were not dependent on oxygen. Airway resistance was significantly decreased 1 hour after the furosemide dose. However, this effect returned to baseline values after 2 hours (Reference 42). Age appears to be a contributing factor in the beneficial response of furosemide in infants with BPD. In a systematic study of premature infants with, or developing, BPD who received intravenous or oral furosemide, no benefits were detectable in infants younger than 3 weeks. However, in infants older than 3 weeks, the acute and chronic administration of furosemide improved lung compliance, airway resistance, and oxygenation for at least 1 hour after the furosemide dose (Reference 43). Although short-term improvements in

pulmonary mechanics have been observed, there is no current evidence that furosemide improves clinically significant outcomes such as mortality or decreases the incidence of BPD (Reference 38).

Chronic therapy with a loop diuretic may present several complications, including electrolyte disturbances, osteopenia, and ototoxicity (Reference 1). Hypokalemia, hyponatremia, and contractional metabolic alkalosis are often observed in clinical practice, and supplementation with potassium chloride is usually required. Furosemide also increases urinary calcium excretion, which could lead to nephrocalcinosis and nephrolithiasis in infants (Reference 44). Although rare, ototoxicity and transient deafness are possible when furosemide is used chronically or in conjunction with other ototoxic medications such as aminoglycosides. Inhaled furosemide has been studied in BPD as a result of complications seen with systemic diuretics. Because of the limited body of evidence and conflicting results related to pertinent clinical outcomes, the routine use of inhaled furosemide in infants with BPD is not recommended (References 45, 46).

Thiazide diuretics act in the distal convoluted tubule, where active reabsorption of only 4% to 8% of filtered sodium, chloride, and calcium occurs. Thiazide diuretics also improve pulmonary mechanics in premature infants with BPD who are older than 3 weeks (Reference 47). The two most extensively studied thiazide diuretics in neonates are chlorothiazide and hydrochlorothiazide. These agents are useful in the pharmacologic armamentarium for infants experiencing complications or tolerance of furosemide. Electrolyte abnormalities may be observed but to a considerably lesser degree than with

furosemide therapy. Nephrocalcinosis is usually not seen because less calcium resorption occurs with a thiazide than with a loop diuretic (Reference 38). Although less potent and modestly effective compared with furosemide, hydrochlorothiazide or chlorothiazide may be a better alternative for the chronic management of BPD because of its more favorable adverse effect profile (References 38, 40).

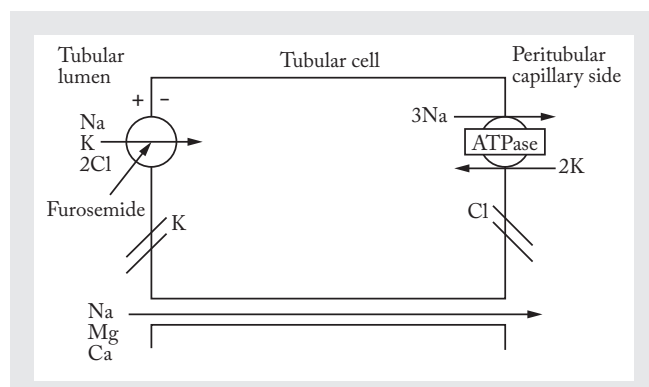

Loop diuretics are most beneficial in the acute BPD phase, and thiazide diuretics are often used in ventilator-dependent infants with chronic BPD when fluid restriction is ineffective. However, whether the chronic use of diuretics improves important clinical outcomes remains to be seen (Reference 38). The duration of diuretic therapy depends on individual responses to diuretics and improvement in symptoms during acute exacerbations. Close monitoring of electrolyte abnormalities is important, and appropriate electrolyte supplementation is required during diuretic therapy.

#### *Inhaled Bronchodilators*

Bronchodilators act to dilate the small airways caused by muscle hypertrophy observed in infants with moderate or severe BPD (References 22, 48). They improve airway hyperactivity that causes flow limitation and obstruction through narrowing of the bronchi and may be effective as an adjunctive therapy for the treatment of acute exacerbations to obtain a short-term resolution of symptoms. Two classes of inhaled bronchodilators used in BPD are  $\beta$ -agonists and anticholinergic agents (Reference 1). However, the use of bronchodilators has not been well studied, and their impact on the course of BPD has not been elucidated (Reference 1).

$\beta$ -agonists acutely improve pulmonary resistance and lung compliance through bronchial smooth muscle relaxation. Unfortunately, these effects are short term, with a return to baseline 4 hours after drug administration. In a double-blind, placebo-controlled study of 173 ventilator-dependent infants younger than 31 weeks' gestation, albuterol did not show any difference in important outcomes such as mortality, chronic lung disease, or duration of ventilator support (Reference 49). Adverse effects of inhaled  $\beta$ -agonists include hypokalemia, tachycardia, hypertension, and arrhythmias.

Inhaled anticholinergic agents such as atropine and ipratropium block the action of acetylcholine in bronchial smooth muscle, resulting in bronchodilation. Adverse effects of inhaled anticholinergic agents are dyspnea, palpitations, dyspepsia, and upper respiratory tract infections. Ipratropium is a more potent bronchodilator than atropine with a more favorable adverse effect profile (Reference 50). Although rarely used in clinical practice, an inhaled anticholinergic may be a

**Figure 2.** Furosemide binds to the chloride site of the sodium/potassium/chloride cotransporter in the tubule lumen to cause increased excretion of water, sodium, chloride, magnesium, and calcium.

Reproduced from Moghal NE, Shenoy M. Furosemide and acute kidney injury in neonates. *Arch Dis Child Fetal Neonatal Ed* 2008;93:F313–F316 (Reference 41) with permission.

therapeutic option in addition to  $\beta$ -agonist therapy to improve symptomatic and reversible airway obstruction. Synergy occurs by interfering with vagal-mediated bronchoconstriction (Reference 48).

In the chronic stage, lung pathology becomes fibrotic and less sensitive to the effects of inhaled therapy; thus, a positive response to inhaled bronchodilators may not be observed in all infants (Reference 48). To ensure optimal drug therapy, a spacer and mask should be used when delivering bronchodilators through a metered dose inhaler. Routine or chronic use of inhaled bronchodilators is not recommended but may be considered if short-term clinical improvements (e.g., resolution of airway obstruction) are observed. The long-term efficacy of bronchodilators in BPD has not been studied, and their effects on lung development, prevention of exacerbations, and improvement of the quality of life remain to be seen (Reference 23).

#### *Corticosteroids*

Airway inflammation in BPD suggests a beneficial role for systemic and inhaled corticosteroids. Corticosteroids decrease inflammation by suppressing neutrophil migration and production of inflammatory mediators. Their use in neonatal lung disease was first reported in the 1950s, and in the 1980s and 1990s they became commonly used in practice (Reference 51). The decision to use corticosteroids to treat BPD remains controversial because of their high risk potential and long-term consequences.

Dexamethasone is the first well-studied corticosteroid in the management of BPD for its potent anti-inflammatory properties. Short-term treatment with dexamethasone reduces the need for supplemental oxygen, with no difference in mortality before hospital discharge (Reference 48). A higher incidence of growth failure, hyperglycemia, hypertension, and hypertrophic cardiomyopathy was noted in the infants treated with dexamethasone. Follow-up data in the late 1990s showed an increased risk of neurodevelopmental consequences. Infants who received a 4-week course of dexamethasone within 12 hours of birth had twice the risk of cerebral palsy compared with the control group (Reference 52). In systematic reviews, the most common dexamethasone dosing regimen was 0.5 mg/kg/day divided in two doses for 3 days, followed by 0.25 mg/kg/day for 3 days, 0.12 mg/kg/day for 3 days, and 0.05 mg/kg/day for 3 days. These were discovered to be relatively high-potency doses of corticosteroid and may have contributed to the harmful neurodevelopmental outcomes (References 53–55). The use of dexamethasone for BPD is no longer recommended because of the significant risk of long-term neurodevelopmental sequelae.

Data on the adverse effects of dexamethasone have led to studies with other corticosteroids, specifically hydrocortisone, for the treatment and prevention of BPD. In a retrospective study evaluating the short- and long-term outcomes of hydrocortisone- and dexamethasone-tapering regimens, both corticosteroids showed effectiveness in decreasing oxygen requirements. Follow-up at 5–7 years of age found that children treated with hydrocortisone needed less special school education and had better neurodevelopmental outcomes than those treated with dexamethasone (Reference 56). Although hydrocortisone appears to have a better adverse effect profile, its routine use for the prevention and treatment of BPD in preterm infants is not recommended by the American Academy of Pediatrics (Reference 57). Therapy may only be reasonable for ventilator-dependent infants with exceptional BPD on maximum support in which hydrocortisone may be lifesaving (Reference 1). Inhaled corticosteroids could improve short-term pulmonary exacerbations with minimal systemic absorption, but evidence is limited for their role in preventing and treating BPD (Reference 58).

#### ***BPD Prevention***

The most effective means of preventing BPD is the prevention of prematurity, RDS, and subsequent lung injury. However, several pharmacologic therapies have been investigated to prevent BPD development (Table 3). These therapies remain largely controversial without many controlled studies, but they could be effective in combination with other preventive strategies. The clinician should outweigh the risks and benefits of each preventive modality.

#### *Vitamin A*

Vitamin A is essential for tissue differentiation and cell growth. Premature neonates with extremely low birth weights have inherently low plasma concentrations of vitamin A, possibly predisposing these infants to BPD. A multicenter, randomized trial evaluated the effectiveness of vitamin A supplementation in 807 infants with birth weights between 401 g and 1000 g who were ventilator- or oxygen-dependent at 24 hours of life (Reference 59). Vitamin A (5000 international units) was administered three times/week intramuscularly for 4 weeks. The vitamin A group had a significant reduction in mortality or BPD at 36 weeks of age (55% vs. 62%). Infants with birth weights less than 1000 g may benefit from vitamin A supplementation to decrease the risk of BPD.

#### *Inhaled Nitric Oxide*

Inhaled nitric oxide (iNO) may prevent BPD in premature patients at high risk of developing the disease by decreasing ventilation-perfusion mismatch, reducing inflammation, and restoring normal growth in

**Table 3. Medications That Have Been Studied for BPD Prevention**

	Vitamin A	Nitric Oxide	Caffeine Citrate
Administration route	Intramuscular	Inhalation	Oral, intravenous
Dosing	5000 international units three times/week	20 ppm for 2–3 days; then decrease to doses of 10, 5, and 2 ppm at weekly intervals	Loading dose: 20–25 mg/kg/dose; Maintenance dose: 5–10 mg/kg/day
Therapy duration	28 days	24 days	Until apnea of prematurity resolves
Adverse effects	Allergic reactions (rare)	Hypotension Rebound syndrome	Failure to gain weight Jitteriness Hyperreflexia Seizures

the premature lung. A multicenter, randomized study involving 793 premature newborns with respiratory failure requiring mechanical ventilation evaluated the effectiveness of low-dose iNO (5 ppm) or placebo for 21 days (Reference 60). There was no difference in the incidence of mortality or BPD between the two groups (71.6% vs. 75.3%). However, infants with a birth weight greater than 1000 g had a 50% reduction in the incidence of BPD; initiation of low-dose iNO may be beneficial in this weight group. Another randomized study of 294 premature neonates who received decreasing concentrations of iNO for a minimum of 24 days (starting dose of 20 ppm) showed a difference in survival rate without BPD (43.9% vs. 36.8%) when iNO was initiated between 7 and 21 days of age (Reference 61). The use of iNO for BPD prevention is not routinely recommended in clinical practice by the National Institutes of Health because of inconclusive evidence and overall cost of therapy.

#### *Caffeine Citrate*

Caffeine is a respiratory stimulant in premature neonates and is effective in the treatment of apnea of prematurity (see Apnea of Prematurity chapter). A large, international, randomized, placebo-controlled trial of caffeine citrate was conducted in 2006 infants with birth weights of 500–1250 g (Reference 62). Eligible patients received an intravenous loading dose of caffeine citrate of 20 mg/kg, followed by a maintenance dose of 5 mg/kg or normal saline. The daily maintenance dose was increased to a maximum of 10 mg/kg if apneic episodes persisted. Although BPD was not the primary outcome assessed, a significant reduction in BPD was observed in the caffeine group. Of the 963 infants in the caffeine group who survived at 36 weeks' postmenstrual age, significantly fewer infants in the caffeine group developed BPD compared with infants in the control group (36.3% vs. 46.9%). The investigators speculated that the reduced incidence in BPD was a result of the decreased duration of supplemental oxygen and positive-pressure

ventilation observed in the caffeine group. Caffeine citrate should be routinely used in all premature infants at risk of severe apnea. It could prevent the need for invasive mechanical ventilation and progression of BPD.

#### Discharge Planning

Infants with BPD may be ready for discharge if their respiratory status is stable during periods of sleep, feeding, or activity without significant oxygen desaturation. Although supplemental oxygen is often discontinued before discharge from the neonatal intensive care unit, home oxygen therapy is available and may be offered with periodic assessment of oxygen saturation (Reference 27). Parents should learn about cardiopulmonary resuscitation techniques, signs of decompensation, equipment use, medication administration, and nutritional guidelines before discharge. Infants with BPD are at high risk of long-term pulmonary complications (Reference 62). They should receive routine vaccinations, including pneumococcal and influenza vaccines, and prophylaxis for respiratory syncytial virus with palivizumab (see Lower Respiratory Tract Infections chapter) (Reference 46).

#### CONCLUSIONS

The discovery of surfactant has significantly improved the morbidity and mortality of premature infants with RDS. Because of the improved survival of these infants, the rate of BPD has also increased (Reference 50). Although several strategies have been proposed to prevent and treat BPD, an evidence-based approach should be used when managing this vulnerable population. Future research should be aimed at identifying optimal treatment strategies to improve the long-term outcomes of premature infants with RDS and BPD.

# CHAPTER 13

## APNEA OF PREMATURITY

Kimberly Le Dinh, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. Describe the clinical presentation and pathophysiology of apnea of prematurity (AOP).
2. Identify nonpharmacologic approaches to the treatment of AOP.
3. Discuss the pharmacologic agents for the treatment of AOP.
4. Evaluate the risks and benefits of treatment modalities aimed at improving the clinical symptoms of infants with AOP.

### ABBREVIATIONS IN THIS CHAPTER

AOP	Apnea of prematurity
CPAP	Continuous positive airway pressure
CYP	Cytochrome P450
V/Q	Ventilation Perfusion

### INTRODUCTION

Apnea, a brief cessation of breathing lasting 5–10 seconds, is common in premature neonates as a manifestation of an immature respiratory control system (Reference 1). These episodes become pathologic when they are prolonged more than 20 seconds (Reference 2). Apnea of prematurity (AOP) is defined by the American Academy of Pediatrics as the “cessation of breathing for at least 20 seconds or as a briefer episode of apnea associated with bradycardia, cyanosis, or pallor” (Reference 3). Symptomatic neonates may have changes in hemodynamic, ventilation, and oxygenation parameters that are largely dependent on the duration of the apneic episodes (References 4–6). Apnea of prematurity has potentially life-threatening or severe neurodevelopmental consequences if left untreated (References 5, 7). Fortunately, nonpharmacologic and pharmacologic treatment strategies have made AOP a manageable condition of prematurity.

### EPIDEMIOLOGY

The exact incidence of AOP is unknown because a standardized criterion for the diagnosis of symptomatic apnea is not currently available. However, apnea occurs more frequently in premature neonates than in term neonates (Reference 8). It is estimated that 70% of premature neonates with a birth weight less than

1500 g will have at least one clinically observed episode of symptomatic apnea while admitted in the neonatal intensive care unit. Around 20% of these neonates will have an identified etiology, and the other 80% will have a nonspecific medical cause of apnea (Reference 9). Because of maturational development, the resolution of apneic episodes typically occurs before 37 weeks' postmenstrual age in neonates born after 28 weeks' gestation. However, infants born before 28 weeks' gestation may have frequent and persistent apnea after 37 weeks' postmenstrual age (References 8, 10). After 43 weeks' postmenstrual age, severe apneic events are rare and do not occur any more frequently in premature infants than in healthy term infants (Reference 11).

### PATHOPHYSIOLOGY

Three main components are required for normal rhythmic breathing in the neonate: (1) central respiratory drive, (2) maintenance of airway patency, and (3) adequate respiratory muscle function. Consequently, apnea in premature neonates can be precipitated by an immature central respiratory drive, a dysfunctional upper airway, and underdeveloped respiratory muscles (References 12, 13). An immature brainstem is the primary reason for hypoventilation and cyanotic episodes in an apneic premature neonate (Reference 14). Central respiratory control involves a complex interaction of sensory stimulation from the medulla of the brain. The chemoreceptor stimuli are transmitted through the afferent pathways to regulate the respiratory system. In AOP, there is either an improper transmission of these signals or a lack of appropriate respiratory pump control (References 9, 15, 16).

Maintaining airway patency is challenging in neonates because of immature neuromuscular function and reflexes in the upper airway. This results in nasal and hypopharyngeal airway obstruction leading to apnea (References 17, 18). Overall weakness in the muscles involved in respiration (diaphragm and intercostal muscles) and in the muscles that maintain upper airway patency (larynx and pharynx) can lead to impaired ventilation and oxygenation, resulting in apneic episodes. Because the respiratory system is immature, suck and swallow activity during feeding may also cause apnea and bradycardia. This is primarily because of inhibitory

reflexes triggered by laryngeal receptors (Reference 19). Furthermore, premature neonates have a reduced lung volume, triggering periods of hypoventilation or oxygen desaturation and apnea (Reference 6).

Prolonged apnea will cause a significant decrease in ventilation and subsequent decrease in heart rate. In very premature infants, apnea and bradycardia episodes may precede hypoventilation and oxygen desaturation (Reference 19). Ventilation-perfusion (V/Q) match is optimum when the ratio of volume of gas to volume of blood in the lungs is equal. Periods of hypoventilation could lead to V/Q mismatching, also resulting in oxygen desaturation. The relationship between apnea, oxygen desaturation, and bradycardia is schematically shown in Figure 1.

### CLASSIFICATIONS

The three classifications for apneic episodes are (1) central, (2) obstructive, and (3) mixed. The absence of airflow movement is observed with central apneas, whereas reduced or no airflow caused by upper airway obstruction is observed with obstructive apneas. Mixed apnea is a combination of these effects in which apnea follows airway obstruction with persistent inspiratory efforts (Reference 20). Apnea lasting longer than 20 seconds is very often accompanied by airway obstruction (Reference 21).

One study reviewed 2082 apneic episodes lasting more than 15 seconds in 47 infants younger than 34 weeks' gestational age with idiopathic AOP (Reference 22). The investigators identified that 40% of these episodes were central, 50% were mixed, and 10% were obstructive. A correlation existed with decreased oxygen

saturation and increased duration of apnea regardless of the type of apnea or treatment. Infants with central apneas had a higher incidence of bradycardia than infants having mixed or obstructive apneas.

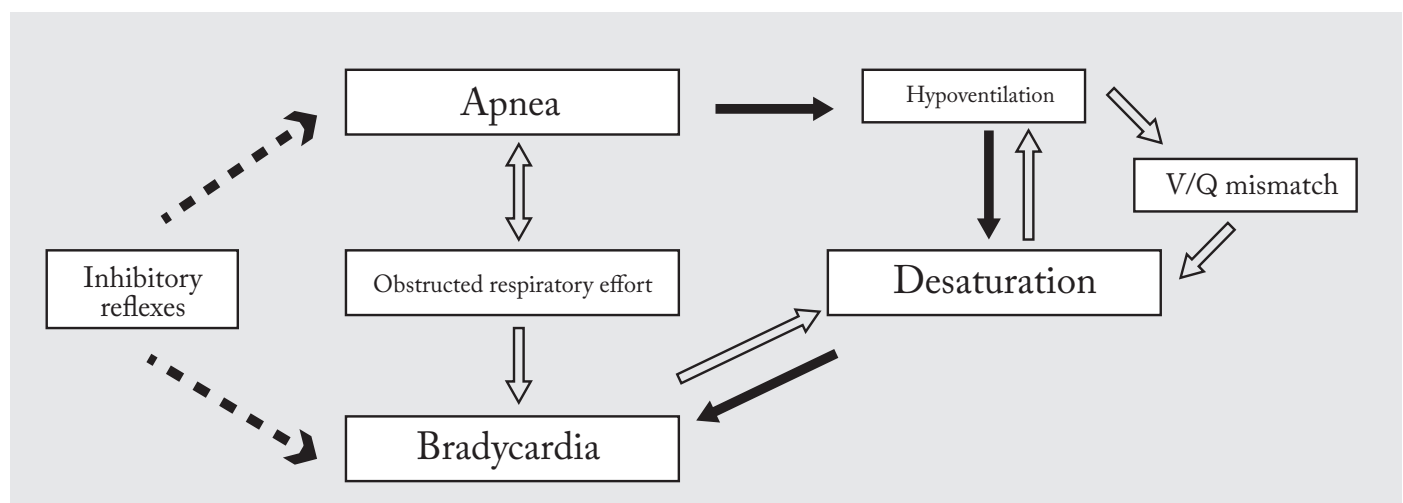

### CLINICAL PRESENTATION

Apnea of prematurity presents as a transient cessation in respiratory airflow. These short breathing pauses can persist for 5–20 seconds or more. After about 20 seconds of hypoventilation or apnea, the infant progresses to hypoxemia and ultimately bradycardia and cyanosis. Pallor and hypotonia may occur after 30–45 seconds of no airflow (Reference 23). All premature infants younger than 35 weeks' gestational age should be monitored for AOP within the first week of life.

Premature infants who are spontaneously breathing without mechanical respiratory support typically present with apnea on the first or second day of life. Infants who require mechanical ventilation at birth may not show symptoms of AOP until ventilator support is discontinued (Reference 24). Apnea presenting after the first week of life in infants who are spontaneously breathing or apnea recurring after 1–2 weeks of an apnea-free period is often associated with a serious underlying condition (such as sepsis or necrotizing enterocolitis), warranting a thorough evaluation for precipitating causes (Reference 10).

### DIAGNOSIS

No objective threshold criteria or diagnostic tests currently exist for the diagnosis of AOP. Consequently, the diagnosis is one of exclusion in which causes of secondary apnea should be excluded before initiating treatment

**Figure 1.** Pathogenesis of apnea of prematurity. Filled arrows represent the most common sequence.

Reprinted by permission from Macmillan Publishers Ltd: Mathew OP. Apnea of prematurity: pathogenesis and management strategies. *J Perinatol* 2001;31:302–10 (Reference 15).

for AOP (Reference 9). An extensive evaluation of apneic episodes is required to rule out other conditions (refer to Box 1) to accurately diagnose AOP (Reference 25). Pertinent patient history should include a review of maternal risk factors, medications, and birth history. Findings of lethargy, temperature instability, cyanosis, and respiratory distress are observed through a physical examination. Laboratory studies should include serum electrolytes to rule out metabolic disturbances, a complete blood cell count with differential and platelet count to rule out sepsis and anemia, and an arterial blood gas for evidence of hypoxia. A thorough workup is necessary to identify the precipitating cause of apnea, if present.

If apneic events are persistent and a specific cause has not been identified, electronic cardiorespiratory monitoring may be necessary (Reference 3). Individual apneic episodes are often detected by the presence of three primary symptoms: (1) apnea lasting greater than 20 seconds, (2) bradycardia based on cardiorespiratory monitoring, and (3) oxygen desaturation based on pulse oximetry (References 19, 20). Evaluation should also include an assessment of breathing regulation while the neonate is sleeping, feeding, and awake. The severity of AOP and the threshold for initiating or adjusting treatment depend on the frequency and severity of clinically observed apneic episodes (Reference 9).

## MONITORING AND EVALUATIONS

It is recommended that all premature neonates younger than 35 weeks' gestational age be monitored for at least 1 week after birth because of the higher risk of apneic episodes in this population (Reference 26). Cardiorespiratory monitoring should be performed while the neonate is in the hospital, with assessment during different phases of sleeping, feeding, and alertness. Tactile stimulation

**Box 1.** Risk factors for apnea in a neonate (Reference 6).

### Common Causes of Neonatal Apnea

- Prematurity
- Airway abnormalities
- Gastroesophageal reflux
- Hypoglycemia
- Impaired oxygenation
- Infection (sepsis, meningitis)
- Intracranial pathology (hemorrhage)
- Medications (opiates, general anesthesia)
- Metabolic disorders (acidosis, electrolyte disturbances)
- Maternal drugs (antepartum magnesium sulfate, opiates)
- Perinatal asphyxia
- Seizures
- Temperature instability

usually resolves most apneic episodes in premature neonates. However, some neonates may require assistance with ventilation using a bag and mask when they do not respond to stimulation (Reference 26).

## THERAPY GOALS

The primary goal of therapy is to decrease or eliminate the frequency of prolonged apnea lasting greater than 20 seconds or apnea associated with cyanosis and bradycardia. Other causes of apnea must be excluded, and the diagnosis of AOP should be made before initiating an individualized treatment. Treatment is warranted in premature neonates if apneic episodes are frequent and prolonged or if they are associated with hypoxemia and bradycardia (Reference 25). The premature neonate will usually require several weeks of therapy until lung function matures and apnea resolves (References 8, 10). Because apnea is multifactorial in pathophysiology and presentation, a single intervention may not be entirely efficacious, and both nonpharmacologic and pharmacologic therapies may be required for the treatment of AOP.

## NONPHARMACOLOGIC THERAPY

Because a potential cause of apneas is hypoxemia, it would be reasonable to initiate therapies to improve oxygenation. Supplemental oxygen works to decrease the frequency of hypoxic episodes (Reference 27). Although few approaches have been studied in clinical trials, oxygen saturations generally should be maintained between 85% and 95% to minimize the complications of oxygen toxicity such as retinopathy of prematurity (Reference 28). In addition, transfusion of red blood cells can increase the blood-carrying oxygen capacity, but this treatment approach remains controversial. Cohort studies reporting variable differences in the frequency, severity, or duration of apnea after a blood transfusion are conflicting (References 29, 30). However, blood transfusions may be considered if the infant also has other comorbidities such as anemia of prematurity, which is common among premature neonates. Therefore, the potential benefits gained from a transfusion should be outweighed against the complications and hazards of this therapy.

If the cause of apnea is airway obstruction and hypoventilation, strategies to maintain airway patency may be beneficial. For example, positions of extreme flexion or extension of the neck can contribute to upper airway obstruction; thus, they should be avoided (Reference 26). Nasal patency can be preserved by avoiding unnecessary nasal suctioning or nasogastric tubes. Other general measures include preventing reflexes that could trigger apnea and maintaining a stable environmental temperature using a radiant warmer or incubator (Reference 26).

Continuous positive airway pressure (CPAP), a method of assisted respiratory ventilation often administered with nasal prongs, is effective in decreasing the incidence of mixed and obstructive apnea by opening the upper airways (Reference 27). This method is most useful in neonates younger than 32–34 weeks' postmenstrual age and those with residual lung disease because these groups are most susceptible to pharyngeal collapse (References 27, 31, 32).

If clinically significant apneic episodes accompanied by bradycardia and cyanosis still occur despite optimal drug therapy and CPAP, endotracheal intubation and assisted ventilation may be required as a last-line therapy. This method is not often necessary for the treatment of AOP unless other illnesses such as sepsis or meningitis are present (Reference 26). If significant obstructive or mixed apneic episodes are unresolved, pharmacologic therapy aimed at treating central apneas is essential and should be used in conjunction with nonpharmacologic interventions.

## PHARMACOLOGIC THERAPY

### Methylxanthines

Methylxanthines, a group of purine alkaloids, have been the mainstay of therapy for AOP since the early 1970s (Reference 33). They stimulate the central respiratory drive to reduce the incidence of apneas and need for mechanical ventilation (References 9, 34). The most common agents include caffeine citrate, theophylline, and aminophylline (a theophylline salt). Controlled studies comparing aminophylline, theophylline, and caffeine have found them to be comparable in efficacy for the control of AOP (References 35, 36). However, caffeine remains the standard therapy because of its wide therapeutic index, ease of administration, tolerability, and limited adverse effects. Theophylline and aminophylline are rarely used in clinical practice but are potential alternatives if infants are refractory to caffeine therapy.

### *Mechanism of Action*

Although methylxanthines are frequently used and have been shown to be effective, their exact mechanism of action in the treatment of AOP is unclear. It is proposed that methylxanthines stimulate the central nervous system, increase carbon dioxide sensitivity, and enhance the force of diaphragmatic contraction (Reference 9). There is also some action on the cardiovascular system to increase cardiac output and heart rate while decreasing peripheral vascular resistance (Reference 37).

Methylxanthines are nonspecific inhibitors of adenosine and phosphodiesterase. Adenosine acts to depress the central respiratory drive. Because methylxanthine blocks the action of adenosine, the respiratory drive is

enhanced to reduce apneic episodes in neonates (Reference 38). Meanwhile, phosphodiesterase inhibition results in increased levels of cyclic adenosine monophosphate and cyclic guanine monophosphate to relax the airway (References 39, 40). The combined effects of adenosine and phosphodiesterase inhibition stimulates the central respiratory center to enhance ventilation and blood gas exchange, increase diaphragmatic contractility, and improve upper airway muscle tone (Reference 9).

### *Pharmacokinetics and Dosing*

Pharmacokinetic parameters vary widely in premature and term infants and exhibit high inter-individual variability due to developmental changes in metabolism and excretion (Reference 41). Caffeine and theophylline are extensively metabolized in the liver by cytochrome P450 (CYP) monooxygenases (CYP1A2) and xanthine oxidase (Reference 37). Metabolism is limited in premature infants because of an immature hepatic enzyme system, but it increases significantly with postnatal age. Metabolic interconversion of active metabolites has been observed in infants. An estimated 3% to 8% of administered caffeine is converted to theophylline, and 25% of administered theophylline is converted to caffeine (Reference 42).

Renal excretion is the primary mechanism of elimination for methylxanthines. In infants, around 80% of caffeine and its metabolite, theophylline, is excreted unchanged in the urine (References 43, 44). The half-life of each drug is highly variable and generally decreases in term infants and with postnatal age. Caffeine has an elimination half-life of 52–96 hours compared with theophylline, with a half-life of 17–43 hours in premature infants (References 42, 44, 45). The longer half-life of caffeine allows for once-daily dosing, which offers an advantage over the multiple-daily dosing required with theophylline and aminophylline. Most studies also recommend a loading dose followed by a maintenance dose. Table 1 lists additional dosing and pharmacokinetic differences between caffeine citrate, theophylline, and aminophylline in neonatal apnea.

### *Therapeutic Drug Monitoring*

Theophylline at the desired plasma concentrations of 6–12 mg/L provides an adequate clinical response in most infants, although lower concentrations of 3–4 mg/L have also been reported to be effective (Reference 46). The unbound fraction of theophylline is the pharmacologically active compound. Although a neonate and an adult may have the same total theophylline plasma concentration, the unbound concentration is generally higher in the neonate because of reduced protein binding. Therefore, measuring unbound serum

theophylline levels is recommended in neonates (Reference 47). The narrow therapeutic index requires frequent therapeutic drug monitoring of theophylline to prevent adverse effects or suboptimal therapy.

Theophylline plasma concentrations are recommended before and after a dosage adjustment, after treatment failure such as an increased frequency of apneas, or with evidence of toxicity (References 44, 45). Doses should be individualized on the basis of peak levels measured 30 minutes after the end of the bolus infusion and at steady-state concentration, usually after 3 days of therapy. Repeat levels are indicated around 3 days after each dosage titration or weekly if the infant is on a stable maintenance dose (Reference 45). Of importance, patient factors that could potentially affect the clearance and metabolism of theophylline should be carefully observed (Reference 48). For example, anticonvulsants such as phenytoin and phenobarbital are CYP-inducing agents that can decrease the plasma concentration of theophylline (Reference 49). Because of the substantial individual variability in pharmacokinetics, narrow therapeutic index, and severe toxicity profile with theophylline, therapeutic drug monitoring should be closely followed.

Caffeine, by contrast, exhibits a wide therapeutic index, with plasma concentrations ranging from 8 mg/L to 20 mg/L. Serious toxicities are rare but have been reported with concentrations greater than 40 mg/L to 50 mg/L (References 34, 50). Most infants are predicted to reach a therapeutic plasma concentration using the standard recommended caffeine citrate dosing

(Table 1). After an oral loading dose of caffeine citrate of 20 mg/kg in preterm neonates, the measured peak plasma concentration for caffeine ranged from 6 mg/L to 10 mg/L (Reference 42). In an observational study of 101 infants, a median caffeine maintenance dose of 5 mg/kg resulted in caffeine levels from 3 mg/L to 23.8 mg/L. About 95% of samples resulted in levels between 5 mg/L and 20 mg/L, and similar results were observed in patients with renal and liver dysfunction (Reference 51). If clinical response is lacking at high doses or toxicity is suggested, a therapeutic plasma concentration may be considered, but routine monitoring of concentrations is not typically necessary. The wide therapeutic index without the need to closely follow serum drug levels makes caffeine the therapy of choice for AOP.

### *Duration of Therapy*

The necessary duration of therapy is highly variable in neonates with AOP and is dependent on the maturity of the brainstem and respiratory control system. Caffeine therapy should be continued until there are no clinically observed apneic episodes for several consecutive days, which is generally observed before 37 weeks' postmenstrual age (References 9, 26). Because of the long elimination half-life, cardiorespiratory monitoring should continue for about 1 week after discontinuing therapy until the drug is completely eliminated from the body (Reference 26). Consider reinitiating therapy if apnea recurs soon after therapy discontinuation.

**Table 1.** Dosing and Pharmacokinetics of Caffeine, Theophylline, Aminophylline, and Doxapram in AOP (References 42, 44, 45)

	<b>Caffeine Citrate</b>	<b>Theophylline, Aminophylline</b>	<b>Doxapram</b>
Route of administration	Oral, intravenous	Oral, intravenous	Intravenous
Loading dose	20–25 (10–12.5 active base) mg/kg/dose	5–6 mg/kg/dose	2.5–3 mg/kg/dose
Maintenance dose	5–10 (2.5–5 active base) mg/kg/day	2–6 mg/kg/day	1 mg/kg/hour
Dosing interval	Every 24 hours	Every 8–12 hours	Continuous infusion
Therapeutic plasma concentration (mg/L)	8–20	6–12	Unknown
Toxic plasma concentration (mg/L)	> 50	> 15	Unknown
Elimination half-life (hours)	52–96	17–43	6–12
Signs of toxicity	Failure to gain weight Jitteriness Hyperreflexia Seizures	Restlessness Vomiting Arrhythmias	Hypertension Skeletal muscle hyperactivity

AOP = apnea of prematurity.

Note: When converting from intravenous to oral aminophylline, increase the dose by 20%. No dose change is required when converting from intravenous aminophylline to oral theophylline.

Clinicians will usually assess postmenstrual age, length of time since the last documented apneic episode, and general clinical status to determine when to discontinue therapy (Reference 9).

### *Adverse Effects*

Methylxanthines are generally a safe therapy if caffeine is prescribed within the usual recommended dosing range and theophylline plasma concentrations are carefully monitored. Adverse effects of methylxanthine treatment may include feeding intolerance, sinus tachycardia, diuresis, diaphoresis, and urinary calcium excretion. Severe toxicity can be manifested as hypertonia, cardiac failure, pulmonary edema, metabolic acidosis, and hyperglycemia (References 42, 44, 45). These adverse effects are more commonly observed with theophylline than with caffeine. In addition, dosing changes because of an adverse effect are less likely with caffeine therapy (Reference 52).

### *Caffeine for AOP Trials*

A landmark randomized controlled trial of caffeine citrate in 2006 infants with birth weights of 500–1250 g evaluated the short- and long-term safety and efficacy of methylxanthine therapy (Reference 53). Caffeine citrate was indicated for the prevention or treatment of AOP and the facilitation of endotracheal tube removal. Eligible patients received an intravenous loading dose of caffeine citrate of 20 mg/kg, followed by a maintenance dose of 5 mg/kg or normal saline. The daily maintenance dose was increased to a maximum of 10 mg/kg if apneas persisted. Caffeine was initiated at a median postmenstrual age of 28 weeks and discontinued before 35 weeks of age. The caffeine group discontinued adjunct nonpharmacologic treatments, such as mechanical ventilation and oxygen therapy, 1 week earlier than the placebo group. In addition, the frequency of bronchopulmonary dysplasia, a chronic lung disease of prematurity, was significantly reduced in the caffeine group, 36.3% compared with 46.9%.

The long-term follow-up study at 18–21 months included 937 infants in the caffeine group and 932 infants in the placebo group (Reference 54). Among the primary outcomes assessed were a composite of death, cerebral palsy, cognitive delay, deafness, or blindness at a corrected age of 18–21 months. Significantly fewer infants in the caffeine group died or survived with a neurodevelopmental disability compared with the placebo group (40.2% vs. 46.2%). Treatment with caffeine also showed a reduction in the incidence of cerebral palsy (4.4% vs. 7.3%) and cognitive delay (33.8% vs. 38.3%). There were no differences in rates of death, deafness,

and blindness or mean percentiles for height, weight, and head circumference at follow-up between the caffeine and placebo groups.

These trials provide strong evidence that caffeine citrate is a beneficial therapy for AOP. A loading dose of caffeine citrate followed by maintenance dosing has shown favorable short- and long-term outcomes with minimal adverse effects. It also improves survival without neurodevelopmental disability. Although aminophylline, theophylline, and caffeine show similar efficacy for the treatment of AOP, caffeine has been the most rigorously studied and is the mainstay treatment for AOP in clinical practice. It is the preferred pharmacologic treatment for its lower toxicity and longer half-life without the need for routine therapeutic drug monitoring.

### **Doxapram**

Doxapram is one of the first drugs investigated for the treatment of AOP. It is a potent respiratory stimulant that acts on peripheral chemoreceptors and the respiratory center in the medulla (Reference 9). Doxapram has been used in infants with AOP refractory to methylxanthine therapy. Early trials have shown doxapram to be effective in treating infants with neonatal apnea who are unresponsive to methylxanthine therapy (References 55, 56). However, these studies were small, and additional information is needed to define the role of doxapram in the treatment of AOP. The usual dosing for doxapram infusions ranges from 0.5 to 2 mg/kg/hour (Table 1). The lowest effective dose of doxapram should be used initially and titrated upward based on clinical response.

The commercially available intravenous formulation of doxapram contains benzyl alcohol, a preservative associated with a potentially fatal toxicity known as “gaspings syndrome” in neonates, and should be used with caution (Reference 57). Other important adverse effects include hypertension, seizures, cardiac conduction disorders, hypoglycemia, and gastric irritation (Reference 9). Overall, there is a paucity of data on the tolerability, efficacy, and pharmacokinetics of doxapram. Until larger, controlled trials are available, doxapram should not be used for the treatment of AOP (Reference 58).

### **DISCHARGE PLANNING**

Most premature neonates will have resolution of AOP symptoms at 34–36 weeks’ postmenstrual age (Reference 9). However, some infants, especially those at gestational ages younger than 28 weeks, may continue to have persistent apneic episodes beyond 38 weeks’ postmenstrual age when they may be otherwise ready for discharge (Reference 8). There are no defined treatment guidelines for these infants, but the goal is aimed at reducing the risk and incidence of the apneic episodes so that the infant may be cared for at home. A major dilemma in the

management of AOP is deciding whether to continue methylxanthine therapy after discharge or to delay discharge until apnea completely resolves. The decision to provide a home apnea monitor or to continue methylxanthine after discharge should be individualized for each patient. It is difficult to establish the minimum number of symptom- and treatment-free hospital days to ensure an absence of apneic episodes after discharge.

In a retrospective study of premature infants younger than 32 weeks' gestational age and weighing less than 1500 g at birth, the investigators observed that an 8-day absence of symptoms of apnea, bradycardia, and/or color change was a good predictor of AOP resolution (Reference 59). However, published literature does not clearly indicate whether hospital discharge should be delayed or whether AOP treatment and monitoring should be continued at home. The clinician should exert judgment when making this decision on the basis of the infant's history and presentation.

## CONCLUSIONS

Apnea is a significant problem for premature infants. Unfortunately, a standard treatment guideline for AOP is currently unavailable. A careful assessment of the infant is necessary to identify the etiology and an individualized treatment plan. Although several nonpharmacologic and pharmacologic treatment strategies exist, the clinician must carefully weigh the risks and benefits associated with each treatment modality. Caffeine is the optimal pharmacologic treatment strategy for AOP for its favorable pharmacokinetic safety profile and long-term outcomes. Infants treated with caffeine have fewer incidences of bronchopulmonary dysplasia and better neurodevelopmental outcomes. Apnea of prematurity can have an excellent prognosis with appropriate management and recognition of symptoms.

# CHAPTER 14

## PEDIATRIC ASTHMA

*Jeffrey L. Wagner, Pharm.D., MPH, BCPS*

### LEARNING OBJECTIVES

1. Define asthma and describe its epidemiologic prevalence on the basis of risk factors, genetics, and population characteristics.
2. Explain the underlying pathology that results in disordered lung function and recognize the associated symptoms and diagnostic criteria of asthma.
3. Classify asthma on the basis of severity and control to develop an approach to effective management.
4. Evaluate nonpharmacologic and pharmacologic therapies for their effect and mechanism in reducing impairment and risk of asthma.
5. Develop an understanding of available therapy and appropriate use of delivery devices to maximize therapeutic outcomes and medication safety and to reduce risk of asthma.

### ABBREVIATIONS IN THIS CHAPTER

FEV <sub>1</sub>	Forced expiratory volume in 1 second
ICS	Inhaled corticosteroids
IgE	Immunoglobulin E
LABA	Long-acting $\beta$ -agonist
NAEPP	National Asthma Education and Prevention Program
SABA	Short-acting $\beta$ -agonist

### INTRODUCTION

Asthma, the most common chronic disease in childhood, is an inflammatory disease of the airways caused by a complex interaction of factors. Asthma is characterized by symptoms occurring in paroxysms that are usually related to specific triggering events, airway narrowing that is partly or completely reversible, and increased airway responsiveness to a variety of stimuli (Reference 1). Inflammation and airflow obstruction, which are often reversible, cause episodes of cough, wheezing, dyspnea, and chest tightness. Despite the long history since the disease was first recognized, the development of a greater understanding of asthma etiology and treatment has recently occurred.

In 1991, the National Heart, Lung, and Blood Institute of the National Institutes of Health published the first Expert Panel Report on asthma, which established guidelines for asthma diagnosis and management. Significant advances have been made since the release of the first clinical practice guidelines, with a decline in the number of deaths caused by asthma despite increasing prevalence, decrease in reports of activity limitation by patients with asthma, and increased proportion of people with asthma who receive formal patient education (Reference 2). Despite advances in and availability of medical interventions that help prevent morbidity and improve quality of life, the unknown cause, complex disease development, and the burden of prevalence, resource use, and mortality continue to pose a significant problem in public health.

### EPIDEMIOLOGY

The epidemiology of asthma is difficult to define given the lack of a standard definition and methods used to identify affected individuals in epidemiologic studies (Reference 3). Despite these epidemiologic challenges and the wide global variation in the prevalence of asthma, it is one of the leading chronic childhood diseases in the United States (Reference 4).

### Asthma Prevalence and Mortality

The recent estimated worldwide asthma prevalence is 7% to 10%, with more than 300 million people affected. Prevalence has more than doubled from 1980 to the mid-1990s in the United States alone according to available and published data, with the number of children who currently have asthma in the United States estimated to be 7.1 million (Reference 5).

Asthma prevalence across the world is disparate, with a trend toward higher prevalence in developed countries. Although westernization may account for some of the differences in prevalence by country, these differences may be explained by variability in genetic, social, and environmental risk factors (Reference 6).

Asthma leads to about 250,000 deaths worldwide each year. Annual death rate from asthma in the United States increased from 1982 to 1995, but it has declined each year since, according to surveillance and epidemiologic data (Reference 7).

## Demographic Characteristics

Among children aged 0–17, asthma affects more males than females (11.3% vs. 7.9%, respectively). Asthma prevalence increases with age, though health care use is highest among the youngest children (Reference 7). The racial disparity in asthma prevalence and health care resource use is extensive. Black and Puerto Rican children have the highest prevalence rates compared with children of other races, whereas Asian children have the lowest prevalence rates. The higher rates of emergency department visits, hospitalizations, and deaths among minority children have been well documented. The disparity in asthma mortality between black and white children has increased in recent years, with black children having higher mortality rates (Table 1).

## ETIOLOGY

### Pathophysiology

Asthma is a complex, inflammatory disease process with physiologic reduction in airway luminal diameter, which is critical to the flow of air in the lungs. The relationship between luminal diameter and resistance can be explained with Poiseuille's law, which is based on the physical principle that resistance is inversely proportional to flow; therefore, the greater the resistance, the less the flow.

Poiseuille's law

$$R = \frac{8nl}{\pi r^4}$$

$R$  = resistance  
 $n$  = viscosity of air  
 $l$  = length of tube  
 $r$  = radius of tube

Given that the viscosity of air ( $n$ ) and the length of the tube ( $l$ ) remain relatively constant in the lung, the radius ( $r$ ) has a dramatic effect on resistance to airflow. For example, if there is a 50% decrease in the radius of an airway, the resistance to airflow increases by a factor of 16. Therefore, Poiseuille's law is paramount to understanding the impact of the inflammatory processes and airway narrowing in asthma on airflow.

The pathophysiology of asthma is characterized by airway and bronchial hyperresponsiveness, bronchoconstriction, and airway inflammation involving inflammatory cells and mediators (Reference 1). Airway and bronchial hyperresponsiveness, defined as the degree to which airways narrow in response to a nonspecific stimulus or an environmental trigger, correlates with asthma severity in children (References 7–9). Reversible bronchoconstriction and bronchospasm result from bronchial smooth muscle contraction in response to a variety of stimuli. The episodic and sudden onset of bronchoconstriction is commonly referred to as an “asthma attack,” the dominant physiologic event leading to clinical

symptoms. The continuous underlying airway inflammation has a central role in the disease pathophysiology, causing epithelial cell damage and increased mucosal permeability (References 10–12). Airway inflammation is evidenced by the presence of inflammatory cells (neutrophils, eosinophils, T lymphocytes, alveolar macrophages, and mast cells); mediators (leukotrienes, histamine, prostaglandins, thromboxanes, platelet-activating factor, and adhesion molecules found in bronchoalveolar lavage fluid); immunoglobulin E (IgE) antibodies, which are linked to the progression of lung disease; and exaggerated inflammatory response, which is associated with impaired glutathione homeostasis, a biomarker of oxidant stress (References 13–15).

In addition, many pathologic changes are reflected in the sputum, including Charcot-Leyden crystals (eosinophil remnants), Curschmann spirals (airway lumen casts of exudate), and Creola bodies (clumps of sloughed epithelial cells) (Reference 16). A histologic examination of asthmatic lungs shows hyperplasia and hypertrophy of airway smooth muscle, increased airway wall thickness, and mucous gland hypertrophy and mucus hypersecretion.

### Genetic Basis

Complex interactions between genetics and environmental influences contribute to asthma as an inflammatory disease. Epidemiologic studies suggest a genetic predisposition to asthma development because twins and families show patterns of disease consistent with heritable factors (References 17–19). In fact, studies of twins suggest that genetic factors account for 50% of susceptibility (Reference 20). Some components of the asthma phenotype appear strongly heritable, although the genes responsible for these components remain to be identified, and inheritance does not follow the mendelian pattern of genetics. The genetic predisposition for developing an IgE-mediated response to common aeroallergens, known as atopy, remains the strongest identifiable predisposing factor for developing asthma (Reference 1). The hygiene hypothesis states that lack of exposure to infectious agents and microorganisms in early childhood increases the susceptibility to allergic diseases, including asthma, by suppressing appropriate immune system development and response.

### Risk Factors for Disease

The host and environment play a significant role in the risk of developing asthma. Table 2 lists the host factors and environmental factors that have been associated with asthma development (References 1, 5, 21–25).

**Table 1.** Asthma Prevalence and Mortality Among Children 0–17 Years of Age by Race and Ethnicity, United States, 2003–2005

Race and Ethnicity	Current Prevalence, % (2004–2005)	Deaths per 1,000,000 (2003–2004)
Race only		
White	7.9	1.5
Black	12.8	9.0
American Indian or Alaska Native	9.9	–
Asian	4.9	–
Race/ethnicity		
Hispanic	7.8	1.8
Puerto Rican	19.2	–
Mexican	6.4	1.7
Non-Hispanic white	8.0	1.3
Non-Hispanic black	12.7	9.2
Total	8.7	2.6

– = no data.

**Table 2.** Factors Associated with Asthma

Host Factors	Environmental Factors
<ul style="list-style-type: none"> <li>▪ Genetics</li> <li>▪ Innate immunity               <ul style="list-style-type: none"> <li>○ Atopy – rhinitis and dermatitis</li> <li>○ Hygiene hypothesis – lack of early childhood infection modifies immune response and reduces tendency to produce IgE antibodies to environmental allergens</li> </ul> </li> <li>▪ Race/ethnicity</li> <li>▪ Sex</li> </ul>	<ul style="list-style-type: none"> <li>▪ Urbanization and socioeconomic status</li> <li>▪ Allergens: house dust mites, animal proteins (cat and dog allergens), cockroaches, fungi</li> <li>▪ Endotoxin exposure – inflammatory lipopolysaccharide molecules from gram-negative bacteria</li> <li>▪ Respiratory infections – particularly viral infections (RSV and rhinovirus)</li> <li>▪ Others: tobacco smoke, pollutants (may be caused by specific pollutants [CO, NO<sub>2</sub>, SO<sub>2</sub>])</li> </ul>

IgE = immunoglobulin E; RSV = respiratory syncytial virus.

In addition to the risk factors for disease, predictors of asthma include family history of asthma, eczema, and/or smoking; history of allergic rhinitis, sinusitis, nasal polyps, eczema, or bronchopulmonary dysplasia; and recurrent cough, bronchitis, and bronchiolitis (References 1, 26–28).

## CLINICAL PRESENTATION AND DIAGNOSIS

### Signs and Symptoms

The symptoms of asthma result from airflow obstruction and the cumulative effects of smooth muscle constriction around airways, airway wall edema, intraluminal mucus accumulation, inflammatory cell infiltration of the submucosa, and basement membrane thickening (References 10–12). Inflammation causes recurrent

episodes of dyspnea, cough, and wheezing that can be nonspecific, making asthma difficult to distinguish from other respiratory diseases in the pediatric patient. Older children may experience shortness of breath and chest tightness, whereas younger children may have nonfocal chest pain. In addition, younger children may have more subtle symptoms such as decreased physical activity, general fatigue, and difficulty keeping up with peers.

Asthma exacerbations are associated with widespread but variable airflow obstruction and are often reversible with or without treatment. Life-threatening asthma is a constellation of symptoms that can occur in any patient with asthma; these symptoms include the following (Reference 1):

- Marked chest tightness
- Wheezing, severe shortness of breath

- Retractions
- Cyanosis
- Inability to speak or speak in sentences because of dyspnea
- Hunched posture
- Altered mental status (agitation, anxiety, lethargy)

## DIAGNOSTIC CRITERIA

The initial diagnosis of asthma in children is often difficult and requires the exclusion of other diagnoses. Clinical history or presence of respiratory symptoms consistent with asthma, combined with the demonstration of variable expiratory airflow obstruction is required for the diagnosis of asthma. Asthma diagnostic criteria include history, physical examination, pulmonary function testing, and laboratory evaluations (Reference 1). Comorbid conditions associated with asthma include gastroesophageal reflux disease, obstructive sleep apnea, obesity, rhinitis, and sinusitis (References 1, 29, 30).

A detailed clinical history involves assessing the patient for cough, wheeze, shortness of breath, and/or chest tightening that occurs in an “episodic” fashion. These symptoms may occur or worsen with exercise, weather changes, night hours, viral infection, inhalant trigger exposure (smoke, fur, dust mites, mold, pollen), irritant trigger exposure (e.g., airborne chemicals [aerosols], smoke), strong emotional expressions (laughing, crying), and menstrual cycles (References 1, 31–34).

The physical examination should assess for severity of respiratory symptoms; rhinitis, increased nasal secretions, mucosal swelling, or nasal polyps; and presence of airflow obstruction or airway hyperresponsiveness that is partly reversible (e.g., spirometry shows a percent change in forced expiratory volume in 1 second [FEV<sub>1</sub>] of 12% or more from baseline or 10% or more of predicted after the patient inhales a short-acting bronchodilator) (References 1, 35). To establish the diagnosis and facilitate severity assessment, the National Asthma Education and Prevention Program (NAEPP) recommends spirometry in children older than 5 years. In infants and children younger than 5 years, the diagnosis centers on the same evaluation as discussed, although spirometry often cannot be performed in this age group because of developmental ability (e.g., ability to breathe in and exhale fully). Debate is ongoing about how best to diagnose and classify infants and young children with recurrent wheezing.

Tests to exclude other diagnoses when the history and physical examination are equivocal include a chest radiograph, bronchoprovocation test, and allergen testing (eosinophilia, total IgE, rarely aspergillosis) (Reference 1).

## Disease Course and Prognosis

The progression of asthma is marked and measured by decline in lung function (Reference 1). Reduction in the FEV<sub>1</sub>/forced vital capacity ratio is evidenced in children who have mild or moderate asthma compared with children who do not have asthma. According to longitudinal epidemiologic studies and clinical trials, the characteristic decline in lung function varies by age group. Children with symptoms before 3 years of age show a decline in lung function growth by 6 years of age, but children 5–12 years of age who have mild or moderate persistent asthma usually have no decline in lung function through 17 years of age, although a subset of children experience progressive reductions in lung growth.

In addition to the natural progression of asthma, other factors place patients at risk of asthma-related death. These include comorbid conditions such as heart or lung disease; previous severe exacerbation (e.g., intubation or intensive care unit admission); two or more hospitalizations or more than three emergency department visits in the past year; use of more than one canister of short-acting  $\beta$ -agonist (SABA) per month; difficulty perceiving airway obstruction or the severity of worsening asthma (parent and/or child); low socioeconomic status or inner-city residence; illicit drug use; and major psychosocial problems or psychiatric disease (References 1, 36).

## Asthma Severity and Control

Asthma severity is determined by a constellation of impairment and risk and is defined along a continuum from intermittent, mild persistent, moderate persistent, and severe persistent asthma. In addition to patient history, the tools used to assess severity through measures of lung function are performed by spirometry for children 5 years and older (FEV<sub>1</sub>), pulmonary function testing, and airway hyperresponsiveness testing using methacholine (References 1, 35). A patient’s level of control is determined at follow-up visits on a scale of well, poorly, and very poorly controlled as well as on the basis of the domains of impairment and risk. Asthma severity and control are used to determine the recommended step for initial and stepwise therapy, which are discussed in the subsequent “Treatment” section of this chapter.

## TREATMENT

### Therapy Goals

The NAEPP has defined the primary goal of asthma management as “asthma control,” which involves a reduction in both impairment and risk (Reference 1).

The reduction in frequency and severity of asthma exacerbations and long-term sequelae should be achieved by maintaining asthma control with the fewest therapeutic interventions possible. Intensive education and monitoring are required in caring for all children with asthma and are discussed further in sections below (References 1, 22, 23, 37).

### Nonpharmacologic Therapy

The primary principles of nonpharmacologic therapy and cornerstone to asthma management are patient/caregiver education and self-management. Nonpharmacologic therapy seeks to control exposure to environmental factors, reduce risk from comorbid conditions, and allow appropriate use of therapy and health care resources. Evidence suggests that educational interventions improve asthma outcomes. Table 3 lists the key components to asthma education (References 1, 37–39).

Other suggested nonpharmacologic therapies include breathing techniques (Buteyko breathing technique, Papworth method, and yoga breathing [pranayama]), acupuncture, relaxation techniques (meditation,

biofeedback, hypnosis, and progressive muscle relaxation), herbal remedies (butterbur, dried ivy, and ginkgo extract), omega-3 fatty acids, and homeopathy, though not well established (Reference 1).

### Pharmacologic Therapy

Pharmacologic therapy is used to prevent and control asthma symptoms, improve quality of life, reduce the frequency and severity of asthma exacerbations, and reverse airflow obstruction. Tables 4–6, adapted from the NAEPP Guidelines for the Diagnosis and Management of Asthma, show the classification of asthma severity and assessment of asthma control, each of which guide therapy initiation and subsequent stepwise adjustment of medications for asthma management (Reference 1). To initiate pharmacologic therapy, asthma severity is first classified into intermittent or persistent asthma (Table 4) on the basis of symptoms during the specified time. On the basis of the severity classification, the appropriate step for therapy initiation is determined. Then, on the basis of an assessment of asthma control (Table 5), an action for treatment is recommended within the stepwise management approach. The specific

Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health, 2007 (Reference 1).

**Table 4.** Classifying Asthma Severity and Initiating Therapy

Components of Severity		Persistent			
		Intermittent	Mild	Moderate	Severe
Impairment	Symptoms	≤ 2 days/week	> 2 days/week	Daily	Throughout the day
	Nighttime awakenings	< 5 years: 0  ≥ 5 years: ≤ 2×/month	< 5 years: 1 or 2×/month  ≥ 5 years: 3 or 4×/month	< 5 years: 3 or 4×/month  ≥ 5 years: > 1×/week	< 5 years: > 1×/week  ≥ 5 years: Often 7×/week
	SABA use for symptoms	≤ 2 days/week	> 2 days/week	Daily	Several times per day
	Limitation of normal activity	None	Minor	Some	Extreme
	Lung function <sup>a</sup>	5–11 years: FEV <sub>1</sub> > 80% FEV <sub>1</sub> /FVC > 85%  ≥ 12 years: FEV <sub>1</sub> > 80% FEV <sub>1</sub> /FVC normal	5–11 years: FEV <sub>1</sub> ≥ 80% FEV <sub>1</sub> /FVC > 80%  ≥ 12 years: FEV <sub>1</sub> ≥ 80% FEV <sub>1</sub> /FVC normal	5–11 years: FEV <sub>1</sub> 60% to 80% FEV <sub>1</sub> /FVC 75% to 80%  ≥ 12 years: FEV <sub>1</sub> 60% to 80% FEV <sub>1</sub> /FVC reduced by 5%	5–11 years: FEV <sub>1</sub> < 60% FEV <sub>1</sub> /FVC < 75%  ≥ 12 years: FEV <sub>1</sub> < 60% FEV <sub>1</sub> /FVC reduced > 5%
Risk	Exacerbations requiring oral corticosteroids <sup>b</sup>	0–1×/year	< 5 years: ≥ 2× in 6 months requiring steroids <i>or</i> ≥ four wheezing episodes a year and lasting > 1 day AND risk factors for persistent asthma  ≥ 5 years: ≥ 2×/year		
Recommended Step for Initiating Therapy (see Table 6)		Step 1	Step 2	Step 3	< 5 years: Step 3  5–11 years: Step 3 or 4  ≥ 12 years: Step 4 or 5

<sup>a</sup>Note that some individuals with smaller lungs in relation to their height may NORMALLY have FEV<sub>1</sub> < 80% and/or FEV<sub>1</sub>/FVC < 85%. Lung function measures should be correlated with clinical assessment of asthma severity.

<sup>b</sup>For initial therapy of moderate or severe persistent asthma, consider short course of oral corticosteroids.

FEV<sub>1</sub> = forced expiratory volume in 1 second; FVC = forced vital capacity; SABA = short-acting β-agonist.

Adapted from National Heart, Lung, and Blood Institute, National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, Full Report. Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health, 2007 (Reference 1).

step of therapy gives a preferred and alternative treatment for various age groups (Table 6). When following the stepwise approach to therapy, monotherapy is typically initiated; however, it would be reasonable to prescribe a combination product to achieve asthma control.

It is also important to assess the severity of exacerbations because this implicates the clinical course as well as the outcomes (Table 7 and Table 8) (Reference 1). The management of exacerbations depends on the severity, identification of triggers and management of control measures, and therapy initiation and adjustment

as appropriate (Table 9) (Reference 1). Management of an asthma exacerbation may occur at home, in the physician's office, or in an urgent care or in-hospital setting. Step therapy can be resumed after recovery from an exacerbation.

Several medications are used in the treatment of asthma and exacerbations. Table 10 and Table 11 provide an overview of the classes of medications, including mechanism of action, indication, and adverse effects, as well as medication dosing based on age category (Reference 1).

**Table 5.** Assessing Control and Adjusting Therapy

Components of Control		Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Symptoms	≤ 2 days/week	< 5 years: > 2 days/week  5–11 years: >2 days/week or several times on ≤ 2 days/week  ≥ 12 years: > 2 days/week	Throughout the day
	Nighttime awakenings	< 12 years: ≤ 1×/month  ≥ 12 years: ≤ 2×/month	< 5 years: > 1×/month  5–11 years: ≥ 2×/month  ≥ 12 years: 1–3×/week	< 5 years: > 1×/week  5–11 years: ≥ 2×/week  ≥ 12 years: ≥ 4×/week
	Interference with normal activity	None	Some limitation	Extremely limited
	SABA use for symptoms	≤ 2 days/week	>2 days/week	Several times per day
	Lung function <sup>a</sup>	5–11 years FEV <sub>1</sub> > 80% FEV <sub>1</sub> /FVC > 80%  ≥ 12 years: FEV <sub>1</sub> >80%	5–11 years: FEV <sub>1</sub> 60% to 80% FEV <sub>1</sub> /FVC 75% to 80%  ≥ 12 years: FEV <sub>1</sub> 60% to 80%	5–11 years: FEV <sub>1</sub> < 60% FEV <sub>1</sub> /FVC < 75%  ≥ 12 years: FEV <sub>1</sub> < 60%
Risk	Exacerbations requiring OCS <sup>b</sup>	0–1×/year	< 5 years: 2–3×/year  ≥ 5 years: ≥ 2×/year	< 5 years: > 3×/year  ≥ 5 years: ≥ 2×/year
	Reduction in lung growth	Requires long-term follow-up		
	Treatment-related adverse effects	Medication adverse effects do not correlate with specific levels of control, but they should be considered in overall assessment of risk.		
Recommended Action for Treatment (see Table 6)		Consider step-down if well controlled for ≥ 3 months	Step up 1 step. Reevaluate in 2–6 weeks.	Consider short-course oral corticosteroid. Step up 1 or 2 steps. Reevaluate in 2 weeks.

<sup>a</sup>Note that some individuals with smaller lungs in relation to their height may NORMALLY have FEV<sub>1</sub> < 80% and/or FEV<sub>1</sub>/FVC < 85%. Lung function measures should be correlated with clinical assessment of asthma severity.

<sup>b</sup>For initial therapy of moderate or severe persistent asthma, consider short course of oral corticosteroids.

FEV<sub>1</sub> = forced expiratory volume in 1 second; FVC = forced vital capacity; OCS = oral corticosteroids; SABA = short-acting β-agonist.

Adapted from National Heart, Lung, and Blood Institute, National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, Full Report. Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health, 2007 (Reference 1).

**Table 6.** Stepwise Approach to Asthma Management

	Preferred treatment(s)	Alternative treatment(s)
<b>Step 1</b>	SABA PRN	
<b>Step 2</b>	Low-dose ICS	<p>&lt; 5 years: Cromolyn <i>or</i> montelukast</p> <p>≥ 5 years: Cromolyn, nedocromil, LRTA, or theophylline</p>
<b>Step 3</b>	<p>&lt; 5 years: Medium-dose ICS</p> <p>5–11 years: Low-dose ICS + LABA, LTRA, or theophylline <i>OR</i> Medium-dose ICS</p> <p>≥ 12 years: Low-dose ICS + LABA <i>OR</i> Medium-dose ICS</p>	<p>≥ 12 years: Low-dose ICS + LRTA, theophylline, or zileuton</p>
<b>Step 4</b>	<p>&lt; 5 years: Medium-dose ICS + either LABA or montelukast</p> <p>≥ 5 years: Medium-dose ICS + LABA</p>	<p>5–11 years: Medium-dose ICS + either LTRA or theophylline</p> <p>≥ 12 years: Medium-dose ICS + LRTA, theophylline, or zileuton</p>
<b>Step 5</b>	<p>&lt; 5 years: High-dose ICS + either LABA or montelukast</p> <p>5–11 years: High-dose ICS + LABA</p> <p>≥ 12 years: High-dose ICS + LABA <i>AND</i> consider omalizumab for patients who have allergies</p>	<p>5–11 years: High-dose ICS + either LRTA or theophylline</p>
<b>Step 6</b>	<p>&lt; 5 years: High-dose ICS + oral systemic corticosteroids + either LABA or montelukast</p> <p>5–11 years: High-dose ICS + LABA + oral systemic corticosteroids</p> <p>≥ 12 years: High-dose ICS + LABA + oral systemic corticosteroids <i>AND</i> consider omalizumab for patients who have allergies</p>	<p>5–11 years: High-dose ICS + either LRTA or theophylline + oral systemic corticosteroids</p>

Note: The stepwise approach is meant to assist in, not replace, clinical decision-making. If clear benefit is not observed within 4–6 weeks when patient technique and adherence are satisfactory, consider adjusting therapy and/or consider alternative diagnoses. Before increasing a step, review patient adherence, inhaler technique, environmental control, and comorbid conditions. When possible, step down if asthma is well controlled for at least 3 months.

ICS = inhaled corticosteroids; LABA = long-acting  $\beta$ -agonist; LTRA = leukotriene receptor antagonist; PEF = peak expiratory flow; PRN = as needed; SABA = short-acting  $\beta$ -agonist.

Adapted from National Heart, Lung, and Blood Institute, National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, Full Report. Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health, 2007 (Reference 1).

**Table 7.** Classifying the Severity of Asthma Exacerbations

	<b>Signs and Symptoms</b>	<b>Initial PEF (or FEV<sub>1</sub>)<sup>a</sup></b>	<b>Clinical Course</b>
<b>Mild</b>	Dyspnea only with activity (assess tachypnea in young children)	PEF ≥ 70% of predicted or personal best	<ul style="list-style-type: none"> <li>▪ Usually cared for at home</li> <li>▪ Prompt relief with inhaled SABA</li> <li>▪ Possible short course of oral systemic corticosteroids</li> <li>▪ May consider early escalation to high-dose inhaled corticosteroid</li> </ul>
<b>Moderate</b>	Dyspnea interferes with or limits usual activity	PEF 40% to 69% of predicted or personal best	<ul style="list-style-type: none"> <li>▪ Usually requires office or EC visit</li> <li>▪ Relief from frequent inhaled SABA</li> <li>▪ Oral systemic corticosteroids</li> <li>▪ Some symptoms last for 1–2 days after treatment is begun</li> </ul>
<b>Severe</b>	Dyspnea at rest; interferes with conversation	PEF < 40% of predicted or personal best	<ul style="list-style-type: none"> <li>▪ Usually requires emergency department visit and likely hospitalization</li> <li>▪ Partial relief from frequent inhaled SABA</li> <li>▪ Oral systemic corticosteroids; some symptoms last for &gt; 3 days after treatment is begun</li> <li>▪ Adjunctive therapies are helpful</li> </ul>
<b>Life Threatening</b>	Too dyspneic to speak; perspiring	PEF < 25% of predicted or personal best	<ul style="list-style-type: none"> <li>▪ Requires emergency department hospitalization; possible ICU</li> <li>▪ Minimal or no relief from frequently inhaled SABA</li> <li>▪ Intravenous corticosteroids</li> <li>▪ Adjunctive therapies are helpful</li> </ul>

<sup>a</sup>Note that some individuals with smaller lungs in relation to their height may NORMALLY have FEV<sub>1</sub> < 80% and/or FEV<sub>1</sub>/FVC < 85%. Lung function measures should be correlated with clinical assessment of asthma severity. For infants, assessment depends primarily on physical examination (use of accessory muscles, inspiratory and expiratory wheezing, paradoxical breathing, cyanosis, and a respiratory rate > 60 breaths/minute are key signs of serious distress), although objective measurements, such as oxygen saturation < 90%, also indicate serious distress.

EC = emergency center; FEV<sub>1</sub> = forced expiratory volume in 1 second; FVC = forced vital capacity; PEF = peak expiratory flow; SABA = short-acting  $\beta_2$ -agonist; ICU = intensive care unit.

Adapted from National Heart, Lung, and Blood Institute, National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, Full Report. Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health, 2007 (Reference 1).

### $\beta_2$ -Agonists

The  $\beta_2$ -agonists are the most effective drugs in reversing bronchoconstriction and relaxing airway smooth muscle. Delivery of these medications directly to the airway by inhalation enhances broncho-selectivity, provides a more rapid response, and protects against triggers of bronchospasm. The SABAs—albuterol, levalbuterol, metaproterenol, terbutaline, and pirbuterol—have an onset of action within 1–5 minutes and bronchodilation that lasts 2–6 hours. Although their  $\beta_2/\beta_1$  potency ratios vary, they are all selective for the  $\beta_2$  subtype. There is little evidence that intravenous terbutaline has an added benefit for acute exacerbations compared with SABAs, corticosteroids, and ipratropium. Two of the long-acting  $\beta_2$ -agonists (LABAs), formoterol and salmeterol, have higher lipophilicity compared with the SABAs, which regulate

the diffusion rate from the receptor (Reference 41). The LABAs are used with inhaled corticosteroids (ICS) to prevent symptoms and do not provide quick relief of symptoms. Given the frequency of use of LABAs and ICS, several products combine the two classes of medication into one delivery device.

### Corticosteroids

Corticosteroids have long been employed to treat severe chronic asthma and severe exacerbations by the systemic route, but the development of aerosol formulations has allowed improved safety to extend their use in the treatment of persistent asthma. Evidence suggests that currently available therapy controls, but does not modify, the underlying disease process, and evidence supports the immediate use of systemic steroids during an exacerbation (References 1, 42–45).

**Table 8.** Formal Evaluation of Asthma Exacerbation Severity

	Mild	Moderate	Severe	Imminent Risk of Respiratory Arrest
<b>Symptoms</b>				
Breathlessness	While walking Can lie down	While at rest (infant - softer, shorter cry, difficulty feeding) Prefers sitting	While at rest (infant stops feeding) Sits upright	
Talks in	Sentences	Phrases	Words	
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
<b>Signs</b>				
Respiratory rate	Increased Guide to rates of breathing in awake children: <i>Age</i> < 2 months 2–12 months 1–5 years 6–8 years	Increased <i>Normal rate</i> < 60/minute < 50/minute < 40/minute < 30/minute	Often > 30/minute	
Use of accessory muscles	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheeze	Moderate; often only end expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absence of wheeze
Heart rate/minute	< 100 Guide to normal heart rates in children: <i>Age</i> 2–12 months 1–2 years 2–8 years	100–120 <i>Normal rate</i> < 160/minute < 120/minute < 110/minute	> 120	Bradycardia
Pulsus paradoxus	Absent < 10 mm Hg	May be present 10–25 mm Hg	Often present > 25 mm Hg (adult) 20–40 mm Hg (child)	Absence suggests respiratory muscle fatigue
<b>Functional Assessment</b>				
PEF % of predicted or % of personal best	≥ 70%	Around 40% to 69% or response lasts < 2 hours	< 40%	< 25% Note: PEF testing may not be needed in very severe attacks.
Pao <sub>2</sub> (on air)	Normal (test not usually necessary)	≥ 60 mm Hg (test not usually necessary)	< 60 mm Hg: possible cyanosis	
and/or Pco <sub>2</sub>	< 42 mm Hg (test not usually necessary)	< 42 mm Hg (test not usually necessary)	≥ 42 mm Hg: possible respiratory failure	
Sao <sub>2</sub> % (on air) at sea level	> 95% (test not usually necessary) Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.	90% to 95% (test not usually necessary)	< 90%	

PEF = peak expiratory flow.

Adapted from National Heart, Lung, and Blood Institute, National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, Full Report. Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health, 2007 (Reference 1).

### *Methylxanthines*

Methylxanthines are ineffective when aerosolized; they must therefore be administered systemically for effect. Theophylline is primarily eliminated through metabolism by the hepatic cytochrome P450 (CYP) mixed-function oxidase microsomal enzymes, primarily the CYP1A2 and CYP3A3 isozymes. The inhibition and induction of the hepatic CYP enzymes by environmental factors and drugs alter the metabolism of theophylline, necessitating a review of potential interactions. In addition, intra-patient variability in theophylline clearance is considerable; thus, serum theophylline concentrations should be monitored routinely.

### *Anticholinergics*

Anticholinergic medications are effective bronchodilators but are not as potent as  $\beta_2$ -agonists. The use of ipratropium bromide during acute exacerbations in the emergency department setting is well supported by evidence; however, there is evidence against their routine use as well as their use for in-hospital care (References 46, 47).

### *Mast-Cell Stabilizers*

The mast-cell stabilizers cromolyn and nedocromil do not produce a bronchodilatory effect and are effective only by inhalation. These medications are limited by their adverse effect profile and dosing frequency. They are thus not the first choice for childhood asthma because of their lack of efficacy and safety.

### *Leukotriene Modifiers*

Three of the leukotriene modifiers, montelukast, zafirlukast, and zileuton, may be used as alternatives for mild persistent asthma or as adjuncts to ICS for other asthma severities. They are not indicated for treating acute episodes of asthma and must be taken regularly, even during symptom-free periods.

### *Immunomodulators*

Subcutaneous immunotherapy with omalizumab is indicated for adolescents who have a clearly documented allergen relationship with their moderate-severe persistent asthma symptoms (Reference 48).

### *Other Medications*

Other medications that have been suggested in the treatment of asthma include antihistamines, methotrexate, macrolides, other antibiotics, hydroxychloroquine, dapsone, gold, intravenous gamma-globulin, cyclosporine, colchicine, NSAIDs (nonsteroidal anti-inflammatory drugs), inhaled heparin, inhaled furosemide, expectorants, and magnesium sulfate. Information to

recommend these therapies routinely for the long-term management and treatment of acute exacerbations is limited, but there is evidence supporting the use of magnesium sulfate only in acute severe exacerbations (References 49–53). Heliox, a mixture of helium and oxygen, has also been studied for the treatment of acute exacerbations, but the results to support their routine use as an added benefit to  $\beta_2$ -agonists and corticosteroids are lacking (References 54–56).

### *Delivery Devices*

Many delivery devices are used for administering medications to manage and treat asthma. Table 12 lists several different asthma devices, their limitations, and the optimal technique to ensure the best possible delivery for various pediatric patients (Reference 1).

## MONITORING THERAPY

Given that asthma is a chronic inflammatory disease with episodes of acute exacerbation, the need to follow therapeutic outcomes through the assessment and monitoring of severity, control, and responsiveness is paramount. In addition to regularly scheduled follow-ups, patients should monitor their asthma control and severity and adhere to their asthma action plan. A peak flow meter is recommended for those with moderate to severe persistent asthma, as well as for those with a history of exacerbations, to regularly monitor lung function and response to treatment. If the patient is unable to use a peak flow meter, a symptom-based action plan is useful in the home management of acute exacerbations. Therapeutic outcomes must be balanced against adverse events and toxicity.

## FUTURE THERAPIES

Given the significant impact of asthma, advances are continuously being made to create and identify novel therapies that are effective at reducing impairment and risk as well as the underlying disease pathology. Therapies under evaluation include bronchial thermoplasty, which delivers thermal energy to the airway wall to reduce excessive airway smooth muscle; anticytokine therapies (interleukin-5, interleukin-4), which reduce inflammation; and novel steroids, referred to as “soft steroids,” which are intended to produce an anti-inflammatory effect with minimal adverse effects.

## CONCLUSIONS

The management of asthma involves the interplay of four essential components: (1) routine monitoring of symptoms and lung function, (2) patient education, (3) control of trigger factors and comorbid conditions, and

**Table 9. Exacerbation Management**

In-home and/or Office

**Assess Severity**

- Patients at risk of life-threatening asthma require immediate medical attention after treatment.
- Symptoms and signs suggestive of a more serious exacerbation should result in initial treatment while immediately consulting with a clinician.
- Less severe signs and symptoms can be treated initially with assessing response to therapy and taking further steps as listed below.
- If available, measure PEF.
  - 50% to 79% of predicted or personal best indicates need for quick-relief medication.
  - < 50% indicates need for immediate medical care.

**Initial Treatment**

Inhaled SABA: up to two treatments 20 minutes apart of 2-6 puffs by MDI or nebulizer treatments. Children may need fewer puffs.

**Good Response**

No wheezing or dyspnea (tachypnea - young children)

PEF  $\geq$  80% of predicted or personal best

- Contact clinician for follow-up instructions and further management.
- May continue inhaled SABA every 3-4 hours for 24-48 hours.
- Consider short course of oral systemic corticosteroids.

**Incomplete Response**

Persistent wheezing and dyspnea (tachypnea).

PEF 50% to 79% of predicted or personal best

- Add oral systemic corticosteroid.
- Continue inhaled SABA.
- Contact clinician urgently for further instruction.

**Poor Response**

Marked wheezing and dyspnea

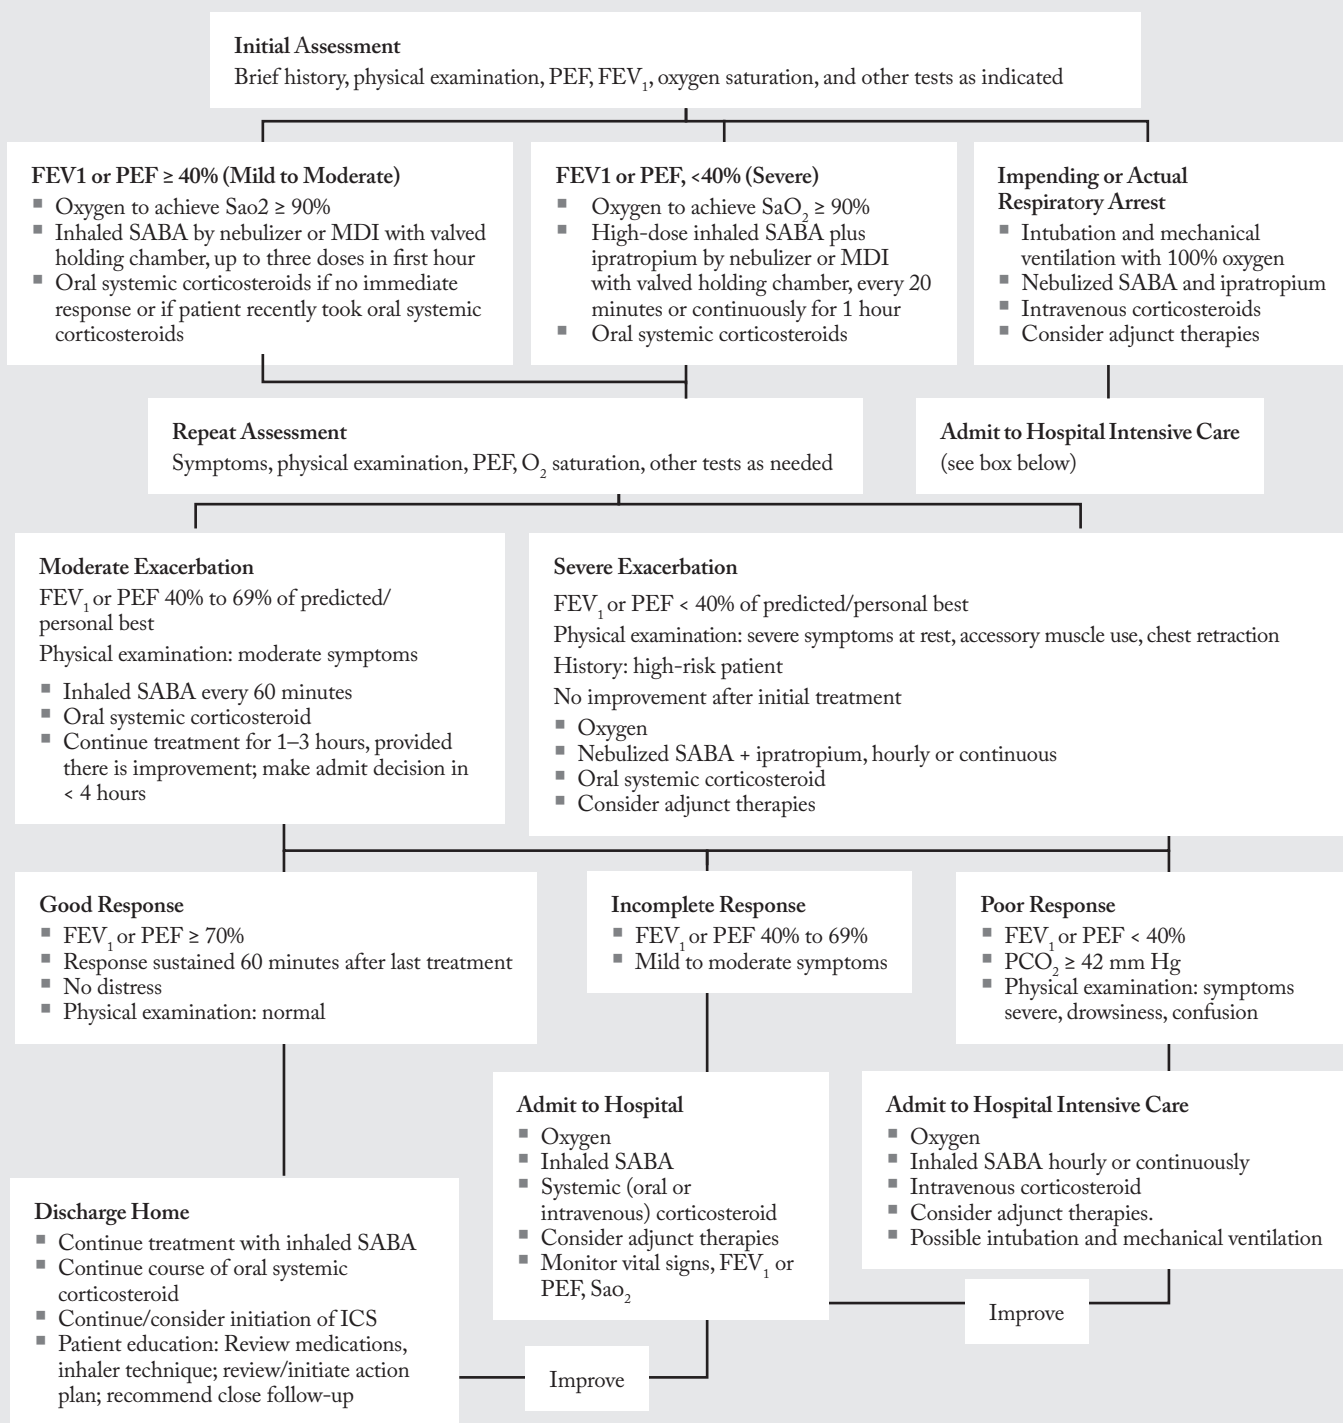

PEF < 50% of predicted or personal best

- Add oral systemic corticosteroid.
- Repeat inhaled SABA immediately.
- If distress is severe and unresponsive to initial treatment:
  - Call your clinician AND
  - Proceed to emergency department
  - Consider calling 911

*(continued)*

**Table 9. Exacerbation Management (continued)**

Emergency Department and Hospital

EIB = exercise-induced bronchospasm; FEV<sub>1</sub> = forced expiratory volume in 1 second; ICS = inhaled corticosteroids; MDI = metered dose inhaler; PEF = peak expiratory flow; SABA = short-acting β-agonist.

Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health, 2007 (Reference 1).

**Table 10.** Medications Used in the Treatment of Asthma

Class and Medication	Mechanism and Indication(s)	Potential Adverse Effects	Therapeutic Issues
<b><math>\beta_2</math>-Agonists</b>	<p><i>Mechanism</i></p> <ul style="list-style-type: none"> <li>▪ <b>Bronchodilation.</b> Stimulation of <math>\beta_2</math>-adrenergic receptors leads to activation of adenylate cyclase and increase in cyclic adenosine monophosphate, which results in smooth muscle relaxation, producing functional antagonism of bronchoconstriction.</li> </ul> <p><i>Indications</i></p> <ul style="list-style-type: none"> <li>▪ Relief of acute symptoms; quick-relief medication</li> <li>▪ Preventive treatment for EIB before exercise</li> </ul>	<ul style="list-style-type: none"> <li>▪ Inhaled route, in general, causes few systemic adverse effects.</li> <li>▪ Tachycardia, skeletal muscle tremor, hypokalemia, increased lactic acid, headache, hyperglycemia, prolongation of QTc interval in overdose</li> <li>▪ A diminished bronchoprotective effect may occur within 1 week of chronic therapy. Clinical significance has not been established.</li> <li>▪ In addition to above, restlessness, irritability, nervousness, and insomnia</li> </ul>	<ul style="list-style-type: none"> <li>▪ Drugs of choice for acute bronchospasm. Inhaled route has faster onset and fewer adverse effects and is more effective than systemic routes. The less <math>\beta_2</math>-selective agents (isoproterenol, metaproterenol, isoetharine, and epinephrine) are not recommended because of their potential for excessive cardiac stimulation, especially in high doses.</li> <li>▪ Regularly scheduled daily use is not recommended.</li> <li>▪ Regular use &gt; 2 days/week for symptom control (not prevention of EIB), increasing use, or lack of expected effect indicates inadequate asthma control and need for anti-inflammatory medication.</li> </ul>
SABAs <i>Inhaled:</i> Albuterol Levalbuterol Pirbuterol	<p><i>Indications</i></p> <ul style="list-style-type: none"> <li>▪ Long-term prevention of symptoms, added to ICS</li> <li>▪ Prevention of EIB</li> <li>▪ <i>Not to be used to treat acute symptoms or exacerbations</i></li> </ul>	<ul style="list-style-type: none"> <li>▪ In addition to above, potential risk of uncommon, severe, life-threatening, or fatal exacerbation (black box warning for asthma-related deaths)</li> </ul>	<ul style="list-style-type: none"> <li>▪ Not to be used to treat acute symptoms or exacerbations</li> <li>▪ Should not be used as monotherapy for long-term control of asthma or as anti-inflammatory therapy.</li> <li>▪ May provide more effective symptom control when added to standard doses of ICS compared with increasing the ICS dosage</li> <li>▪ Clinical significance of potentially developing tolerance is uncertain because studies show symptom control and bronchodilation are maintained.</li> </ul>
<i>Oral:</i> Albuterol, sustained release			<ul style="list-style-type: none"> <li>▪ Inhaled route is preferred because LABAs are longer acting and have fewer adverse effects than oral sustained-release agents. Oral agents have not been adequately studied as adjunctive therapy with ICS.</li> </ul>
<b>Corticosteroids (glucocorticoids)</b>	<p><i>Mechanism</i></p> <ul style="list-style-type: none"> <li>▪ <b>Anti-inflammatory.</b> Block late reaction to allergen and reduce airway hyperresponsiveness. Inhibit cytokine production, adhesion protein activation, and inflammatory cell migration and activation.</li> <li>▪ Reverse <math>\beta_2</math>-receptor down-regulation. Inhibit microvascular leakage</li> </ul>		

**Table 10.** Medications Used in the Treatment of Asthma (*continued*)

Class and Medication	Mechanism and Indication(s)	Potential Adverse Effects	Therapeutic Issues
<i>Inhaled (ICS):</i> Beclomethasone dipropionate Budesonide Ciclesonide Flunisolide Fluticasone propionate Mometasone furoate Triamcinolone acetonide	<i>Indications</i> <ul style="list-style-type: none"> <li>Long-term prevention of symptoms; suppression, control, and reversal of inflammation</li> <li>Reduce need for oral corticosteroid</li> </ul>	<ul style="list-style-type: none"> <li>Cough, dysphonia, oral thrush (candidiasis)</li> <li>In high doses, systemic effects (e.g., adrenal suppression, osteoporosis, skin thinning, and easy bruising) may occur, although studies are not conclusive, and clinical significance of these effects has not been established.</li> <li>In low to medium doses, suppression of growth velocity has been observed in children, but this effect may be transient, and the clinical significance has not been established.</li> </ul>	<ul style="list-style-type: none"> <li>Spacer/holding chamber devices with non-breath-activated MDIs and mouth washing after inhalation decrease local adverse effects.</li> <li>The risks of uncontrolled asthma should be weighed against the limited risks of ICS therapy. The potential but small risk of adverse events is well balanced by their efficacy.</li> <li>Dexamethasone is not included as an ICS for long-term control because it is highly absorbed and has long-term suppressive adverse effects.</li> </ul>
<i>Systemic:</i> Methylprednisolone Prednisolone Prednisone	<i>Indications</i> <ul style="list-style-type: none"> <li>For short-term (3–10 days) “burst” to gain prompt control of inadequately controlled persistent asthma</li> <li>For moderate or severe exacerbations to prevent progression of exacerbation, reverse inflammation, speed recovery, and reduce rate of relapse</li> <li>For long-term prevention of symptoms in severe persistent asthma: suppression, control, and reversal of inflammation</li> </ul>	<ul style="list-style-type: none"> <li><i>Short-term use:</i> reversible abnormalities in glucose metabolism, increased appetite, fluid retention, weight gain, facial flushing, mood alteration, hypertension, peptic ulcer, and rarely aseptic necrosis</li> <li><i>Long-term use:</i> adrenal axis suppression, growth suppression, dermal thinning, hypertension, diabetes, Cushing syndrome, cataracts, muscle weakness, and impaired immune function</li> <li>Consideration should be given to coexisting conditions that could be worsened by systemic corticosteroids, such as herpes virus infections, varicella, tuberculosis, hypertension, peptic ulcer, diabetes mellitus, osteoporosis, and <i>Strongyloides</i>.</li> </ul>	<ul style="list-style-type: none"> <li>Other systemic corticosteroids such as hydrocortisone and dexamethasone given in equipotent daily doses are likely to be as effective as prednisolone.</li> <li>Short-term therapy should continue until patient’s symptoms resolve. This usually requires 3–10 days but may require longer. Action may begin within 1 hour.</li> <li>Use at lowest effective dose. For long-term use, alternate-day morning dosing produces the least toxicity.</li> <li>There is no evidence that tapering the dose after improvement is useful in preventing a relapse in asthma exacerbations.</li> </ul>
<b>Methyloxanthines</b> Theophylline, sustained-release tablets and capsules	<i>Mechanism</i> <ul style="list-style-type: none"> <li><b>Bronchodilation.</b> Smooth muscle relaxation from phosphodiesterase inhibition and possibly adenosine antagonism</li> <li>May affect eosinophilic infiltration into bronchial mucosa as well as decreases in T-lymphocyte numbers in epithelium</li> <li>Increases diaphragm contractility and mucociliary clearance</li> </ul> <i>Indication</i> <ul style="list-style-type: none"> <li>Long-term control and prevention of symptoms in mild persistent asthma or as adjunctive with ICS, in moderate or persistent asthma</li> <li>NHLBI guidelines (2007) do not recommend oral theophylline as a long-term control medication for asthma in children ≤ 5 years.</li> </ul>	<ul style="list-style-type: none"> <li>Dose-related acute toxicities include tachycardia, nausea and vomiting, tachyarrhythmias (SVTs), central nervous system stimulation, headache, seizures, hematemesis, hyperglycemia, and hypokalemia.</li> <li>Adverse effects at usual therapeutic doses include insomnia, gastric upset, aggravation of ulcer or reflux, and increase in hyperactivity in some children.</li> </ul>	<ul style="list-style-type: none"> <li>Maintain steady-state serum concentration 5–15 mcg/mL. Routine serum concentration monitoring is essential because of significant toxicities, narrow therapeutic range, and individual differences in metabolic clearance. Absorption and metabolism may be affected by several factors that can produce significant changes in steady-state serum theophylline concentrations.</li> <li>Patients should be told to discontinue if they experience toxicity.</li> <li>Not generally recommended for exacerbations. There is minimal evidence for added benefit to optimal doses of SABA.</li> <li>Serum concentration monitoring is mandatory.</li> </ul>

Class and Medication	Mechanism and Indication(s)	Potential Adverse Effects	Therapeutic Issues
<b>Anticholinergics</b> Ipratropium bromide	<p><i>Mechanism</i></p> <ul style="list-style-type: none"> <li>▪ <b>Bronchodilation.</b> Competitive inhibition of muscarinic cholinergic receptors</li> <li>▪ Reduces intrinsic vagal tone of the airways. May block reflex bronchoconstriction secondary to irritants or to reflux esophagitis</li> <li>▪ May decrease mucous gland secretion</li> </ul> <p><i>Indication</i></p> <ul style="list-style-type: none"> <li>▪ Relief of acute bronchospasm</li> </ul>	<ul style="list-style-type: none"> <li>▪ Drying of mouth and respiratory secretions, increased wheezing in some individuals, blurred vision if sprayed in eyes. If used in the emergency department, produces less cardiac stimulation than SABAs</li> </ul>	<ul style="list-style-type: none"> <li>▪ Reverses only cholinergically mediated bronchospasm; does not modify reaction to antigen. Does not block EIB</li> <li>▪ Several doses of ipratropium in the emergency department provide additive effects to SABA.</li> <li>▪ May be alternative for patients who do not tolerate SABAs</li> <li>▪ Treatment of choice for bronchospasm because of <math>\beta</math>-blocker medication</li> <li>▪ Has not proven efficacious as long-term control therapy for asthma</li> </ul>
<b>Mast-cell stabilizers</b> Cromolyn sodium Nedocromil	<p><i>Mechanism</i></p> <ul style="list-style-type: none"> <li>▪ <b>Anti-inflammatory.</b> Blocks <i>early</i> and late reaction to allergen. Interferes with chloride channel function</li> <li>▪ Stabilizes mast-cell membranes and inhibits activation and release of mediators from eosinophils and epithelial cells</li> <li>▪ Inhibits acute response to exercise, cold dry air, and <math>SO_2</math></li> </ul> <p><i>Indications</i></p> <ul style="list-style-type: none"> <li>▪ Long-term prevention of symptoms in mild persistent asthma; may modify inflammation</li> <li>▪ Preventive treatment before exposure to exercise or known allergen</li> </ul>	<ul style="list-style-type: none"> <li>▪ Cough and irritation</li> <li>▪ 15% to 20% of patients experience an unpleasant taste from nedocromil.</li> </ul>	<ul style="list-style-type: none"> <li>▪ Therapeutic response to cromolyn and nedocromil often occurs within 2 weeks, but a 4- to 6-week trial may be needed to determine maximal benefit.</li> <li>▪ Dose of cromolyn by MDI may be inadequate to affect airway hyperresponsiveness. Nebulizer delivery may be preferred for some patients.</li> <li>▪ Safety is the primary advantage of these agents.</li> </ul>
<b>LTRAs</b>	<p><i>Mechanism</i></p> <ul style="list-style-type: none"> <li>▪ Selective competitive inhibitor of CysLT1 receptor, a potent constrictor of bronchial smooth muscle</li> </ul> <p><i>Indication</i></p> <ul style="list-style-type: none"> <li>▪ Long-term control and prevention of symptoms in mild persistent asthma for patients <math>\geq 1</math> year. May also be used with ICS as combination therapy in moderate persistent asthma</li> </ul>	<ul style="list-style-type: none"> <li>▪ Postmarketing reports of behavioral changes (e.g., agitation, aggression, depression, insomnia, tremor) have been noted in pediatric patients.</li> <li>▪ Rare cases of Churg-Strauss have occurred, but the association is unclear.</li> </ul>	<ul style="list-style-type: none"> <li>▪ May attenuate EIB in some patients, but less effective than ICS therapy</li> <li>▪ A flat dose-response curve, without further benefit, if dose is increased beyond recommendations</li> </ul>

Hudson, OH: Lexi-Comp, 2011; and the National Heart, Lung, and Blood Institute, National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, Full Report. Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health, 2007 (References 1, 40). Dosages that are italicized are based on data from clinical trials that support use in patients beyond the FDA-approved labeling.

**Table 12.** Delivery Devices

Device/Drugs	Population	Optimal Technique	Therapeutic Issues
MDI $\beta_2$ -Agonists Corticosteroids Cromolyn sodium Anticholinergics	$\geq 5$ years old ( $< 5$ with spacer or VHC mask)	Actuation during a slow (3–5 seconds), deep inhalation, followed by a 10-second breath hold	Slow inhalation and coordination of actuation during inhalation may be difficult, particularly in young children. Patients may incorrectly stop inhalation at actuation. Deposition of 50% to 80% of actuated dose in oropharynx. Mouth washing and spitting is effective in reducing the amount of drug swallowed and absorbed systemically.
Breath-actuated MDI $\beta_2$ -Agonists	$\geq 5$ years old	Tight seal around mouthpiece and slightly more rapid inhalation than standard MDI, followed by a 10-second breath hold	May be useful for patients unable to coordinate inhalation and actuation. Patients may incorrectly stop inhalation at actuation. Cannot be used with spacer/VHC devices
DPI $\beta_2$ -Agonists Corticosteroids Anticholinergics	$\geq 4$ years old	Rapid (1 or 2 seconds), deep inhalation. Minimally effective inspiratory flow is device-dependent. Most children $< 4$ years do not generate sufficient inspiratory flow to activate the inhaler.	Dose is lost if patient exhales through device after actuating. Delivery may be greater or lesser than MDI, depending on device and technique. Rapid inhalation promotes greater deposition in larger central airways. Mouth washing and spitting is effective in reducing amount of drug swallowed and absorbed.
Spacer or VHC	$\geq 4$ years old	Slow (3–5 seconds), deep inhalation, followed by 10-second breath hold immediately after each actuation.	Indicated for patients who have difficulty performing adequate MDI technique. The VHC improves lung delivery and response in patients who have poor MDI technique. Face mask allows MDIs to be used with small children. However, use of a face mask reduces delivery to lungs by 50%.
	$< 4$ years old VHC with face mask	If face mask is used, it should have a tight fit and allow 3–5 inhalations per actuation.	Spacers and/or VHCs decrease oropharyngeal deposition. Rinse plastic VHCs once a month with dilute household dishwashing detergent.
Nebulizer $\beta_2$ -Agonists Corticosteroids Cromolyn sodium Anticholinergics	Patients of any age who can- not use MDI with VHC and face mask	Slow tidal breathing with occasional deep breaths. Tightly fitting face mask for those unable to use mouthpiece. Using the “blow-by” technique (holding the mask or open tube near the infant’s nose and mouth) is not appropriate.	Less dependent on patient’s coordination and cooperation May be expensive; time-consuming Use of a face mask reduces delivery to lungs by 50%. Nebulizers are as effective as MDIs plus VHCs for delivering bronchodilators in mild to moderate exacerbations. Potential for bacterial infections if not cleaned properly

DPI = dry powder inhaler; MDI = metered dose inhaler; VHC = valved holding chamber.

(4) pharmacologic therapy. The primary goal of asthma management is centered on the principle of asthma control through the reduction of risk and impairment. Effective asthma management, which varies on the basis of patient age, requires a preventive approach, with routine visits to assess symptoms, monitor pulmonary function, adjust medications, and ensure education is provided to allow self-management and control. Efforts should be made to identify and address environmental triggers and comorbid conditions that affect asthma management. Pharmacologic therapy varies according to asthma severity and asthma control through a stepwise approach, in which the class and number of medications, dosing, and frequency of administration are increased when necessary and reduced when possible. Pharmacists play an important role in educating and ensuring understanding of pharmacologic and nonpharmacologic means for the effective management of asthma.

Asthma is the most common chronic disease in childhood, and despite the long course of its history, its etiology is still not clearly understood. The burden that this chronic inflammatory disease places on those whom it affects and the amount of resources is significant. Until we have a greater understanding of its cause and identify a means of preventing the development of this disease, pharmacologic and nonpharmacologic therapy to control asthma through the reduction of risk and impairment is of extreme importance.

# CHAPTER 15

## CYSTIC FIBROSIS

Hanna Phan, Pharm.D., BCPS; and  
Robert J. Kubn, Pharm.D.

### LEARNING OBJECTIVES

1. Describe the incidence and inheritance pattern of cystic fibrosis (CF).
2. Recognize common signs and symptoms of CF, including its initial presentation and multiorgan system effects throughout life.
3. Identify and apply CF-specific pharmacokinetic differences in the selection of antimicrobial therapy.
4. Determine appropriate chronic and acute exacerbation therapy and accompanying monitoring parameters to meet efficacy and safety needs of patients with CF.
5. Discuss the role of a pharmacist as part of the CF interdisciplinary care team and community.

### ABBREVIATIONS IN THIS CHAPTER

BMI	Body mass index
CF	Cystic fibrosis
CFRD	CF-related diabetes
CFTR	CF-transmembrane conductance regulator
DIOS	Distal intestinal obstruction syndrome
FEV <sub>1</sub>	Percent predicted forced expiratory volume in 1 second
GERD	Gastroesophageal reflux disease
GI	Gastrointestinal
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
PA	<i>Pseudomonas aeruginosa</i>
PERT	Pancreatic enzyme replacement therapy
SIBO	Small intestinal bacterial overgrowth

### INTRODUCTION

Cystic fibrosis (CF) is a genetic, autosomal-recessive, multiorgan disease affecting more than 30,000 and 70,000 individuals in the United States and worldwide, respectively (Reference 1). Cystic fibrosis is the most common inherited disease in the white population worldwide. This disease has an incidence of 1 in 3500 births in the United States and an overall incidence as

high as about 1 in 1300 in European countries such as Ireland (References 2, 3). Cystic fibrosis also affects a variety of races and ethnicities, with the greatest incidence within the white population (more than 90% of patients with CF in the United States) and a lower incidence among Hispanic (1 in 1900), Asian (1 in 32,000), and African American (1 in 15,000) populations (Reference 3). Without a current cure, CF continues to be a life-shortening, genetic disease most commonly affecting the pulmonary and gastrointestinal (GI) systems with additional effects on the reproductive system, bone, and sudoriferous (sweat) glands. Because of the technological advances of airway clearance, paired with the discovery of effective drug therapies, the median life span of patients with CF has extended from 10 years in 1960 to 37.4 years in 2010 (References 1, 2). Given the multifaceted aspect of CF as a disease, there is a need for an interdisciplinary approach to patient care because of complex drug therapy regimens.

### PATHOPHYSIOLOGY AND GENETICS OF CF

Cystic fibrosis is the result of a mutation of a single gene in the long arm of chromosome 7. This mutation affects the CF-transmembrane conductance regulator (CFTR), a membrane ion channel in secretory epithelial cells notably found in airway lumens and the pancreatic duct. The CFTR is mediated by cyclic adenosine 3',5'-monophosphate (cAMP). In an individual without CF, cAMP activates the transport of chloride (Cl<sup>-</sup>) from the cell by CFTR, which corresponds with sodium (Na<sup>+</sup>) and water efflux. In individuals with CF, Cl<sup>-</sup> and Na<sup>+</sup> movement is significantly decreased or absent, resulting in decreased secretion of Cl<sup>-</sup> paired with increased Na<sup>+</sup> retention and water retention in the submucosa (Figure 1). The subsequent loss of volume in epithelial secretions causes them to be thick and viscous, decreasing mucociliary function and causing mucus-associated obstruction and inflammation. This dysfunction usually affects pulmonary epithelia; however, depending on a patient's phenotype, the patient may also exhibit effects to the pancreatic and hepatobiliary ducts as well as to the microvilli of the GI tract (Reference 3).

The five main classes of mutations associated with CFTR include more than 1,200 known mutations. The CFTR mutations are classified by the mechanism from which they affect CFTR function (Table 1 and Figure 2). Class I mutations affect the synthesis of CFTR,

whereas class II mutations affect the location of CFTR from the apical membrane surface. F508del, a class II mutation, is the most common mutation within the CF population, accounting for almost 70% of mutation alleles in white patients with CF. Class III and IV mutations affect the function of CFTR, specifically the regulation of CFTR function in response to cAMP and  $\text{Cl}^-$  transport, respectively. Class V mutations, also recognized as “nonsense” mutations, affect the amount of functional CFTR produced (References 3, 4).

Other ion channels influence the flux of fluid and ions as part of CF and may also present with dysfunction, including the ORCC (outwardly rectifying  $\text{Cl}^-$  channel) and the ENaC (epithelial sodium channel) (References 5–7). Like CFTR, these channels are potential therapeutic targets for future CF therapies.

The phenotype of CF disease varies on the basis of genotype combination (e.g., F508del homozygotes vs. F508del/R117H); however, phenotypes can also be heterogeneous between siblings with identical mutations (Reference 8). Thus, it is evident that other genetic factors and environmental factors affect phenotype in patients with CF (References 3, 4). Newborn genetic screening has now made it possible to detect CF at a much earlier age than the historical phenotypic-dependent screening and presentation of CF-related symptoms at a later age. The use of sweat tests, which measure the dermal excretion of  $\text{Cl}^-$ , and advanced DNA analysis, have also advanced the ability to confirm diagnosis and identify specific genotype, respectively (Reference 9). Prenatal

**Figure 1.** Electrolyte movement in epithelial cell in (A) individual with CF and (B) individual without CF.

$\text{Ca}^{2+}$  = calcium; cAMP = cyclic adenosine monophosphate; CF = cystic fibrosis; CFTR = CF-transmembrane conductance regulator;  $\text{Cl}^-$  = chloride;  $\text{K}^+$  = potassium;  $\text{Na}^+$  = sodium.

screening can include CF carrier status testing of parents as well as fetal testing when both parents are carriers. Fetal testing would involve chorionic villus sampling through amniocentesis, where CF gene mutations in the DNA from chorionic villus cells can be identified early in pregnancy (i.e., 11–14 weeks' gestation) (Reference 10).

## PULMONARY DISEASE IN CF

### Physical Manifestation

The accumulation of thick, viscous pulmonary secretions (known as airway surface liquid) results in poor mucociliary clearance of debris and mucus by respiratory cilia. Consequently, the dehydrated nature of the airway surface liquid and mucus accumulation result in the obstruction of small and large airways. This obstruction leads to air trapping, bronchiectasis, and atelectasis. Bacteria and other foreign particles remain in the airways, leading to colonization and subsequent infection (e.g., bronchopneumonia) and inflammation. Because of the continued obstruction and inflammatory state, hyper-inflammation and dilation of airspaces are often noted in diagnostic imaging. Hemoptysis is also commonly noted in patients with CF, especially as part of pulmonary exacerbations, ranging from streaking in the sputum to massive hemoptysis. Other complications include pneumothorax, occurring in about 1 in 167 patients per year (Reference 12).

Patients with CF have distinct phenotypes of their disease, ranging from mild disease with few acute exacerbations to moderate or severe disease requiring more frequent hospitalization and acute treatment (Reference 12). In addition, patients can be stable for years and then experience a rapid loss of pulmonary function during a relatively short period. With each pulmonary

infection and resulting inflammation, pulmonary function is decreased, which is commonly termed the *vicious cycle* of CF pulmonary disease (Figure 3). Percent predicted forced expiratory volume in 1 second (FEV<sub>1</sub>) is considered a strong predictor of survival and pulmonary function in patients with CF. Studies have shown that loss of FEV<sub>1</sub> is greatest during adolescence when a nadir of adherence to airway clearance and drug therapy occurs, with an overall average loss of FEV<sub>1</sub> of between 1 and 3 FEV<sub>1</sub> points per year (Reference 13).

Often, the lungs of individuals with CF are colonized with gram-positive (e.g., *Staphylococcus aureus*) and/or gram-negative (e.g., *Pseudomonas aeruginosa* [PA]) pathogens in childhood (References 3, 12, 13). Pulmonary colonization and/or infection by other microbes are also noted, which can vary with factors such as age, geographic location, and exposure to pathogens (e.g., hospitalization) (References 3, 14).

## Therapies for Pulmonary Disease in CF

### Airway Clearance

The increased viscosity of the mucus of patients with CF and the subsequent obstruction and even mucus plugging dictate the use of physiotherapy to help loosen this mucus and help with expectoration. First approaches include chest percussion and postural drainage by positioning of the patient in multiple positions to help drain the mucus from the various lobes of the lung while cupping the hands and percussing the chest. This procedure should be done at least two or three times/day and requires about 30 minutes to complete. Because this is very difficult to do given the considerable requirement for caregiver time to manually provide physiotherapy, mechanical devices have been developed to facilitate this procedure. Chest therapy vests have been developed that use a fitted vest and pneumatic

**Table 1.** CFTR Mutation Classification, Effect, and Genotype Example (References 3, 4)

Mutation Class	Effect on CFTR	Common Genotype Example
I	Premature termination of production, resulting in decreased or no functional CFTR Cl <sup>-</sup> channels	G542X
II	Defective processing of CFTR; CFTR does not reach the apical membrane surface for function	F508del <sup>a</sup>
III	CFTR reaches membrane surface but does not respond to cAMP stimulation resulting in defective regulation	G551D
IV	CFTR reaches membrane surface, but Cl <sup>-</sup> transport is defective.	R117H
V	Synthesis of functional CFTR is reduced, resulting in a small amount of functional CFTR to the membrane surface.	3,849 + 10 kb C→T

<sup>a</sup>Most common CF mutation.

cAMP = cyclic adenosine monophosphate; CF = cystic fibrosis; CFTR = CF-transmembrane conductance regulator; Cl<sup>-</sup> = chloride.

pressure to automate the process and help improve adherence and benefit to the patient. This type of therapy continues today, including the use of physical exercise and other devices that aid in mucus clearance to help maintain airway clearance and prevent clinical deterioration (Reference 15).

### Pharmacotherapy

#### Treatment Guidelines

In the past 5 years, a concerted effort has been made by the Cystic Fibrosis Foundation to help establish guidelines for the treatment of both chronic therapies and acute exacerbations. These key drug therapy findings for chronic therapies and acute exacerbations were based on a level of evidence from the literature as determined by a consensus committee (References 15, 16).

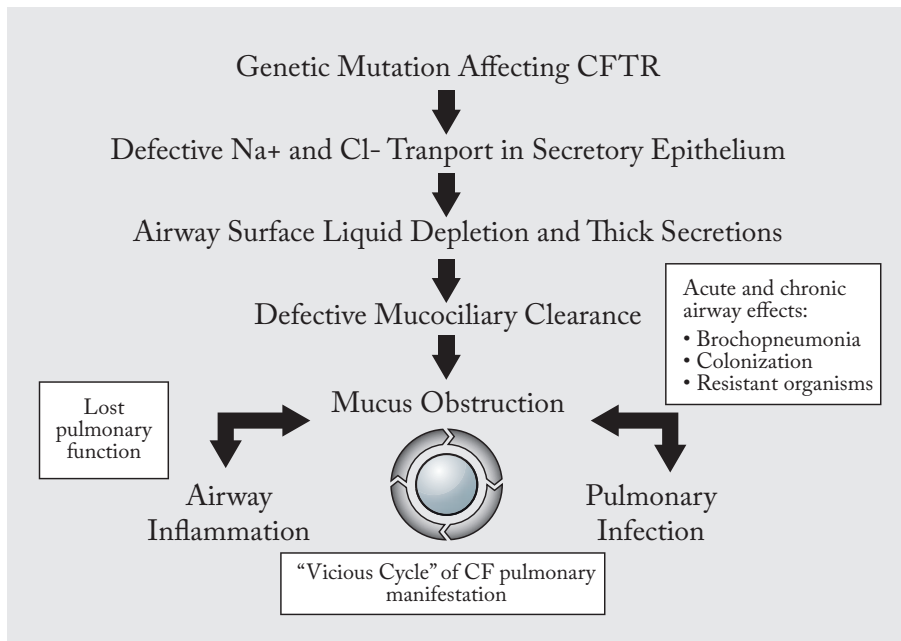

#### Chronic Maintenance Therapy

Although CF is a disease of exocrine dysfunctional and CFTR abnormalities, the pulmonary manifestations of this disease are the most difficult to treat and account for most of the morbidity and mortality in patients with CF (Reference 17). Because this disease is progressive, therapies to maintain or preserve lung function and quality of life are now the mainstay of treatment. These approaches include the use of long-term inhaled antibiotics and bronchodilators, as well as chest physiotherapy and other methods to facilitate mucociliary clearance (Reference 15).

#### CHRONIC AEROSOLIZED ANTIBIOTICS

Inhaled antibiotics show long-term benefit in patients with PA colonization (Reference 12). For almost 50 years, patients with CF have received inhaled antibiotics. Initially, they were heroic approaches to very ill patients that involved parenteral formulations placed in traditional jet nebulizers by local centers (References 18–20). In 1999, the first inhaled aerosolized antibiotic, tobramycin solution for inhalation, was approved with a 300-mg dose twice daily, alternating every 28 days. Because the drug is directly administered to the airway and little systemic absorption occurs, larger doses of aminoglycosides can be used for chronic administration with little risk of long-term nephrotoxicity. Efficacy of this regimen has been shown in children 6–12 years of age as well as in those 13–18 years of age, with an average improvement in the FEV<sub>1</sub> of 11 (Reference 21). Potential adverse effects of tobramycin solution for inhalation include bronchospasm, hoarseness, and tinnitus. This was the only approved drug formulation until 2011, when aztreonam lysine was approved with a dose of 75 mg three times/day with a similar 28-day alternating-therapy regimen (References 22, 23). This alternating-day regimen was selected to minimize the development of resistance of PA and other sensitive isolates to these chronic therapies. Potential adverse effects of aztreonam lysine include bronchospasm, sore throat, nasal congestion, and fever (in children). Data from inhaled tobramycin document a rise in the minimum inhibitory concentration (MIC) of the PA isolated, but this increase, seen in the first few cycles, seems to plateau with time (Reference 24). Given that the aerosolized concentration in sputum is 50–100 times higher than microbiologic breakpoints and that it has a concentration-dependent killing of this organism, the clinical utility of these breakpoints may not be relevant to patient care (Reference 24). Currently, doses for tobramycin solution for inhalation and aztreonam lysine are standard for all age patients requiring therapy.

In addition, before the availability of approved aerosolized antibiotics, other parenteral formulations were used by aerosolized administration to medically manage patients with CF. Colistimethate has been used for almost 40 years in Europe as well as the United States as an aerosol with a dose of 75–150 mg two times/day (References 20, 25). Various formulations of this product have been used by centers around the world, and

**Figure 3.** Pulmonary manifestation in CF.

CF = cystic fibrosis; CFTR = CF-transmembrane conductance regulator; Cl<sup>-</sup> = chloride; Na<sup>+</sup> = sodium.

with changing formulations of this natural product, adverse events have occurred, including bronchospasm. Therefore, many centers pretreat with albuterol before a dose of colistin, and careful respiratory monitoring is warranted with the first dose of this medication. Reconstitution of colistin should be done just before administration to minimize the potential formation of broncho-irritative metabolites.

As aerosolized antibiotics have developed during the past decade, nebulizer technology has dramatically changed, and improvements have been made to maximize the amount of drug delivered to the patient. Drug delivery can be greatly affected by different devices, and care should be taken to make sure the correct nebulizers are used to deliver the drug. Compressed gas-jet nebulizers were used with most nebulized antibiotics until recently. Piezoelectric cell vibrating-mesh nebulizers (e.g., Trio and Altera) now can deliver a uniform particle size aerosol in a very short time (Reference 26). Care must be taken not to universally interchange these devices for antibiotic aerosols or mix them with bronchodilators because performance can be greatly affected. The use of these new improved delivery systems will benefit patients with CF in the coming years, and this technology will help with the delivery of other inhaled medications.

#### OTHER AEROSOLIZED AGENTS

There are two agents that help increase the removal of the thick sputum produced by patients with CF by breaking down extracellular DNA or increasing the amount of fluid in the airway. Dornase alfa inhalation has also shown long-term benefit in preserving lung function as part of chronic therapy in CF. This compound works by hydrolyzing extracellular DNA in the sputum to decrease the viscosity of the sputum and improve sputum expectoration by the patient. It has been used for more than a decade with few adverse effects to patients and is one of the first aerosolized therapies initiated in young children with CF. This drug cannot be mixed with other aerosol medications because it often denatures the product, especially with hypertonic solutions.

Since the latest guidelines, studies with aerosolized 7% hypertonic saline have also shown benefit for chronic therapy, but long-term data (beyond 48 weeks) are currently lacking (Reference 27). Hypertonic saline works by increasing the volume of fluid on the epithelial lining of the airway to maintain normal ciliary flow and increase sputum expectoration. Hypertonic saline concentrations from 3% to 10% were studied, and a 7% solution was found to have the best response with a low rate of bronchospasm, the major adverse effect of this therapy. Some patients may only be able to tolerate 5%

solutions, and concentration adjustments may need to be made on an individual basis. To our knowledge, no studies have addressed the concomitant use of these agents for chronic therapy.

#### ANTI-INFLAMMATORY THERAPY

The vicious cycle of infection and inflammation is now recognized as a key component of the pulmonary manifestations of CF. The focus has been on long-term anti-inflammatory therapy for patients with CF, although earlier studies with systemic corticosteroids showed improvement in lung function but with an unacceptable toxicity profile, with increases in hyperglycemia, osteoporosis, and growth retardation. Some clinicians use a short course of corticosteroids during an acute pulmonary exacerbation or other illness, but long-term use is not warranted. The use of high-dose, chronic ibuprofen in pediatric patients during a 4-year period showed a decrease in the rate of decline in pulmonary function (Reference 28). This approach, used in only a few patients today, requires pharmacokinetic dose monitoring of serum concentrations to maximize the dose. Serum concentrations of 50–100 mcg/mL are required to maximize the effect of this intervention (Reference 29). Because of concerns about the long-term toxicity of ibuprofen (e.g., gastrointestinal irritation and renal dysfunction), this therapy is not widely used.

In the past decade, the anti-inflammatory properties of azithromycin and other related compounds have been studied, and recent clinical studies have shown benefit in preservation of lung function and decreased pulmonary exacerbations (Reference 30). This therapy accentuates the anti-inflammatory properties of this drug, not its antimicrobial effect. Many patients, including young children, receive this therapy chronically either on a daily or every-other-day basis. According to the Cystic Fibrosis Foundation guidelines regarding chronic medications, patients with *P. aeruginosa* consistently in respiratory or sputum cultures should be considered candidates for chronic azithromycin therapy (Reference 15). Doses of 250–500 mg given three to seven times/week (not to exceed 10 mg/kg/day) are used by most CF clinicians for long-term therapy. Because the emphasis of this medication is on its anti-inflammatory effects, dosing can be adjusted for convenience because its effect is much longer than its serum half-life. Long-term therapy with azithromycin has not shown any direct adverse reactions. Recent data suggest that the chronic long-term use of azithromycin increases the incidence of nontuberculous mycobacterial infections in patients with CF. Azithromycin blocks autophagosome clearance, which facilitates the intercellular killing of mycobacteria (Reference 31). Careful follow-up of the CF population receiving azithromycin will help clarify the clinical impact of this observation.

### Treatment of Acute Pulmonary Exacerbations

Despite the use of daily medications and airway clearance therapies, patients with CF often experience rapid clinical deterioration and increased respiratory symptoms. The increasing cycle of airway inflammation and mucus accumulation in the airway continues, and patients often experience increasing work of breathing, fever, increased mucus production, fatigue, and weight loss (Reference 12). This relatively rapid onset of symptoms is referred to as an acute pulmonary exacerbation. The hallmark of this disease has been that almost every patient experiences some episodes with variable frequency (e.g., four or five times/year and others, with milder disease, having an exacerbation every 2–3 years). Complete eradication of bacterial and other microbes in the airways becomes more challenging with increased age and/or incidence of pulmonary exacerbations; thus, the selection of antimicrobial treatment is a common challenge in the treatment of CF pulmonary exacerbations.

#### ANTIBIOTIC SELECTION

At present, acute pulmonary exacerbation is not well defined, and no clear consensus has been reached regarding what antibiotics should be prescribed or whether the therapy should be inpatient or outpatient. The choice of antibiotics is directed at the most common organisms found in the respiratory tract of each patient because most patients undergo routine quarterly sputum culture collections. Two important caveats in the surveillance and selection of antibiotics should be noted. First, traditional sensitivity results do not predict clinical success of patients with resistant organisms. This was described 20 years ago in a study comparing treatment with antibiotics versus placebo for acute pulmonary exacerbations, which found no difference in short-term pulmonary function changes (Reference 32). Other studies have confirmed improvement with antibiotics—usually dual antipseudomonal therapy and additional antibiotics directed at other microbiologic isolates (References 33, 34). Second, less robust evidence is available to validate the benefit of the duration, number of antibiotics, dosing strategy, and environment of treatment (e.g., inpatient vs. home therapy for the treatment of acute exacerbation) (Reference 16). Given this background, most centers still use two-drug antipseudomonal therapies for exacerbation in PA-positive patients for at least 10–14 days. The overall improvement in life expectancy and preservation of lung function globally in the CF community for the past 20 years has been an important observation to continue this practice of dual antipseudomonal therapy. Current guidelines from a consensus conference by the Cystic Fibrosis Foundation support the use of antibiotics, but they do not endorse two drug treatments over one susceptible drug. Treatment guidelines have

focused on patients with PA, and many patients harbor several other gram-negative organisms and very difficult-to-treat organisms such as *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, and methicillin-resistant *S. aureus* (MRSA), making antibiotic selection complex. Antibiotic selection can be guided, but not dictated, by the results of microbiologic testing. Current practice at most centers would use dual antipseudomonal drug therapy for synergy. During the past 2 decades, several reports of rapid clearance of aminoglycosides and semisynthetic penicillins have been described in patients with CF; therefore, recommended doses of these agents are higher than in patients without CF. Consensus guidelines suggest that once-daily high-dose aminoglycosides like tobramycin at a starting dose of 10 mg/kg/day are warranted (Reference 16). As a patient's weight changes with growth, the previous pharmacokinetic parameters can be used to adjust doses and determine clearance with subsequent serum concentrations. Once-daily aminoglycoside therapy in CF results in a lower occurrence of nephrotoxicity, as defined by increased serum creatinine and urinary NAG (*N*-acetyl- $\beta$ -D-glucosaminidase), compared with thrice-daily dosing (Reference 35). No changes in pulmonary function were seen between the two groups. Of importance, given the short half-life of tobramycin and other aminoglycosides, single daily doses will result in a very long time below the MIC in many pediatric patients. Although the postantibiotic effect of tobramycin against mucoid PA is not clearly understood, it certainly does not exceed 4–6 hours. Therefore, in some patients with very rapid clearances (e.g., with a half-life of less than 2 hours), some centers administer doses of 6–8 mg/kg every 12 hours to shorten this postantibiotic period and still allow substantial clearance of the drug (Reference 36). In any case, careful monitoring of serum concentrations is necessary to prevent accumulation and potential nephrotoxicity and ototoxicity. Recent work suggests that patients with CF are indeed candidates for vestibular loss, especially given the many courses of aminoglycosides they have received (Reference 37). With the tremendous increase in life expectancy, the next decade will tell whether total dose or dosing regimens played the most important role in toxicity. Table 2 includes various doses of drugs used for chronic administration and for managing these acute exacerbations in patients.

Because most of the morbidity and mortality with CF is related to lung decline and deterioration, strategies are now being applied to CF from other diseases and conditions. Continuous-infusion antibiotics with concentration-dependent killing or prolonged infusion of these antibiotics are now being used with intermittent high-dose aminoglycosides to help maximize the treatment of PA exacerbations and other organisms

**Table 2.** Antibiotics and Dosing Regimens Commonly Used in the Treatment of Acute Pulmonary Bacterial Exacerbations in Patients with Cystic Fibrosis<sup>a</sup>

Antibiotic	Dosing Regimen <sup>b</sup>
<b>For <i>Pseudomonas aeruginosa</i></b>	
Amikacin	7.5–10 mg/kg/dose IV q8h <sup>c</sup> or 30 mg/kg/day
Aztreonam	50–70 mg/kg/dose IV q8h (up to 8 g/day)
Cefepime	50–70 mg/kg/dose IV q8h (up to 2.5 g/dose)
Ceftazidime	50–70 mg/kg/dose IV q8h (up to 8 g/day) <sup>d</sup>
Ciprofloxacin (IV)	10 mg/kg/dose IV q8h (up to 400 mg/dose)
Ciprofloxacin (oral)	40–50 mg/kg/day PO q8–12h (up to 750 mg/dose)
Colistin	3–6 mg/kg/day IV q8–12h
Imipenem/cilastin	25–40 mg/kg/dose IV q6h (up to 1 g/dose)
Levofloxacin	Children 7–10 mg/kg/day IV or PO q24h Adults 500–750 mg/day IV or PO q24h
Meropenem	40 mg/kg/dose IV q8h (up to 2 g/dose)
Piperacillin/tazobactam	300–500 mg/kg/day IV q4–6h (up to 24 g/day) <sup>e</sup>
Ticarcillin/clavulanate	300–500 mg/kg/day IV q6–8h (up to 24 g/day) <sup>e</sup>
Tobramycin	10 mg/kg/dose IV q24h <sup>c</sup> or 6–7 mg/kg q12h
<b>For <i>Staphylococcus aureus</i>, methicillin resistant</b>	
Daptomycin	Should not be used for acute exacerbations
Linezolid	Children 10 mg/kg/dose IV or PO q8h Adults 600 mg IV or PO q12h
Tigecycline	Children – N/A Adults – 100 mg loading dose; then 50 mg IV q12h
Vancomycin	15–20 mg/kg/dose IV q6–8h
<b>Inhaled Drugs</b>	
Aztreonam lysine for inhalation	75 mg inhaled three times/day for 28 days; then off for 28 days
Dornase alfa	2.5 mg inhaled daily
Hypertonic saline 7%	4 mL inhaled twice daily
Tobramycin solution for inhalation	300 mg inhaled twice daily for 28 days; then off for 28 days

<sup>a</sup>Combination therapy is recommended.

<sup>b</sup>Doses assume normal renal and hepatic function. Dose adjustment may be necessary for renal and hepatic impairment.

<sup>c</sup>Use of historical therapeutic milligram-per-kilogram dosage if available.

<sup>d</sup>Reference 38.

<sup>e</sup>Based on piperacillin or ticarcillin component.

h = hours; IV = intravenous(ly); N/A = not applicable; PO = orally; q = every.

(Reference 39). Practical solutions for ambulatory patients are now available, and many patients can finish their course of antibiotics at home or may receive the entire course at home after a clinic visit. This is particularly true of adults with CF given their work and school demands. No definitive study has been conducted with these approaches to date, but given the success of these strategies in other pulmonary infections, such studies may be of considerable long-term benefit to patients with CF.

Therapy duration is usually determined by careful monitoring of overall symptoms and improvement in pulmonary function (e.g., FEV<sub>1</sub>), with treatment often lasting 10–14 days (References 16, 40). Patients often have a serial pulmonary function test every few days to show improvement as well as symptom improvements and weight gain. Many clinicians are following biomarkers like C-reactive protein and procalcitonin to evaluate the progress of an exacerbation, especially for patients in whom pulmonary function testing may be difficult. In one recent study, lower procalcitonin was correlated with patient improvement (Reference 41). Therapy can continue beyond this time if the patient's clinical course does not improve significantly and/or changes in antimicrobial agents are required.

#### MONITORING OF PULMONARY THERAPY

A return to baseline FEV<sub>1</sub> after recovering from a pulmonary exacerbation is ideal but not always possible—thus, the importance of continued suppression of inflammation and infection through airway clearance and accompanying drug therapy (Reference 42).

Because of the aggressive and often-repeated nature of antimicrobial courses, patients with CF require careful monitoring both for long- and short-term events. Initial serum concentrations should be obtained within the first 72 hours of therapy unless the patient has a history of delayed clearance or nephrotoxicity. At some CF care centers, it is common to wait 2–3 days to make sure the patient has been adequately rehydrated because many of the patients have had decreased oral intake and increased losses with their increasing symptoms during the previous 5–7 days. Because of the increased incidence of MRSA and PA sputum isolates with pulmonary exacerbation, patients are often treated with intravenous vancomycin in combination with an aminoglycoside. These patients should be monitored often, with care taken for drug accumulation and increased trough concentration during the traditional 10–14 days of therapy. With increasing age and a larger incidence of CF-related diabetes (CFRD), a decrease in aminoglycoside clearance should be anticipated with time. Whether this is caused by age or cumulative toxicity is unclear, but as care moves to adult centers and physicians, previous dosing of drugs should be adjusted accordingly.

## NUTRITION IN CF

### Physical Manifestations

Because of defective CFTR and subsequently impaired transport of Na<sup>+</sup> and Cl<sup>-</sup> resulting in viscous epithelial secretions, the pancreatic duct becomes obstructed. This obstruction prevents proper secretion of pancreatic enzymes into the digestive tract, otherwise known as pancreatic insufficiency. Chronic pancreatic insufficiency is a common complication affecting around 85% of individuals with CF (Reference 43). Pancreatic insufficiency causes malabsorption of fat and protein, leaving individuals with CF to face challenges in nutritional status. This decrease in nutrient absorption subsequently leads to overall poor growth and, potentially, failure to thrive, especially in infants and younger children. In addition to fat malabsorption, fat-soluble vitamin (i.e., vitamins A, D, E, and K) deficiency is common. Pancreatic damage, including pancreatitis, can also manifest because of defective pancreatic exocrine secretion (References 44, 45). Other complications secondary to nutrient malabsorption caused by CF include anemia (often iron-deficient) and osteopenia or osteoporosis.

### Caloric Needs and Nutritional Status in CF

Individuals with CF often face challenges of poor nutritional status, including poor growth (i.e., weight, stature, and weight-for-stature) and vitamin deficiency. Infants and young children with CF are at increased risk of failure to thrive. Older children and adolescents also face challenges of poor growth because of nutritional risk secondary to CF. Energy needs in this population are increased because of expenditure secondary to their pulmonary condition, including chronic cough, infection, and increased work of breathing. Thus, it is highly recommended that children with CF be provided greater dietary energy intake than children without CF. Weight gain and growth have been shown with intakes from 110% to 200% that of healthy individuals. High-calorie or calorically dense foods, such as fortified infant formulas or breast milk for infants and full-fat dairy products and proteins for children and adults, are encouraged. Consistent, high-calorie dietary intake can be a challenge in patients with CF because of several physiologic factors, including loss of taste or smell caused by chronic sinusitis and chronic gastroesophageal reflux. In addition, behavioral factors may affect intake, which can require behavioral intervention by nutritionists and/or psychologists. For patients of all ages with continued suboptimal growth, use of enteral feeding modes may also be necessary, commonly provided by a gastrostomy tube (i.e., G-tube). With enteral feeding, concentrated, calorically dense formulas may be used to provide more calories with less volume.

## Therapies for Nutrition Challenges in CF

### *Pancreatic Enzyme Replacement Therapy*

A diagnosis of pancreatic insufficiency includes genotype evaluation (i.e., two mutations associated with pancreatic insufficiency), growth failure, symptoms including steatorrhea (fatty stool), and measurement of fecal elastase. Measurement of fecal elastase is used for diagnosis versus monitoring of enzyme replacement efficacy. Because fecal elastase involves a general measurement, it is not used for assessing therapy efficacy because it is not a quantitative test. Fecal elastase values less than 200 mcg/g are indicative of pancreatic insufficiency (Reference 46). The 72-hour fecal fat test is an option for quantifying fat malabsorption. However, this approach is not commonly used because it is tedious for caregivers and potentially poor in accuracy (Reference 43).

The mainstay of therapy for pancreatic insufficiency caused by CF is pancreatic enzyme replacement therapy (PERT). These supplements should be taken or administered at meal and snack times, as well as in coordination with enteral feeds if this mode of nutritional provision

is used. Pancreatic enzyme formulations contain different combinations of lipase, protease, and amylase from porcine sources (Table 3). Although once thought of as dietary supplements and previously poorly regulated in manufacturing and labeling, CF PERT products are now reviewed for approval by the U.S. Food and Drug Administration (FDA). The movement toward full review of PERT products arose because of inconsistencies regarding enzyme concentrations between brand and generic formulations. The Cystic Fibrosis Foundation does not recommend the use of generic PERT preparations because of therapeutic failure, secondary to unregulated manufacturing (References 43, 55). The beads or microspheres within the dosage forms (i.e., capsules) are often enteric coated to protect them from acid-mediated destruction in the stomach. This coating dissolves in the less acidic environment of the duodenum, where the enzymes act to aid in digestion and nutrient absorption (i.e., fats, protein, carbohydrates) (Reference 56). Dosing of PERT is weight-based and dependent on the lipase component of dosage forms. The recommended starting dose for children younger than 4 years is 1000

**Table 3.** Examples of Pancreatic Enzyme Replacement Dosage Forms Used in Cystic Fibrosis (References 47–54)

Brand Name (dosage form)	Amounts in Units per Dosage Form		
	Lipase	Protease	Amylase
Creon (capsules with enteric-coated, delayed-release microspheres, porcine derived)	3000	9500	15,000
	6000	19,000	30,000
	12,000	38,000	60,000
	24,000	76,000	120,000
Pancreaze (capsules with enteric-coated, delayed-release microspheres, porcine derived)	4200	10,000	17,500
	10,500	25,000	43,750
	16,800	40,000	70,000
	21,000	37,000	61,000
Pertzye (capsules with enteric-coated, bicarbonate buffered, delayed-release capsules; porcine derived)	8000	28,750	30,250
	16,000	57,500	60,500
Ultresa (capsules with enteric-coated, delayed-release microspheres; porcine derived)	13,800	27,600	27,600
	20,700	41,400	41,400
	23,000	46,000	46,000
Zenpep (capsules with enteric-coated, delayed-release microspheres; porcine derived)	3000	10,000	16,000
	5000	17,000	27,000
	10,000	34,000	55,000
	15,000	51,000	82,000
	20,000	68,000	109,000
	25,000	85,000	136,000

units of lipase per kilogram per meal. For children 4 years and older, a starting dose of 500 units of lipase per kilogram per meal is recommended. Doses should not usually exceed 2500 units of lipase per kilogram per meal, with a maximum of 10,000 units of lipase per kilogram per day (References 55, 57). When doses are approaching or exceeding usual maximum doses, further assessment of adherence, administration technique, or other potential gastrointestinal comorbidities is recommended. Doses are primarily adjusted on the basis of patient response, with efficacy assessment including patient weight and/or growth markers (e.g., body mass index [BMI]), frequency of stools, stool consistency (e.g., loose vs. formed), abdominal symptoms (e.g., cramping), and incidence of steatorrhea. Dosing for snacks depends on the size and components (i.e., fat content) of the snack. For example, if a snack is about one-half the size of a meal, 50% of the meal dose should be given. However, some patients with CF consume equal-sized portions throughout the day, including both meals and snacks. In these cases, the snack dose would be equivalent to meal dosing.

If PERT dosing requirements exceed recommended meal or daily maximums, further investigation about other factors affecting efficacy may be necessary. These factors include adherence, diet, and other comorbidities that may affect GI symptoms such as loose stools, steatorrhea, or abdominal cramping (Reference 57). When other possible causes of treatment failure are ruled out, the efficacy of PERT should be considered. The efficacy of PERT can vary on the basis of GI tract pH; thus, comorbidities such as gastroesophageal reflux may influence therapy outcomes. When maximal dosing is reached, other etiologies are excluded, and the individual continues to present with symptoms of malabsorption (e.g., steatorrhea), the use of long-duration acid suppression by a proton pump inhibitor may aid in “boosting” the effect of PERT. Studies showing improved growth and decreased incidence of steatorrhea with the addition of a proton pump inhibitor are part of the literature of children as young as 3 years. Dosing is similar to usual starting doses for treatment of gastroesophageal reflux disease (GERD) (e.g., for a 4-year-old with a weight of 13 kg starting omeprazole 10 mg orally daily) with an indefinite duration because the medication is used to aid in the effect of lifelong PERT (References 56, 58, 59). Taurine is an oral supplement that has been proposed as a possible adjunctive therapy when response to PERT is poor, resulting in fat malabsorption. The proposed mechanism of its effect originates in its properties as an organic acid and a component of bile. Data are conflicting regarding its efficacy for enhancing fat absorption in CF; thus, its use is not routinely recommended until further data show benefit (References 60, 61).

### *Vitamin Supplementation*

As part of the malabsorption of nutrients secondary to pancreatic insufficiency, specifically fat, a deficiency in fat-soluble vitamins is a common nutritional complication. Oral supplementation of vitamins A, D, E, and K in individuals with CF, especially those with pancreatic insufficiency, is recommended (Reference 43). This supplementation is often provided by a specific multivitamin containing greater amounts of vitamin A, D, E, and K (e.g., AquADEK, Vitamax, and Source CF), with dosing based on age and product formulation. Individuals deficient in these vitamins may be asymptomatic; thus, the use of laboratory tests to assess status is recommended (Reference 43). Vitamin A is important for several different functions including vision, immune function, and growth. Measurement of the serum level of retinol, a marker of vitamin A, is recommended at least annually. For many patients with CF, supplementation by a CF-specific multivitamin containing water-miscible vitamins A, D, E, and K is sufficient for needed supplementation. Excess vitamin A has been associated with bone and liver disease (Reference 62). Additional oral vitamin A can be provided in doses from 1500 up to 10,000 units/day, depending on age and deficiency (Reference 43).

Vitamin D is necessary for bone health and other functions such as immune function. Deficiency of vitamin D often requires additional oral supplementation with vitamin D<sub>3</sub> (cholecalciferol) or vitamin D<sub>2</sub> (ergocalciferol), ranging from 400 IU to 1000 IU/day to weekly high-dose regimens (e.g., 50,000 IU). Although many forms of vitamin D are available for use by prescription or over the counter, it has been noted that vitamin D<sub>3</sub> is better absorbed and thus perhaps more efficacious than vitamin D<sub>2</sub> for supplementation in deficiency (References 63, 64). Measurement of serum concentrations of vitamin D (i.e., 25-OH-D) are recommended at least annually as part of standard care for patients with CF, with goal concentrations of 35–60 ng/mL (87.5–150 nmol/L) and provision of additional supplementation for concentrations below 35 ng/mL (87.5 nmol/L) (References 43, 65).

Vitamin E, with its function as an antioxidant, also has a postulated role in suppressing inflammation. Similarly, measurement of a serum level (i.e.,  $\alpha$ -tocopherol) is recommended at least annually. Because patients with CF often have lower cholesterol levels than individuals without CF, more accurate assessment of vitamin levels may be achieved by use of an  $\alpha$ -tocopherol/cholesterol ratio. Additional vitamin E oral supplementation, when levels are low despite standard CF supplementation, can be provided in doses of up to 400 units/day, depending on age and deficiency (Reference 43).

Vitamin K, necessary as a cofactor for the coagulation pathway, is often deficient in individuals with CF because of fat malabsorption as well as changes in GI flora. In individuals with CF-associated hepatobiliary disease, this deficiency may be further exacerbated, requiring additional oral supplementation (e.g., phytonadione). Additional oral supplementation of vitamin K may be needed for older children and adults with CF who have chronic deficiency based on laboratory values, who are given long-term antimicrobial therapy, or who have an ongoing history of hemoptysis (Reference 66). Additional vitamin K or phytonadione oral supplementation can be provided in doses ranging from 2.5 to 10 mg/day, depending on age (Reference 43). Monitoring of serum levels of prothrombin or PIVKA-II (proteins induced by vitamin K absence) is suggested at least annually, with PIVKA-II being more sensitive; however, PIVKA-II may not be easily accessible at all institutions (Reference 43).

### *Appetite Stimulants*

For some individuals, dietary intake to reach or maintain nutritional goals in CF is a chronic challenge because of inadequate appetite. Etiology of poor appetite is variable and can be psychological (e.g., depression), result from an adverse effect of a medication (e.g., methylphenidate, bupropion), or be caused by another comorbidity such as poor GI motility (e.g., gastroparesis). Individuals with CF at nutritional risk (i.e., BMI percentile, 25% or less) should be evaluated appropriately before appetite stimulants are initiated. Dietary intake review (e.g., food diaries), laboratory workup for other comorbidities (e.g., CFRD, GERD), and evaluation of psychosocial or socioeconomic status should be part of the assessment for appropriateness of appetite stimulants (Reference 67).

Treatment of the source of poor appetite or oral intake is ideal (e.g., treatment of depression); however, in certain instances, the employment of appetite stimulants may be considered if the use of primary approaches fails to result in improvement. Agents used as appetite stimulants in CF include those used in patients with cancer (e.g., megestrol acetate, cyproheptadine). These agents each possess useful effects of appetite stimulation and weight gain that are useful for individuals with CF who are challenged in weight gain and poor oral food intake. Choice of agent will depend on patient-specific factors such as age, available data, and dosage form needed (e.g., liquid vs. tablet). Safety and efficacy of agents such as cyproheptadine have been studied for as long as 12 months in some children (Reference 68). Dronabinol, the oral dosage form of delta-9-tetrahydrocannabinol, is another potential agent used in patients with cancer and patients with AIDS (acquired immunodeficiency syndrome) wasting syndrome. However, documented

use of this agent in the CF population as an appetite stimulant is limited, with greater experience in adolescents and adults with CF and use of doses of up to 5 mg by mouth twice daily (Reference 69). Other agents that could be considered for use include the antidepressant mirtazapine at doses of up to 45 mg/day orally, with most experience in adolescents and adults with CF (References 70, 71). Antipsychotics such as olanzapine and risperidone have also been used in patients with CF because they have a strong adverse effect of excessive weight gain (Reference 72).

### **Monitoring Nutritional Therapy**

Nutritional status is of utmost importance for children with CF because of the association between normal weight and stature for age and improved FEV<sub>1</sub> and survival. The Cystic Fibrosis Foundation recommends that children with CF be in at least the 50th percentile in weight-for-length during the first 2 years of life and that individuals with CF who are 2–20 years of age maintain at least the 50th percentile or higher for BMI to optimize FEV<sub>1</sub> (References 43, 55). Some CF centers have developed color-coded growth charts (Figure 4) to help facilitate the monitoring of nutritional risks on the basis of guidelines and cite specific designated progression of nutritional risk (References 43, 55, 73). Additional laboratory monitoring is recommended to assess the nutritional status of individuals with CF. Tests that should be performed upon diagnosis and at least annually include vitamin levels, albumin and prealbumin for assessment of protein stores, and hemoglobin and hematocrit for basic assessment of potential iron-deficiency anemia. Additional workups of iron-deficiency (e.g., total iron-binding capacity, total ferritin level) anemia may be considered. Other laboratory tests to consider include serum sodium in cases of potential dehydration and essential fatty acids in cases of poor nutritional status. Because patients with CF are at increased risk of osteopenia, the use of tests to assess bone mineral density (e.g., DXA [dual {energy} x-ray absorptiometry]) may be warranted (Reference 43).

## **OTHER GI DISEASES IN CF**

### **Physical Manifestation**

With the obstruction of the pancreatic duct caused by viscous epithelial secretions, some neonates with CF may exhibit an early GI manifestation of CF known as meconium ileus. Meconium ileus is an obstruction of the small intestines by meconium, the early stool of a neonate composed of ingested material including mucus, amniotic fluid, and bile. With a less common occurrence, meconium ileus presents in only 10% to 15% of patients with CF. Distal intestinal obstruction syndrome (DIOS)

**Figure 4.** Centers for Disease Control and Prevention body mass index-for-age, boys 2–20 years, adapted for patients with cystic fibrosis nutritional risk (References 73, 74).

is the meconium ileus equivalent in children and adults with CF. Individuals with a history of meconium ileus may be at increased risk of developing DIOS. In DIOS, intestinal contents (e.g., fecal matter) block the small intestinal lumen, and its etiology is not completely understood. Proposed etiologies of DIOS include pancreatic insufficiency and decreased intestinal motility. Other complications that may or may not accompany DIOS include intussusceptions and rectal prolapse (References 75, 76). Rectal prolapse, associated with malnutrition, constipation, and diarrhea, is another GI complication reported in about 20% of individuals with CF. This most commonly occurs in younger children (e.g., 1–3 years of age), and it is often transient, frequently resolving at 3–5 years of age (Reference 77).

Small intestinal bacterial overgrowth (SIBO) is a condition in which bacterial content increases, resulting in damage to enterocytes and worsening malabsorption and malnutrition, with an incidence as high as 30% to 50% in the CF population (Reference 78). Although SIBO is also seen in patients without CF, individuals with CF are at risk of SIBO because of the potential for poor intestinal motility and use of thrice-weekly azithromycin as part of a chronic pulmonary management regimen (References 75, 76).

Obstruction of the biliary duct and accumulation of viscous bile can lead to focal biliary cirrhosis in 11% to 70% of individuals with CF; however, it is not always apparent because some individuals may be asymptomatic (Reference 79). Like other areas throughout the body where epithelium is located, CFTR is also found in biliary epithelial cells. As a result, bile ducts are obstructed because of viscous bile production, which causes cholelithiasis, cholecystitis, progressive fibrosis, and cirrhosis. In neonates with CF, cholestasis may result, which is sometimes mistaken for biliary atresia. Individuals with CF-associated hepatobiliary disease may also develop steatosis (i.e., fatty liver) because of various factors including essential fatty acid deficiency or malnutrition. Further complications, including portal hypertension, can be found when CF-associated hepatobiliary disease is symptomatic and severe (References 79, 80). With the increased life expectancy of CF, the incidence of CF-associated hepatobiliary disease may increase because this complication is often found in older children and adults with CF. Evaluation of liver enzymes, including  $\gamma$ -glutamyl transferase at least annually in stable patients with CF, is recommended. For individuals who present with persistent elevations, further investigation is warranted, including an assessment of clinical presentation (e.g., stool pattern, jaundice, abdominal pain) and other possible etiologies such as other GI disorders or medication-induced liver injury. Additional testing including imaging evaluation, upper GI endoscopy, or biopsy may be employed to confirm diagnosis.

Gastroesophageal reflux disease is also a common comorbidity among individuals with CF, with an incidence as high as 58% to 86% (Reference 81). It is postulated to be attributable to various causes, including transient relaxation of the lower esophageal sphincter and increased intra-abdominal pressure because of chronic cough. Not only does GERD potentiate the risk of poor nutrition in young children with CF, but it may also pose a risk of other complications such as gastric aspiration (References 81, 82). The diagnosis of GERD in children with CF is similar to the diagnosis of GERD in children without CF.

## Therapies for GI Diseases in CF

### *DIOS and Rectal Prolapse*

Proposed causes of DIOS include iatrogenic decrease of intestinal motility, or abnormalities in fluid and electrolyte balance of secretions in the GI tract, resulting in viscous, mucous-like obstruction. Constipation is often associated with DIOS, and definitions separating the two conditions have been outlined in formal guidelines (Reference 83). Unlike constipation, in which the use of laxatives (e.g., oral polyethylene glycol, lactulose) often alleviates the condition, DIOS often necessitates the use of more aggressive treatment, including laxatives at higher doses, use of electrolyte intestinal lavage solution (e.g., GoLYTELY), or hyperosmolar enemas. Oral *N*-acetylcysteine (5% solution) has also been used for the prevention and treatment of mucus accumulation in the GI tract of some individuals with DIOS (References 83, 84). Distal intestinal obstruction syndrome is thought to be related to pancreatic insufficiency that is poorly controlled with PERT. Similarly, rectal prolapse may respond to an increase in PERT dose and seldom requires surgical intervention (Reference 77).

### *Small Intestinal Bacterial Overgrowth*

Treatment of SIBO in individuals with CF is also similar to that of individuals without CF, such as the use of oral antibiotics (e.g., rifaximin, metronidazole, norfloxacin). Treatment may help improve the nutritional status of patients with CF. Additional treatment modalities may include dietary manipulation, such as reducing carbohydrate consumption, resulting in a high-fat, low-carbohydrate diet. The use of laxatives and inhaled ipratropium has also been associated with a decreased risk of SIBO (Reference 85).

### *Hepatobiliary Disease*

As part of the treatment of hepatobiliary disease in CF, it is imperative to optimize nutrition, especially fat-soluble vitamin and essential fatty acid deficiencies (Reference 72). In addition to nutritional support, treatment with oral ursodeoxycholic acid or ursodiol (20 mg/kg/day

divided three times/day) is currently recommended; however, additional outcomes data are necessary to describe its long-term effect on cholestasis, fibrosis, and cirrhosis in CF (Reference 86). Taurine, an organic acid found in bile, has also been proposed for adjunctive treatment of hepatobiliary disease in CF; however, limited data support its routine use for this purpose (Reference 61).

### ***Gastroesophageal Reflux Disease***

If symptoms of GERD coincide with poor nutritional status (e.g., failure to thrive), treatment is warranted, especially in infants and younger children. Medical management of GERD in children with CF is similar to that in other children without CF, including initial use of histamine-2 receptor blockers (e.g., ranitidine) (Reference 87). However, for some patients with CF, management can be more severe, requiring a change to or addition of a proton pump inhibitor (e.g., lansoprazole). Surgical management of GERD by fundoplication is also considered when complications are severe such as erosive esophagitis, uncontrolled pulmonary condition caused by reflux, or failure to thrive despite medical management (Reference 88).

## **OTHER COMPLICATIONS OF CF**

### **CF-Related Diabetes**

The pathophysiology of the pancreatic disease also involves endocrine function or insulin regulation. Eighty-five percent of patients with CF have pancreatic enzyme insufficiency, and as the cystic changes in the pancreas progress, patients begin to have problems with insulin regulation. Patients with CF develop glucose intolerance as either fasting hyperglycemia or postprandial hyperglycemia. Routine screening is now recommended starting as young as 10 years of age, although some centers are starting even earlier in life because of potential variability in the clinical onset of this manifestation (Reference 89). A fasting blood glucose and a 2-hour postoral glucose load (e.g., glucose tolerance test) are recommended annually. Almost 30% of patients with CF older than 30 years have some form of glucose intolerance. As patients with CF continue to live longer, a higher percentage of them are expected to present with CFRD. This condition is not classic type 1 or 2 diabetes mellitus. Cystic fibrosis-related diabetes can often be initially managed with dietary restrictions from concentrated sugars (e.g., soft drinks). If this approach does not work, insulin is the drug of choice. Cystic fibrosis-related diabetes insulin therapy often involves modest doses of long-acting insulin paired with carbohydrate counting and coverage with rapid-acting insulin (Reference 90). Like with other patients with diabetes and an infection, an acute pulmonary exacerbation or illness may complicate glucose control, especially when systemic corticosteroids are used during

the management of severe pulmonary exacerbations. Addressing issues related to blood glucose control is now paramount in the long-term management of CFRD (References 91, 92).

### **Chronic Sinusitis**

As part of the upper respiratory tract, the sinuses are also affected in the inflammation and infection processes of CF. This is because of their pseudostratified ciliated epithelium and lack of mucociliary clearance as similarly seen in the airways. Individuals with CF often have hypoplasia of the sinuses, which creates a confined area where respiratory pathogens such as PA can remain, causing chronic infection and inflammation. Sinuses can be assessed by a computed tomography scan to confirm the diagnosis of sinonasal disease before treatment or surgical intervention because the sinuses can appear opacified by 8 months of age with conventional sinus radiography (Reference 93). Treatment of the acute exacerbations of sinusitis can include oral and/or intravenous antibiotics, which are also used in pulmonary exacerbations and in intranasal irrigations of antimicrobials such as gentamicin and amphotericin B.

### **Hyponatremia**

The sudoriferous (sweat) glands, an epithelial exocrine system, are also affected by CF. Sweat from individuals with CF contains an abnormally high amount of Na<sup>+</sup> and Cl<sup>-</sup> caused by the defective Cl<sup>-</sup> impermeability of epithelial cells because of dysfunctional or absent CFTR. Thus, these individuals are at increased risk of electrolyte imbalances (e.g., hyponatremia, hypochloremia) during periods of heavy sweat excretion (e.g., warm weather combined with strenuous exercise) (Reference 94).

Because of the excessive loss of Na<sup>+</sup> in sweat, infants with CF are at risk of developing hyponatremic, hypochloremic dehydration. Infant formulas and breast milk do not provide adequate Na<sup>+</sup> for infants with CF; thus, it is recommended that 1/8 teaspoon of table salt be provided from birth and increased with time to 1/4 teaspoon by 6 months through 1 year of age, divided throughout the day by feedings (Reference 46). Additional supplementation may be necessary for any patient living in high-temperature climates, especially patients involved in physical activities in these environments (e.g., athletes) (Reference 43).

## **SPECIAL TOPICS RELATED TO CF**

### **CF in Adulthood**

As patients with CF grow older, complications arise, such as progressive respiratory disease and increased incidence of CFRD and insulin therapy. Additional chronic changes in the destructive nature of the lung in CF (e.g., bronchiectasis) develop, and patients often require

supplemental oxygen therapy and increased frequency of airway clearance. Osteoporosis is often seen in adult patients with CF because of inadequate intake or absorption or chronic hypoxia. Pharmacists in adult CF centers can be invaluable resources to help manage these complications, together with the CF care team.

Males with CF are infertile, but females can conceive and carry children to term. However, the fertility rate of females is reduced compared with that of patients without CF, partly because of the alteration of their cervical mucus, which impairs fertilization. Women with CF and severe lung disease have a higher risk of pregnancy complications (Reference 95). Therefore, it is important to address contraception in CF and explain the options for patients.

### New Therapies

During the past 10 years, a tremendous partnership with the Cystic Fibrosis Foundation and the pharmaceutical industry has produced many new pharmaceuticals for clinical evaluation including aerosolized antibiotics, anti-inflammatory agents, and, most recently, agents that alter CFTR function. Some of these agents are new aerosolized formulations of antibiotics (e.g., tobramycin and amikacin), whereas novel compounds that help CFTR reach the airway surface in larger quantities are referred to as corrector drugs. Compounds that increase CFTR transport or function are referred to as potentiators of CFTR function (Reference 96). Early results of phase II trials of patients who are homozygous F508del mutation, with the combination of VX-809 (a corrector drug) in combination with VX-770 (a potentiator drug), have shown statistical changes in sweat chloride, a marker of Cl function (Reference 97). This approach to increasing CFTR activity at the airway surface and correcting abnormal CF has the potential to radically change how the disease can be managed, and it may profoundly affect survival and quality of life.

Recently, ivacaftor (formerly known as VX-770) was approved by the FDA for chronic therapy in patients with the G551D genotype of CF. Because this drug is a potentiator of this “gating” mutation of CF, therapy is limited to about the 4% of patients with CF having this genotype. It is given orally at a dose of 150 mg twice daily, taken with a fat-containing meal. Clinical trials showed an improvement in FEV<sub>1</sub> of 10% to 12% (Reference 98). Studies are ongoing with ivacaftor and other compounds to see whether other genotypes of CF will respond to this therapy.

In addition, the development of novel approaches continues in the delivery of gene therapy (e.g., corrected CFTR delivery) to the airway. Problems with vectors and host response to repeated doses continue to be an issue, but new approaches may be able to overcome

these limitations of repeated dosing. The promise of these new therapies is indeed exciting and may provide the foundation for a profound change in the outlook of CF in the next decade (Reference 96).

### ADHERENCE IN CF

Adherence to airway clearance and medication therapy is a lifelong challenge for many individuals with CF. Factors affecting adherence are often variable, making adherence difficult to effectively address in the care of patients with CF. Factors can be age-associated, with different reasons for nonadherence to therapies between an infant or small child compared with an adolescent. In the care of an infant or child, caregivers are primarily responsible for therapy administration. As a result, reasons for nonadherence in these instances include forgetting treatments, becoming confused because of several caregivers' responsibilities, discontinuing treatment in response to lack of symptoms, experiencing resistance from the child, developing concerns about medication adverse effects, and misunderstanding the instructions (Reference 99). Conversely, in older patients such as adolescents, self-administration is commonplace, and reasons for nonadherence are more personal and psychosocial. The balance of growing independence and continued parental involvement becomes a challenge for some families. In adolescents, risk-taking behavior, an invincible perspective, or peer influence may negatively affect treatment adherence. When considering the active lifestyles of youth, time can be a limiting factor affecting adherence, especially with respect to airway clearance therapy (Reference 100).

Patient-specific factors including socioeconomic status, culture, and/or caregiver beliefs can also affect adherence to both airway clearance and medication therapies. Studies have shown a potential preference for which therapy patients are adhering to. Medications that may provide perceived immediate relief, or results such as pancreatic enzymes, dornase alfa, albuterol, or hypertonic saline may be missed less often than those that provide conceived long-term benefit such as aerosolized antibiotics or even airway clearance (References 99, 101, 102). Many individuals with CF carry a heavy medication burden, which affects patient adherence to regimens. Polypharmacy is often encountered in the treatment of aggressive CF disease; however, despite the good intention of efficacy, combinations of medications can also place patients at increased risk of adverse drug events. Regular assessment of medication regimens is necessary as part of continued care.

Consequences of poor adherence to airway clearance and medication treatment can include increased frequency of exacerbations and increased rate of decline of lung function. Medication adherence has been related to the

frequency of use of intravenous antibiotics for exacerbation, and exacerbations have been associated with the failure to return to baseline pulmonary function (References 42, 103). Approaches to improve the adherence of individuals with CF include patient and caregiver education, with involvement by a child's school if needed, which should be provided at the start of care and reinforced with each clinic visit and inpatient admission. Interventions to improve adherence can be organizational (e.g., calendars, automated reminders by cell phone alarm), psychoeducational (e.g., reinforced education about disease, treatment, outcomes), or psychotherapeutic or motivational (e.g., therapy diary, setting goals). No single intervention is applicable to all, and because each patient is different, the choice of intervention approach should be a joint, patient-care team decision (Reference 104).

#### **APPROACH TO CARING FOR PATIENTS WITH CF AND THE ROLE OF THE PHARMACIST ON PATIENT-CARE TEAMS AND IN THE COMMUNITY**

The treatment of individuals with CF is often approached in a systematic manner, involving the role of various health care providers including physicians, pharmacists, nurses, respiratory therapists, clinical nutritionists, clinical psychologists, physical therapists, and social workers. Information defining the role of a clinical pharmacy specialist in caring for patients with CF is limited, especially in the outpatient setting (e.g., CF centers). A survey of patients with CF conducted by European CF center investigators revealed that only 59% of patients reported access to specialty pharmacists (Reference 105). One of the first descriptions of pharmacist participation in the care of patients with CF described a role involving multidisciplinary rounds in the inpatient setting and the rotation of pharmacy residents in the CF clinic (Reference 106). Inpatient responsibilities of a pharmacist caring for patients with CF should include medication reconciliation, routine assessment of pharmacotherapy, communication with health care colleagues and families, and an active role in preparation for discharge, including home care (e.g., home intravenous antibiotics). Conversely, outpatient or ambulatory care setting responsibilities can include medication reconciliation, assessment of complementary and alternative therapy use, and assessment and intervention of medication adherence. Pharmacists in both inpatient and outpatient settings have a fundamental role in teaching patients and caregivers how to appropriately take or administer medications, including the timing of oral agents such as pancreatic enzymes and the use of metered dose inhalers and nebulized medications. Pharmacists can also play a central role in evaluating the use of dietary supplements, including complementary and alternative medications, because they may interact with prescribed drug therapy (Reference 107).

Interdisciplinary, family-centered care of patients with CF is a care model involving a variety of health care disciplines and has been an increasingly common practice in the inpatient setting. The central focus of this care model, patients and families play an important role in the successful, comprehensive care of patients with CF. Patients and caregivers are encouraged to participate in decision-making with respect to regimen design and approach to overall care. In fact, many CF centers have a family member serve as a representative of patients and families in a role noted as "family liaison." Pediatric Pulmonary Centers, supported by Maternal and Child Health Training grants, are an example of this patient-care model in the outpatient setting. These care centers involve teams composed of various disciplines including medicine, nursing, nutrition, respiratory therapy, social work, family liaisons or representatives, and, the most recent addition, pharmacy. As part of these programs, not only do the various disciplines work together to provide quality patient care to children, but they also provide a way of training future professionals (e.g., residents, interns).

With the complexity of CF drug therapy management given the challenging pharmacokinetics, the combination of acute and chronic drug therapies, and the diversity of patient ages and conditions secondary to medical advances, continuity of care is imperative to optimize medication efficacy while minimizing adverse drug events. A lack of data remains regarding the use and effect of a patient-care model that bridges specialist outpatient care to the management of acute exacerbations and continuation of clinically important maintenance drug therapy for hospitalized patients with CF. A model of continuity of care for these patients should possess elements of optimal drug therapy selection and consistency between outpatient and inpatient care involving an interdisciplinary approach. Additional investigation about effective combined care models will provide clinicians information regarding the active involvement of clinical pharmacy specialists as part of both the outpatient and inpatient care of patients with CF, thereby improving patient outcomes from drug therapy.

Pharmacists, as patient advocates, have a professional responsibility to undergo continued education and training about innovations in therapy to optimize the health of children and adults with CF. In addition to their role as health care providers, pharmacists can play a key role in clinical research, whether as principal investigator or collaborator. Studies of new agents, approaches to dosing, and innovations in therapy adherence interventions are a continued need for advancing patient care and improving quality of life. Advocacy as a clinician, researcher, educator, and/or community leader is a multifaceted role that pharmacists can play in the CF community—it is with this passion and dedication that the care of individuals with CF advances toward a future cure.

# CHAPTER 16

## GASTROESOPHAGEAL REFLUX DISEASE

Kalen Manasco, Pharm.D., BCPS, AE-C

### LEARNING OBJECTIVES

1. Distinguish between the clinical presentations of gastroesophageal reflux (GER) and gastroesophageal reflux disease (GERD) in pediatric patients.
2. Discuss treatment goals for the management of GER in pediatric patients.
3. List the risk factors for the development of severe, chronic GERD.
4. Discuss the role of both pharmacologic and nonpharmacologic treatment in the management of GER and GERD.
5. Recognize and manage common and potential adverse drug reactions with pharmacologic treatment of GER and GERD.

### ABBREVIATIONS IN THIS CHAPTER

ALTE	Apparent life-threatening event
GER	Gastroesophageal reflux
GERD	Gastroesophageal reflux disease
H <sub>2</sub> RA	Histamine-2 receptor antagonist
LES	Lower esophageal sphincter
PPI	Proton pump inhibitor
TLESR	Transient lower esophageal sphincter relaxation

### INTRODUCTION

Gastroesophageal reflux (GER) is a common clinical manifestation in infancy and childhood. Gastroesophageal reflux disease (GERD) is a pathologic condition that may develop from reflux in patients of all ages. The first international consensus guideline on the diagnosis and management of GER and GERD in the pediatric population was recently published (Reference 1). The previous guideline published in 2001 included recommendations from only the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (Reference 2). These guidelines have changed the medical management of patients with GER and GERD.

### DEFINITIONS

To better understand the disease process associated with reflux, several definitions are important. The first global, evidence-based consensus definition of GERD in the pediatric population was recently published (Reference 3). Gastroesophageal reflux is simply defined as the passage of stomach contents into the esophagus. It is a common occurrence in infancy and is not associated with any pathologic process, but it may be caused by food allergy or colic. Gastroesophageal reflux can manifest as spitting up or regurgitation. Regurgitation is defined as the passage of gastric contents into the oropharynx or mouth or possibly out of the mouth. Gastroesophageal reflux disease is defined as troublesome clinical symptoms and/or complications associated with the passage of stomach contents into the esophagus (Reference 3). Troublesome symptoms are those that affect a patient's quality of life such as heartburn, excessive regurgitation, food refusal, or abdominal pain. Complications of GERD are reflux esophagitis, hemorrhage, stricture, and Barrett esophagus (Reference 3). Reflux esophagitis is inflammation of the esophagus and the presence of damage to the esophageal mucosa (as erosions or ulcerations) as detected by biopsy. Barrett esophagus is a disorder in which the epithelial lining of the esophagus is replaced by epithelium similar to the stomach lining secondary to damage from acid reflux. Patients with this disorder are at high risk of developing esophageal adenocarcinoma. Gastroesophageal reflux disease can be associated with too much acid production, but it can also occur in children who present with no acid reflux. Nonerosive gastroesophageal disease is defined as the presence of typical symptoms of GERD without any erosive lesions within the esophagus.

### GER IN INFANTS

#### Epidemiology and Etiology

Gastroesophageal reflux is a normal physiologic process that occurs many times throughout the day in people of all ages. It is most common in infancy and usually resolves by 12–14 months of age (References 4, 5). Up to two-thirds of infants experience recurrent regurgitation and vomiting within the first 4 months of life, but only 5% of infants have symptoms of reflux beyond 1 year of age (Reference 6).

Physiologic reflux occurs when the lower esophageal sphincter (LES) relaxes and swallowing does not occur. This allows the passage of stomach contents into the esophagus. This can occur more often in neonates and infants because of the shorter length of the esophagus, delayed gastric emptying, decreased LES pressure, and immature peristalsis (Reference 7).

Gastroesophageal reflux can be associated with apnea, failure to thrive, and respiratory problems (recurrent aspiration, wheezing) in preterm infants. However, there is no evidence to suggest a causal relationship between GER and these occurrences. One study evaluating the prevalence of infant regurgitation in infants younger than 2 years found no difference in GER between preterm and term infants (Reference 6).

### Clinical Presentation and Diagnosis

The most common symptom associated with physiologic reflux in the infant is regurgitation or “spitting up.” Reflux can also trigger vomiting. Other signs and symptoms that can be associated with reflux are nonspecific and include irritability, excessive crying, lethargy, feeding refusal, and cough (Table 1). These cannot be distinguished from other causes of reflux such as food allergy or colic. Infants with uncomplicated physiologic reflux are commonly referred to as “happy spitters.” These infants can continue to gain adequate weight despite the problematic symptoms associated with reflux.

Reflux episodes can have a temporal relationship with apnea; however, evidence is conflicting whether there is a temporal or causal relationship between apnea and reflux (Reference 1). Apparent life-threatening events (ALTEs) are episodes of sustained apnea, cyanosis, abnormal muscle tone, and gagging that usually occur in the first 3 months of life. They are frightening

episodes for parents or caregivers that usually result in admission to the hospital for further diagnostic evaluation. An ALTE may be associated with reflux in an infant; however, ALTEs are not thought to be caused by GER (Reference 1).

The diagnosis of physiologic reflux is often based solely on the parental history and physical examination. Clinicians should perform a thorough examination of the child and obtain a detailed feeding history and description of the exact symptoms, including when they occur in relation to feeding. In addition, a thorough medical and family history should be obtained, including a family history of reflux and other gastrointestinal disorders (celiac disease, *Helicobacter pylori* infection). Invasive testing is not usually required unless there is a suggestion of another pathologic diagnosis including GERD.

The I-GERQ-R (Infant Gastroesophageal Reflux Questionnaire Revised) is a validated diagnostic questionnaire composed of 14 items that can be used to guide clinicians when obtaining a history, and it has also been found to help monitor symptom occurrence with time (Reference 8). The items are questions related to the characteristics of regurgitation, crying, feeding refusal, apnea or cyanosis, hiccups, and abnormal body posturing. The Rome III criteria were established to provide diagnostic criteria for infant regurgitation and other functional gastrointestinal disorders. Healthy infants who are 3 weeks to 12 months of age must present with both of the following: (1) regurgitation 2 or more times per day for 3 or more weeks and (2) no retching, hematemesis, aspiration, apnea, failure to thrive, feeding or swallowing difficulties, or abnormal posturing to be diagnosed with infant regurgitation (Reference 9).

**Table 1.** Signs and Symptoms Suggestive of GER

Age group	Infants < 1 year	Children 1–5 years old	Older children and adolescents (6–17 years old)
Symptoms	Regurgitation	Regurgitation	Heartburn
	Vomiting	Abdominal pain	Epigastric pain
	Arching	Cough	Dysphagia
	Irritability		
	Poor weight gain		
	Crying		
Signs	Sandifer syndrome	Food refusal	Reflux esophagitis
	Food refusal	Recurrent pneumonia	
	Failure to thrive	Dental erosions	
	ALTE		

ALTE = apparent life-threatening event; GER = gastroesophageal reflux.  
Adapted from Reference 1.

All infants who present with extraesophageal symptoms (apnea, ALTE, arching of the back, failure to thrive) and/or bilious vomiting should undergo a further diagnostic workup. Extraesophageal symptoms are commonly associated with GERD. Bilious vomiting is usually indicative of an obstruction or pyloric stenosis.

### Prognosis

Most infants with physiologic reflux have a favorable prognosis because they “outgrow” the symptoms by 1 year of age. Children who have persistent symptoms beyond 18 months of age, neurologic impairment, prematurity, or a strong family history of GERD have a worse prognosis compared with infants who have physiologic reflux.

### Treatment

The goals of therapy are to provide parental reassurance and education, alleviate patient symptoms, and prevent complications. The mainstay of treatment in GER is nonpharmacologic. Management strategies include lifestyle changes (feeding and positional changes) and dietary changes. Pharmacologic management is reserved for the management of GERD.

### Nonpharmacologic Therapy

#### Lifestyle Modifications

Lifestyle modifications for infants with physiologic GER include parental reassurance, positional changes, and dietary changes (Box 1). Parental education should include counseling on the management of GER when it occurs, the prevention of reflux episodes, and the natural course and duration of infantile physiologic reflux, as well as counseling on when to seek additional treatment

#### Box 1. Lifestyle changes for patients with GER and GERD.

##### Infants

- Parental reassurance
- Dietary changes
- Positional changes

##### Older children and adolescents

- Dietary changes
- Sleeping position changes
  - Elevate head of bed.
  - Left-sided sleep position
- Weight loss
- Decreased tobacco smoke exposure

GER = gastroesophageal reflux; GERD = gastroesophageal reflux disease.

if symptoms persist or complications are noted. Parents should also be counseled on different positioning during and after feeding, burping, and other techniques to reduce the likelihood of reflux episodes.

In infants, the supine position is preferred to the prone position for sleeping. Despite studies showing the prone position can lessen reflux episodes, a significantly increased risk of sudden infant death syndrome exists compared with the supine position (References 10, 11). For this reason, the prone position is only acceptable when infants are awake and carefully watched after a meal. In addition, holding a sleeping infant in an upright position for the first 20–30 minutes after feeding if they are asleep is acceptable (Reference 1).

#### Dietary Changes

Potential dietary changes include changing the volume or frequency of feeding, trying a hypoallergenic or antireflux formula, and thickening the formula to increase caloric density. One of the most common situations discovered upon questioning parents and caregivers about reflux and regurgitation in their infant is overfeeding. Altering the feeding volume and frequency can be beneficial to infants with GER. Studies have shown that smaller-volume feeds can decrease acid reflux (Reference 12). However, clinicians should be cautioned that decreasing the volume or frequency of feeds may lead to inadequate weight gain.

The most common practice when changing the feeding volume is also to add a thickening agent, which will increase the caloric content of the formula. This is done to ensure adequate weight gain in the infant. Rice cereal is the most common thickening agent used. One tablespoon of rice cereal per 2 oz increases the formula from 20 calories per ounce to 27 calories per ounce (Reference 1). The addition of rice cereal does not change the amount of acid reflux, but it does decrease the amount of regurgitation (References 13, 14). The potential disadvantages of adding rice cereal to formula include increased coughing during feeding and the extra energy expenditure in the infant because of the increased viscosity of the formula (Reference 15). If infants have to suck a thicker substance through the nipple in the bottle, they will use more energy during the feeding process, which can cause an increase in caloric requirements. Infants typically need an enlarged nipple for adequate sucking when using a thickened formula.

Prethickened, anti-regurgitation (AR) formulas are commercially available. These formulas include the addition of starch, which thickens only when mixed with the acid in the stomach. These formulas, which do not require the addition of an enlarged nipple, have been found to decrease both the amount of regurgitation and the amount of acid reflux (Reference 16). Theoretically, there is a potential drug interaction with AR formulas

and histamine-2 receptor antagonists (H<sub>2</sub>RAs). Because acid content in the stomach is required for the formula to work, there may be a decreased effect of the AR formula in a patient also taking a histamine receptor antagonist. Although this interaction has only been reported with the H<sub>2</sub>RAs, it could theoretically occur with a proton pump inhibitor (PPI) as well. It is recommended to have a trial of AR formula first in an infant with GER before initiating any acid suppression therapy.

Because it is difficult to distinguish between infants with reflux and those with a milk protein allergy, changing to a hypoallergenic formula may prove beneficial in many patients. Trials of feeding with either protein hydrolysate or amino acid formulas for infants having regurgitation longer than 4 weeks have been successful in decreasing vomiting and are recommended according to the current guidelines (Reference 17). However, there is no evidence for soy formula in the management of infant reflux (Reference 1).

## GASTROESOPHAGEAL REFLUX DISEASE

### Epidemiology and Etiology

The prevalence of GERD has increased during the past several years in both adults and children. The true prevalence in pediatric patients is unknown because of the lack of a consistent definition used in practice. In addition, both the prevalence and incidence vary among the different age groups (neonates, infants, children, and adolescents). The prevalence is highest in infants younger than 1 year (Reference 18). The incidence of GERD ranges from 5% to 35% (Reference 19). Males are affected more than females. Bottle-fed infants are at an increased risk of GERD compared with breastfed infants.

More than one-half of the pediatric patients who are given a diagnosis of GERD require medical management of their disease. In one study, 4% of all hospital admissions annually were because of GERD (Reference 20). In addition, it is estimated that \$750 million are spent annually on the management of childhood GERD in hospitals (Reference 20).

### Pathophysiology

Gastroesophageal reflux disease is caused by transient lower esophageal sphincter relaxations (TLESRs), decreased LES pressure, delayed gastric emptying, and hiatal hernia.

The movement of reflux from the stomach into the esophagus usually occurs during TLESRs. Normally, the LES relaxes very briefly (3–10 seconds) in response to swallowing. Transient lower esophageal sphincter relaxations occur when the LES relaxes for more than 10 seconds and is not induced by the swallowing mechanism. Reflux episodes can also occur because of

decreased LES pressure or inability of the LES to increase in response to increased intra-abdominal pressure. Factors that can contribute to decreased LES pressure include tobacco smoke exposure, intake of fatty foods, certain medications (theophylline, calcium channel blockers), and gastric distention. In addition, normal digestive defense mechanisms can become impaired in the presence of acid reflux and further exacerbate GERD symptoms. Continued exposure of the mucosa and submucosa within the esophagus to refluxate, primarily containing acid, can lead to the development of erosions in the esophagus.

### Genetic Basis

Evidence suggests that GERD has a genetic component. A specific locus on chromosome 13 (13q14) associated with severe pediatric GERD has been identified (Reference 21). In addition, there are reports of a familial association with GERD. Reflux symptoms, hiatal hernia, erosive esophagitis, Barrett esophagus, and esophageal adenocarcinoma occur more commonly within families (References 22, 23).

### Risk Factors

There are several pediatric patient populations that are at increased risk of severe, chronic GERD and complications associated with GERD. These include neurologic impairment (e.g., cerebral palsy), obesity, esophageal atresia, chronic lung disease, and prematurity. These patient populations have a poor prognosis and require long-term treatment of the symptoms associated with GERD (Reference 1).

### Clinical Presentation

The troublesome signs and symptoms associated with GERD include vomiting, irritability, refusal to feed, heartburn, dysphagia, and Sandifer syndrome. Sandifer syndrome is defined as spasmodic dystonia with arching of the neck and back and abnormal posturing (Reference 3). It is important to distinguish between this clinical presentation and similar movements that may be caused by seizures or infantile spasms. Table 1 lists the most common signs and symptoms seen according to age group.

Gastroesophageal reflux disease may or may not lead to erosive esophagitis. This is because GERD can be caused by both acid and nonacid reflux. Symptoms most commonly associated with nonacid reflux include regurgitation and cough. Patients with erosive esophagitis typically present with heartburn and belching.

Gastroesophageal reflux disease is associated with both esophageal and extraesophageal symptoms. The most common extraesophageal symptoms in children include respiratory symptoms such as apnea, coughing,

and wheezing. Extraesophageal manifestations of GERD include asthma, pneumonia, nocturnal cough, sinusitis, laryngitis, otitis media, and dental erosions. New or expanded sections about the clinical presentation and treatment of certain high-risk populations appear in the new guideline, including neurologic impairment (anoxic brain injury, cerebral palsy, Down syndrome), obesity, esophageal anatomic disorders, chronic respiratory disorders (cystic fibrosis, bronchopulmonary dysplasia), lung transplantation, and prematurity (Reference 1).

## Diagnosis

An initial diagnosis of GERD is often based on the clinical presentation of the patient with typical signs or symptoms for reflux. However, because many of the signs and symptoms are nonspecific (weight loss, dysphagia, cough, irritability), it is difficult to rely only on the clinical presentation for a diagnosis. Other disease states cannot be ruled out on the basis of clinical presentation alone. In addition, children younger than 8–12 years cannot reliably report their subjective symptoms, and children who are unable to communicate (e.g., those with neurologic impairment) will not be able to provide a description of their symptoms (Reference 1). Adolescents who present with typical heartburn symptoms can be given a diagnosis on the basis of symptoms alone, similar to adult patients (Reference 1). This is only applicable to adolescents who are verbal and neurologically intact.

Patients with suspected GERD should undergo a thorough history and physical examination to determine the timing and severity of symptoms and to ascertain whether any complications are present that require further evaluation. Questions should be asked about the feeding history and vomiting, as well as the social, medical, family, and medication history (Reference 24). The history and physical examination can also be used to rule out other disease states such as pyloric stenosis or seizures. Diagnostic questionnaires, such as those previously mentioned for GER, are also helpful for monitoring of symptoms. Unfortunately, there is a poor correlation between symptoms and objective findings in patients with GERD (References 25, 26).

Many diagnostic tests can be used to aid in the diagnosis of GERD. Esophageal pH monitoring involves placing a catheter with electrodes along the length through the nose to the LES to measure the frequency and duration of acid reflux episodes (Reference 27). Recordings of the number and frequency of episodes are completed during a 24-hour period. Esophageal pH monitoring alone is not sensitive for the detection of nonacid or weak acid reflux. Normal esophageal pH is 7.0. Acid reflux is defined as an esophageal pH less than 4.0 lasting 15–30 seconds (Reference 28). The most

reliable marker used during pH monitoring is the reflux index (RI) score. The RI is defined as the percentage of total time that the esophageal pH is less than 4.0. A score greater than 7% is considered abnormal for all patients older than 1 year and 12% or more in infants (References 1, 29). Additional parameters measured by this procedure include the total number of reflux episodes, episodes lasting more than 5 minutes, and duration of pH less than 4.0. Combining pH monitoring with multiple intraluminal impedance allows the type of reflux to be detected: gas, liquid, solid, or mixed. Thus, it can detect weakly acidic and basic reflux episodes. In addition, it detects the volume and direction of the reflux.

An upper gastrointestinal endoscopy allows visualization and evaluation of the esophageal mucosa. This test is useful to determine the presence of esophagitis and complications of GERD such as strictures, hiatal hernia, ulcers, or Barrett esophagus. Biopsies of the mucosa should be obtained during the procedure to evaluate histologic changes in the mucosa. The biopsy can also be used to determine whether there are eosinophils in the tissue, which is consistent with a diagnosis of eosinophilic esophagitis, an allergic inflammatory disorder of the esophagus.

The upper gastrointestinal series is a procedure that uses barium contrast radiography to evaluate the upper gastrointestinal tract. This procedure is not specific or sensitive for GERD, but it can be useful in identifying malrotation, pyloric stenosis, hiatal hernia, and anatomic abnormalities such as tracheoesophageal fistula (Reference 30). These diagnoses may also be considered in pediatric patients with symptoms similar to GERD.

Esophageal manometry measures peristalsis, upper and LES pressures, and coordination of swallowing with these functions. Unfortunately, GERD cannot be diagnosed by manometry because of its low sensitivity and specificity (Reference 1). Instead, manometry is used to determine the presence of motility disorders that may have a clinical presentation similar to GERD.

A trial of acid suppression is no longer recommended for infants and young children as a diagnostic test (Reference 1). Older children and adolescents can still have a 2- to 4-week trial to determine whether therapy is beneficial.

## Treatment

The goals of therapy are to alleviate patient symptoms, heal esophagitis if present, maintain normal growth, prevent complications, and minimize adverse effects of drug therapy. These goals are accomplished with non-pharmacologic interventions such as lifestyle modifications and pharmacologic interventions with acid suppression therapy.

## *Nonpharmacologic Therapy*

Nonpharmacologic therapies include lifestyle modifications and antireflux surgery. Specific lifestyle modifications are listed in Box 1. Mild symptoms of GERD without complications may be managed by lifestyle changes alone. Strategies for infants include those previously discussed for GER. In rare cases, particularly for patients with recurrent pneumonia and GERD, placement of a nasogastric or nasojejunal feeding tube is required to ensure adequate feeding and growth and to prevent aspiration (References 31, 32). Older children and adolescents should be encouraged to avoid the ingestion of large meals, as well as to avoid lying down immediately after eating a meal. They should also avoid foods that may exacerbate reflux symptoms such as caffeine, chocolate, and spicy foods. Of importance, the effectiveness of specific lifestyle modifications, such as positioning during sleep, has not been studied in children and adolescents; rather, data have been extrapolated from adult studies. In adults, only weight loss has been shown to improve pH profiles and symptoms. Studies have shown that elevating the head of the bed in adults is beneficial (fewer episodes of reflux), so older children and adolescents may also benefit as well. Data on the additive benefit of lifestyle changes to pharmacologic therapy are also lacking for children and adolescents (Reference 1).

Antireflux surgery is recommended only for specific patients: (1) children with GERD whose optimal medical therapy fails, (2) patients with a requirement for long-term medical therapy when adherence or patient preference impedes such use, and (3) patients with life-threatening complications (chronic aspiration, respiratory symptoms, or Barrett esophagus) (Reference 1). The most common surgical procedure is the Nissen fundoplication. This procedure can be performed laparoscopically or as an open surgery, with the laparoscopic procedure preferred. The fundus of the stomach is wrapped 360 degrees around the lower end of the esophagus and stitched in place to serve as the closure for the LES. This results in increased LES pressure and a decreased number of TLESRs. Surgery can be curative in a subset of patients; however, success rates vary greatly from about 60% to 90% (Reference 33). Complications after surgery can include gas-bloat syndrome, dysphagia, diarrhea, and retching and gagging after feeding. Patients with neurologic impairment are at highest risk of complications after antireflux surgery. In fact, patients with neurologic impairment have twice the postoperative complication rate, a 3-fold higher morbidity (return to preoperative symptoms), and a 4-fold higher reoperation rate compared with patients who are neurologically intact (Reference 34).

A recent study found a decrease in reflux-related hospitalizations (aspiration pneumonia, pneumonia, esophagitis, esophageal reflux) in patients who received antireflux surgery at younger than 4 years, but no benefit in older children and an increase in hospitalizations in those older than 4 years with developmental delay (Reference 35). The risks and benefits of antireflux surgery should be carefully considered before recommending this as a treatment option.

## *Pharmacotherapy*

Pharmacotherapeutic options for the management of GERD in pediatric patients include gastric acid-suppressing agents, mucosal surface barriers, and prokinetic agents. The H<sub>2</sub>RAs and PPIs are considered first-line therapy for managing GERD in pediatric patients. The role of antacids and prokinetic agents will also be discussed. Table 2 lists pharmacologic agents used in the management of pediatric GERD, including their advantages, disadvantages, and specific place in therapy. Table 3 includes information on the specific dosing and formulations of various products.

### *Histamine-2 Receptor Antagonists*

The H<sub>2</sub>RAs decrease acid production by competitive inhibition of the histamine-2 receptors in gastric parietal cells. They do not inhibit meal-stimulated acid secretion. The H<sub>2</sub>RAs are most effective for the on-demand relief of GERD symptoms and cases of mild esophagitis. The H<sub>2</sub>RAs are less effective than the PPIs for symptom relief and healing of esophagitis (Reference 1). Symptomatic improvement is seen in 70% of patients 1 to 18 years of age, and endoscopic healing rates are reported to be between 50% and 95% in infants and children > 1 month (References 36, 37). One case series in infants 72 hours to 16 years of age, found endoscopic healing rates of 95% with the use of ranitidine (Reference 38). Although H<sub>2</sub>RAs are commonly prescribed in neonates and preterm infants, there are limited efficacy and safety data available for these patients (References 1, 39, 40). Studies have been conducted suggesting an association with H<sub>2</sub>RAs and the development of necrotizing enterocolitis in preterm infants (Reference 41).

Drugs in this class include ranitidine, famotidine, nizatidine, and cimetidine. Ranitidine is the most widely used agent because it is well tolerated, with a low potential for drug interactions. Cimetidine is rarely used because of the high incidence of adverse effects such as gynecomastia, increased risk of liver disease, neutropenia, and thrombocytopenia and because it inhibits cytochrome P450 (CYP), which can lead to significant drug interactions. The H<sub>2</sub>RAs achieve peak plasma concentrations within 2.5 hours, and the duration of acid suppression is 6 hours (Reference 42). This necessitates

CYP = cytochrome P450; GERD = gastroesophageal reflux disease; H<sub>2</sub>RA = histamine-2 receptor antagonist; PPI = proton pump inhibitor.

Adapted from Reference 1.

dosing two or three times/day. Infants usually require thrice-daily dosing because the gastric pH decreases within 5 hours (Reference 17). One study showed that higher doses of ranitidine (20 mg/kg/day compared with 8 mg/kg/day) were as efficacious as omeprazole (Reference 43).

The H<sub>2</sub>RAs are associated with some adverse effects, such as irritability, headache, and somnolence in infants. These effects could be mistaken for continual symptoms of GERD in some patients. Tolerance of the acid-suppressive effect of the H<sub>2</sub>RAs can develop after 6 weeks of therapy (References 44, 45). This phenomenon is not overcome by a dosage increase (Reference 45).

### *Proton Pump Inhibitors*

The PPIs inhibit both basal and meal-induced acid secretion by inactivating the H<sup>+</sup>/K<sup>+</sup>-ATPase pump in parietal cells (the proton pump). This pump acts as the parietal cell membrane transporter. The PPIs irreversibly inhibit the pump; thus, acid secretion can only return once the parietal cell makes new pumps. The PPIs have also been shown to decrease 24-hour intra-gastric volumes, which helps facilitate gastric emptying and decrease the volume of reflux (Reference 46). The PPIs have superior efficacy to the H<sub>2</sub>RAs because they have a longer duration of action for acid suppression,

**Table 3. Pediatric Doses of Medications Used in the Management of GERD**

Agent	Dose (Oral)	Formulations
<b>H<sub>2</sub>RAs</b>		
Ranitidine (Zantac)	Neonates: 2 mg/kg/day divided q12h Infants, children, adolescents: 4–10 mg/kg/day divided bid-tid (max: 300 mg/day; 600 mg/day if erosive esophagitis)	15 mg/mL syrup 75-, 150-, 300-mg tablet 150-, 300-mg capsule 25-mg effervescent tablet for solution
Famotidine (Pepcid)	Neonates to 3 months: 0.5 mg/kg/day once daily ≥ 3 months to 12 years: 1 mg/kg/day divided bid (max: 80 mg/day) > 12–18 years: 20 mg bid (GERD) 10–20 mg before meals (heartburn)	40 mg/5 mL powder for suspension 10-, 20-, 40-mg tablet 20-mg chewable tablet
Cimetidine (Tagamet)	Neonates: 5–10 mg/kg/day divided bid-tid Infants: 10–20 mg/kg/day divided bid-qid Children/Adolescents: 20–40 mg/kg/day divided qid (max 1600 mg/day)	300 mg/5 mL solution 200-, 300-, 400-, 800-mg tablet
Nizatidine (Axid)	6 months to 11 years: 5–10 mg/kg/day divided bid ≥ 12 years: 150 mg bid	15 mg/mL solution 150-, 300-mg capsule
<b>PPIs</b>		
Omeprazole (Prilosec)	Infants < 1 year: 0.7–1.5 mg/kg/day once daily 1–16 years: 5 kg to < 10 kg: 5 mg/day 10 kg to ≤ 20 kg: 10 mg/day > 20 kg: 20 mg/day Alternative: 1 mg/kg/day (range, 0.2–3.5 mg/kg/ day) given qday or bid	10-, 20-, 40-mg delayed-release capsule 20-mg delayed-release tablet 2.5-mg granules for oral suspension packet Extemporaneous suspension formula available
Omeprazole and sodium bicarbonate (Zegerid)	Same as omeprazole	20-, 40-mg immediate-release capsule (contains 1100 mg sodium bicarbonate) 20-, 40-mg of powder for oral suspension packet (contains 1680 mg sodium bicarbonate per packet)
Esomeprazole (Nexium)	Neonates: 0.5 mg/kg/day once daily × 7 days Infants 1–24 months: 0.25–1 mg/kg/day once daily 1–11 years: < 20 kg: 10 mg/day for 8 weeks > 20 kg: 10–20 mg/day for 8 weeks 12–17 years: 20–40 mg/day for 8 weeks	20-, 40-mg delayed-release capsule 10-, 20-, 40-mg granules for suspension packet 20-, 40-mg injection

Agent	Dose (Oral)	Formulations
Lansoprazole (Prevacid)	Neonates: 0.2–1 mg/kg/day once daily Infants: < 10 weeks: 0.2–0.3 mg/kg/day ≥ 10 weeks: 1–2 mg/kg/day once daily 1–11 years: ≤ 30 kg: 15 mg/day > 30 kg: 30 mg/day ≥ 12 years: 15 mg/day (erosive esophagitis: 30–60 mg/day)	15-, 30-mg delayed-release capsule 15-, 30-mg orally disintegrating tablet 15-mg 24-hour tablet Extemporaneous suspension formula available
Dexlansoprazole (Dexilant)	Not recommended for patients < 18 years Adults: GERD: 30 mg/day for 4 weeks Erosive esophagitis: 60 mg/day for 8 weeks; then 30 mg/day for 6 months	30-, 60-mg delayed-release capsule
Pantoprazole (Protonix)	Erosive esophagitis: 15 kg to < 40 kg: 20 mg/day (alternative: 0.5–1 mg/kg/day) ≥ 40 kg: 40 mg/day	20-, 40-mg delayed-release tablet 40-mg granules for suspension 40-mg injection
Rabeprazole (AcipHex)	≥ 12 years: 20 mg/day for 8 weeks	20-mg delayed-release tablet
<b>Prokinetic Agents</b>		
Metoclopramide (Reglan)	Neonates: 0.1–0.15 mg/kg/dose q6h Infants, children, adolescents: 0.4–0.8 mg/kg/day divided qid (max 60 mg/day)	5 mg/5 mL solution 5-, 10-mg tablet
Erythromycin	Infants: 0.75–3 mg/kg/dose q8h (up to 10 mg/kg/dose) Children and adolescents: 10–20 mg/kg/day divided bid-qid before meals (max: 250 mg tid)	200 mg/5 mL, 400 mg/5 mL powder for suspension 250-mg delayed-release capsule 250-, 500-mg tablet 400-mg tablet (as ethylsuccinate) 250-, 333-, 500-mg delayed-release, enteric-coated tablet
Bethanechol	Children: 0.4–0.8 mg/kg/day divided qid	5-, 10-, 25-, 50-mg tablet Extemporaneous suspension formula available

bid = two times/day; GERD = gastroesophageal reflux disease; h = hour; q = every; qid = four times/day; tid = three times/day.

inhibit meal-induced acid secretion, and are not associated with the development of tolerance. Drugs in this class include omeprazole, esomeprazole, lansoprazole, dexlansoprazole, pantoprazole, and rabeprazole.

The PPIs are first-line therapy for the management of chronic heartburn in older children and adolescents, reflux esophagitis in infants and children, and on-demand relief of GERD-related symptoms. For the older child or adolescent with heartburn, a 2- to 4-week diagnostic trial of a PPI (in addition to lifestyle changes) is recommended to determine whether an improvement in symptoms occurs. If there is improvement, the PPI

can be continued for 8–12 weeks. In the management of reflux esophagitis, PPIs produce mucosal healing in 70% to 100% of patients within 12 weeks and symptom improvement in up to 80% of patients (References 47–49). They have also been shown to heal more severe grades of esophagitis and cases refractory to H<sub>2</sub>RAs. For erosive esophagitis, initial treatment should be continued for 12 weeks.

Currently, only esomeprazole has an FDA indication for use in children younger than 1 year. However, off-label use of PPIs in infants younger than 1 year is quite common. The prevalence of PPI use is increasing

among pediatric patients. A 2004 study showed an 11-fold increase in PPI use among infants younger than 12 months during a 6-year period and a shift from omeprazole to lansoprazole as the most commonly prescribed PPI (Reference 50). Evidence exists describing the pharmacokinetics, pharmacodynamics, efficacy, and safety in this age group for both omeprazole and lansoprazole. However, at present, the efficacy data do not support the routine use of PPIs in children younger than 1 year, and concerns have been raised about the safety of these agents in this age group (References 1, 51).

Omeprazole is the most widely studied PPI in pediatric patients. Data support both its efficacy and long-term safety. Until 2004, it was also the most widely prescribed PPI, used in almost 90% of pediatric patients (Reference 52). Since then, lansoprazole has become the most commonly prescribed PPI in pediatric patients (65%), followed by omeprazole (20%), pantoprazole (7%), esomeprazole (5%), and rabeprazole (less than 1%) (Reference 53).

Pantoprazole has been studied in patients 5–18 years of age for both GERD-related symptoms and reflux esophagitis, with healing rates similar to other PPIs (80% to 90%) (Reference 54). Esomeprazole has been studied in all pediatric age groups (including preterm infants), and it has been found both safe and efficacious. Researchers have also found similar age-related pharmacokinetics in metabolism and elimination compared with omeprazole and lansoprazole. Rabeprazole has been studied in adolescents 12–16 years of age, and studies are under way to evaluate its use in younger patients (Reference 55). Rabeprazole has been found to be well tolerated in adolescents at 10- and 20-mg doses. Accumulation of the drug occurred with repeated administrations of the 20-mg dose. Further investigation into the significance of this phenomenon was recommended.

The proton pumps are most active when stimulated by a meal, so the ideal time to take a PPI is 15–30 minutes before the first meal of the day. Because these agents are broken down by gastric acid, most formulations are enteric coated and delayed release. Administration of delayed-release capsules is challenging in infants and young children. No liquid formulations are commercially available, but extemporaneous preparations of lansoprazole and omeprazole have been made using sodium bicarbonate. In addition, immediate-release orally disintegrating tablets of lansoprazole are available. The PPIs have a delayed onset of action of up to 4 days (Reference 1). Once administered, the PPI can continue to inhibit acid secretion for up to 15 hours, requiring only one dose per day in most patients (Reference 56). Despite this, some patients continue to experience heartburn of less severity and may even experience nocturnal acid breakthrough (gastric pH of less than 4.0 for more than 1 hour within 12 hours of a PPI dose) (Reference 57).

Pharmacokinetic data show that children 1–10 years of age require a higher milligram-per-kilogram dose than adolescents and adults. In addition, infants may require lower milligram-per-kilogram dosing than children and adolescents (Reference 1). A recent study with lansoprazole found that infants 10 weeks and younger had higher plasma concentrations and lower clearance compared with infants older than 10 weeks to 1 year. Thus, a lower dose of lansoprazole is recommended in patients 10 weeks or younger (Reference 51).

The PPIs are metabolized by CYP 2C19 and 3A4. The enzymatic activity of 2C19 varies with age. Low at birth, 2C19 enzymatic activity reaches adult values at 6–12 months of age, exceeds adult values between 1 and 4 years of age, and then decreases back to adult levels around puberty (Reference 58). This explains differences in the metabolism and clearance of PPIs among various age groups. There is evidence of reduced metabolism in neonates and preterm infants and increased clearance in children compared with adults. Polymorphisms also exist for CYP2C19 with three phenotypes: homozygous extensive metabolizers, heterozygous extensive metabolizers, and poor metabolizers. When dosing PPIs in pediatric patients, consider interindividual variability caused by the pharmacokinetic and pharmacodynamic relationships that exist, particularly with metabolism and elimination (Reference 59). Rabeprazole metabolism does not appear to be as affected as other PPIs by alterations in the CYP2C19 genetic polymorphisms. This is because rabeprazole undergoes some nonenzymatic metabolism. PPIs decrease the absorption of drugs requiring an acidic environment to be absorbed. Drugs that may be affected include itraconazole and griseofulvin. Omeprazole has also been associated with decreased clearance of diazepam and carbamazepine because of its inhibition of CYP2C19 (References 60, 61). Close monitoring of carbamazepine levels is required when coadministered with omeprazole.

Common adverse effects of PPIs include headache, nausea, constipation, and diarrhea. It is recommended to change to a different agent or decrease the dose if any of these adverse effects occur (Reference 1). The PPIs can also be associated with some severe adverse effects, including acute interstitial nephritis, parietal cell hyperplasia, fundic gland polyps, enterochromaffin cell-like hyperplasia, vitamin B<sub>12</sub> deficiency, and bone loss. These severe effects have been reported more often in patients on prolonged therapy (greater than 2 years) and in adult patients. Because there is a possibility of rebound acid secretion upon PPI discontinuation, the guidelines suggest that PPIs be tapered off over 4 weeks when therapy is complete. However, the evidence supporting this practice is conflicting (Reference 1).

Long-term acid suppression is not without complications. Gastric acid is protective to the digestive system because it inhibits bacterial flora. Bacterial overgrowth can occur in patients taking gastric acid inhibitors. Both H<sub>2</sub>RAs and PPIs have been found to increase the rates of (1) community-acquired pneumonia in children, (2) acute gastroenteritis in children, (3) necrotizing enterocolitis in premature infants, (4) candidemia in premature infants, and (5) *Clostridium difficile*-associated diarrhea in children (References 62–64).

#### *Prokinetic Agents*

Prokinetic therapy used for the management of GERD in pediatric patients includes metoclopramide, erythromycin, bethanechol, and baclofen. A recent systematic review of healthy children 1 month to 2 years of age with GER found that metoclopramide produces modest decreases in daily symptoms but is associated with considerable adverse effects (Reference 65). Serious adverse effects of metoclopramide include extrapyramidal reactions and tardive dyskinesia. Erythromycin has been used to increase gastric emptying in some patients because of its action on motilin, but there is limited evidence on its use in GERD. The dose for its prokinetic activity is less than that for the treatment of bacteria; thus, adverse effects are rare at these lower doses. However, there is still a slight risk of gastrointestinal upset, hepatotoxicity, arrhythmias, and antibiotic resistance with erythromycin use. Bethanechol, a direct cholinergic agonist, has uncertain efficacy and unwanted adverse effects (headache, malaise, abdominal cramps, belching, nausea, vomiting). Baclofen works to decrease TLESRs and can increase gastric emptying. Baclofen has been found efficacious in reducing vomiting in children with neurologic impairment and GERD. Because baclofen works directly on the central nervous system, there is a high incidence of adverse effects, such as somnolence, headache, insomnia, and confusion (Reference 66). From the available evidence, the routine use of prokinetic agents for GERD is not recommended. Despite the lack of evidence supporting its efficacy, metoclopramide is still the most widely used prokinetic agent in the pediatric population for the management of GERD (Reference 1).

#### *Antacids*

Antacids work by buffering gastric acid within the stomach and esophagus, thereby facilitating mucosal healing. Antacid therapy (magnesium hydroxide, aluminum hydroxide, calcium carbonate) is recommended for on-demand relief of heartburn in older children and adolescents. The advantage to antacid therapy is its quick onset of action, but because of its short

half-life, frequent administration is required. All antacids should be used with caution in infants and young children because they increase plasma aluminum levels and can cause milk-alkali syndrome, a condition associated with hypercalcemia, alkalosis, and renal failure. Chronic antacid therapy for pediatric GERD is not recommended because more effective agents are available (Reference 1).

#### *Surface-Protective Agents*

Surface-protective agents contain either sucralfate or alginate. Sucralfate is a mixture of sucrose, sulfate, and aluminum. In an acidic environment, sucralfate forms a gel that coats the mucosal surface. Alginate alone is useful for on-demand therapy. The commercially available product for infants and young children contains only sodium and magnesium alginate. Older children and adolescents may take the adult formulation that contains both alginate and the buffering agents found in antacids. Surface-protective agents are only recommended as adjunctive therapy for the management of esophagitis and severe GERD-related symptoms. They can be used for on-demand therapy in patients with bothersome symptoms despite maximal doses of PPIs, but they are not recommended for chronic therapy (Reference 1).

#### *Combination Therapy*

Recommendations on the use of combination therapy are unavailable in current guidelines (Reference 1). The most common combination of medication classes is an H<sub>2</sub>RA or PPI with a prokinetic agent or an H<sub>2</sub>RA and a PPI. In general, changing to a different agent is preferred to adding another agent for chronic maintenance therapy. With multiple agents, there is a potential for increased adverse effects. In addition, H<sub>2</sub>RAs and PPIs have a theoretical antagonistic mechanism of action because PPIs require the presence of acid to inhibit proton pumps, and H<sub>2</sub>RAs directly inhibit acid production. Twice-daily dosing of both an H<sub>2</sub>RA and PPI would provide potent acid suppression but could further increase the risk of respiratory infections or gastroenteritis.

Adult patients with nocturnal acid breakthrough on PPIs have decreased symptoms with the addition of a bedtime dose of an H<sub>2</sub>RA, suggesting that nocturnal acid breakthrough is histamine-related. However, the effect is not lasting secondary to the tolerance that develops to H<sub>2</sub>RAs. In children, the data are limited to one small study (18 children: 1–13 years), which showed no benefit to this strategy (Reference 67). Therefore, adding a bedtime dose of an H<sub>2</sub>RA to a PPI is not routinely recommended for adult or pediatric patients.

### **Monitoring Parameters**

Patients receiving acid suppression therapy should be monitored for symptom relief, adverse drug reactions, and adherence to the regimen. For the management of chronic heartburn, lifestyle changes and PPIs are recommended for 12 weeks. Patients should be continually monitored during this time to determine whether therapy is providing symptom resolution. If symptoms persist at the end of the treatment period, further diagnostic testing and/or continued maintenance therapy may be required. Patients receiving treatment for reflux esophagitis should be monitored for symptom relief and the presence of any complicating symptoms (dysphagia, odynophagia). In addition, because the long term safety of all medications used for the management of pediatric GERD is unknown, careful and continued monitoring is required throughout the duration of therapy.

Symptoms associated with GERD can have a negative impact on the quality of life of both patients and their caregivers. At present, validated tools to measure the quality of life for children with GERD are limited. Practitioners most often rely on parental reports of symptoms. Assessing improvement in quality of life is important for monitoring the efficacy of treatment strategies.

### **Special Populations**

#### ***Asthma***

Reflux is known to exacerbate asthma. Gastric contents from the stomach can be aspirated into the lower airways and produce both airway inflammation and bronchoconstriction (Reference 1). From 50% to 60% of patients with asthma have abnormal pH studies (Reference 68). Nighttime cough and wheezing have been correlated with GERD. Studies have also shown that the incidence of asthma is higher in children with GER (Reference 69).

Antireflux therapy may be beneficial in patients with concurrent asthma and GER. Current recommendations for patients with persistent asthma and heartburn symptoms or regurgitation include treatment with a PPI. In addition, patients with nocturnal asthma symptoms or steroid-dependent, difficult-to-control asthma may benefit from PPI therapy once other causes of wheezing have been excluded. Therapy should be continued for 12 weeks. Antireflux surgery may also be a treatment option in the patients still symptomatic despite aggressive twice-daily PPIs and patients' adherence to their asthma medications.

#### ***Neurologic Impairment***

The frequency and severity of GERD in patients with neurologic impairment are increased. It is estimated that 50% to 70% of children with neurologic impairment such as cerebral palsy have symptoms associated

with reflux, and that up to 70% have endoscopic evidence of esophagitis (Reference 70). It is more difficult to properly provide a diagnosis for a child with GERD who has neurologic impairment because such children have difficulty communicating their symptoms and may present with atypical symptoms (self-injurious behavior, seizures, and dystonia). The most reliable diagnostic tool for GERD in children with neurologic impairment is pH/multiple intraluminal impedance monitoring (Reference 1). Treatment of GERD in these patients should be individualized and consist of feeding changes, positional changes, muscle spasm control, and antireflux therapy. These patients may benefit from the combination of a PPI and baclofen. Careful monitoring of baclofen's adverse effects is warranted. Baclofen can cause dizziness, drowsiness, and fatigue, as well as lower the seizure threshold. Some patients with neurologic impairment improve with medication therapy alone. Antireflux surgery should be considered in patients who do not respond to aggressive medical management and have concomitant respiratory complications. The risks and benefits must be weighed carefully because surgery in these patients has resulted in higher morbidity, mortality, and symptom recurrence.

### **CONCLUSIONS**

Appropriate management of GER and GERD in the pediatric patient is important because symptoms can have a considerable effect on quality of life and may persist into adulthood, causing complications. The recent clinical practice guidelines provide updated information and evidence to help guide the medical management of children with GER and GERD. Many questions remain for these patients because of the lack of large, well-designed clinical trials of different age groups within the pediatric population. Pharmacists should be familiar with current guidelines so that they can provide evidence-based treatment recommendations.

# CHAPTER 17

## DIARRHEA AND CONSTIPATION

*Christina C. Piro, Pharm.D.*

### LEARNING OBJECTIVES

1. Recognize the worldwide impact of diarrhea as the leading cause of morbidity and mortality among children.
2. Explain general mechanisms of diarrhea and associated common causes.
3. Recommend appropriate management of diarrhea including both nonpharmacologic and pharmacologic therapy.
4. Identify etiologies, with constipation as a primary symptom.
5. Identify medications associated with constipation and the importance of prevention.
6. Recommend nonpharmacologic and pharmacologic treatment options for pediatric patients with constipation (both acute and maintenance therapy).

### ABBREVIATIONS IN THIS CHAPTER

BM	Bowel movement
GI	Gastrointestinal
ORT	Oral rehydration therapy

### INTRODUCTION

Gastrointestinal (GI) disorders in children are a common cause of discomfort, family stress, and provider and hospital visits each year. Gastrointestinal disturbances can begin in the first days of life and can be a clinical indicator of an underlying physiologic or metabolic disorder, or even an infectious process. Diarrhea and constipation are two broad categories that encompass many disease or functional processes often encountered in the pediatric patient. This chapter seeks not only to outline the impact of diarrhea and constipation on children and their families, but also to provide insight into the diagnosis, treatment, and prevention of these disorders.

### DIARRHEA

#### Epidemiology

Worldwide, diarrhea continues to be a leading cause of morbidity and mortality among children. In developing countries, reported mortality rates are just less than 1.5 million for children younger than 5 years (Reference 1).

For that same age group, the World Health Organization (WHO) reported a mortality rate of 14% caused by diarrhea in 2008—a percentage similar to that with pneumonia (Reference 2). However, these percentages differ greatly in developed versus developing countries. Developing countries struggle with the ability to provide safe drinking water, hygiene, and overall health and nutrition, resulting in an environment ideal for the spread of diarrhea-causing pathogens. Although overall living conditions are more favorable in developed countries, the impact of diarrhea on children should not be underestimated. Diarrhea can result from infectious and noninfectious causes, both of which contribute to the cost and significant number of hospitalizations associated with this condition (Reference 3). This chapter will focus on the noninfectious causes of diarrhea and their respective treatment. For diarrhea related to infectious etiologies, see the Infectious Diarrhea chapter.

#### Etiology

Diarrhea is characterized by three or more watery, loose stools per day (or more than normal for an individual). Although a precise definition has not been well described, an increased number and changed consistency of stools for less than 1 week is considered acute diarrhea. Most diarrheas occurring in children, especially those between 6 months and 2 years of age, result from an acute, infectious etiology. Although viral pathogens are the most common, bacterial and parasitic pathogens can also be implicated in diarrhea (see Infectious Diarrhea chapter). Chronic diarrhea is diarrhea lasting more than 14 consecutive days and is usually associated with chronic medical conditions or GI pathology in the pediatric population. Malabsorption syndromes, including cystic fibrosis and celiac disease, often initially present with diarrhea symptoms and should be considered when determining the etiology of new-onset, prolonged diarrhea. Celiac disease is an autoimmune condition triggered by gluten intake that damages the small intestine, preventing good absorption. Iatrogenic malabsorption secondary to short bowel syndrome is also a significant cause of chronic diarrhea. Short bowel syndrome is the result of surgical removal of portions of the intestines secondary to intestinal ischemia caused by various factors. Irritable bowel syndrome is an example of a functional bowel disorder that can cause diarrhea (see Irritable Bowel Syndrome chapter).

Nutrition may also play a role in the infant and child with diarrhea, specifically with respect to type of formula used and preparation technique. Hyperosmolar or concentrated formulas can cause fluid shifts, resulting in osmotic diarrhea. Enzyme deficiencies or food sensitivities like lactase deficiency, or the more common lactose intolerance, make it difficult to digest lactose-containing foods (e.g., milk-containing products), leading to diarrhea. Similarly, food allergies can elicit a diarrheal response when exposure occurs. Often, infants with a cow's milk protein allergy will present to the provider's office with complaints of diarrhea in addition to other allergic symptoms. Ingestion of irritating foods such as nondigestible fibers or insoluble sugar alcohols can also precipitate acute diarrhea. Another well-described etiology in children is medication-induced diarrhea. Antibiotic-associated diarrhea does not generally result in severe sequelae and resolves within a few days after the antibiotic course is completed. Recognizing the potential causes of diarrhea, both acute and chronic, can assist in the appropriate management and prevention of morbidity and mortality in the pediatric population.

### Pathophysiology

Diarrhea results when the normal functions of the GI tract for maintaining fluid and electrolyte balance are impaired. The water content of fecal material determines whether stools are too liquid or too dry, which in turn affects bowel function/status. The amount of fluid in stool depends on the amount ingested through diet, the contribution from intestinal secretions in the small intestine, and the amount reabsorbed by the colon. Chyme, a semifluid mass of partly digested food and digestive secretions formed during digestion, makes up the remainder of stool content, with the absorption of partly digested fats, carbohydrates, and protein occurring as it passes into the ileum. As stool enters the colon, a large amount of water is absorbed, further changing the composition and electrolyte content of the remaining chyme/stool. Normal fecal stool has electrolyte concentrations of sodium 40 mEq/L, chloride 15 mEq/L, potassium 90 mEq/L, and sodium bicarbonate 30 mEq/L (References 4, 5). Alterations in absorption and secretion of water and electrolytes when GI function is impaired can change these values. There are four general mechanisms for disruption of water and electrolyte balance and thus four classifications, or types, of diarrhea: secretory, osmotic, exudative, and altered motility (References 4, 5).

### Secretory Diarrhea

Secretory diarrhea occurs in response to some stimulating substance increasing the secretion of water into or decreasing the absorption of water and electrolytes from the intestinal lumen. Causes of secretory diarrhea include

unabsorbed dietary fat, laxatives, secretin or other hormones (including those released by tumors), bacterial toxins, or increased bile salts. These agents interrupt the normal cell transport processes by stimulating intracellular cAMP (cyclic adenosine monophosphate) and inhibiting  $\text{Na}^+/\text{K}^+$ -ATPase (sodium/potassium/adenosine triphosphatase), causing the secretion of a large amount of water and indirectly preventing ion (electrolyte) absorption (References 4, 6). Although the source of these factors differs, the normal function of the intestine is ultimately compromised, resulting in an amount of water being secreted into the intestine greater than that absorbed. Clinically, this type of diarrhea is identified by large stool volumes with normal electrolyte content.

### Osmotic Diarrhea

Water reabsorption in the intestine is a passive process and is dependent on the absorption of other substances. When poorly absorbed substances remain in the lumen, an osmotic gradient is created, resulting in water being pulled into the lumen producing watery, osmotic diarrhea. This type of diarrhea differs from secretory diarrhea because there is no excess secretion of a substance causing changes in the amount; rather, the mechanism for absorption is somehow impaired (Reference 6). Malabsorption, lactose intolerance, and medications including magnesium (and other divalent ions) and lactulose are associated with osmotic diarrhea. *Malabsorption*, a collective term, occurs when absorption is decreased because of the inability to digest or absorb a particular nutrient. Altered motility or altered digestion (e.g., pancreatic insufficiency), as previously described, contributes to malabsorption. Decreased absorption of solutes and fluid can also result when intestinal cells are damaged by bacterial/viral infection. Determining the cause of malabsorption can assist with treatment decisions. For example, when osmotic diarrhea is dependent on ingested substances, fasting will decrease or eliminate symptoms.

### Exudative Diarrhea

When injury occurs to the mucosal lining of the intestinal tract, exudative diarrhea can occur. Injury can result from inflammation or ulceration, leading to a loss of mucus, serum proteins, or blood into the lumen. The damaged, or inflamed, intestine prevents water and electrolytes from being absorbed, leading to diarrhea. Inflammatory bowel diseases such as Crohn disease and ulcerative colitis are associated with this type of diarrhea. The presence of a large amount of exudates (mucus, proteins, and/or blood) in the stool is characteristic in patients with these inflammatory bowel diseases. Invasive infectious diarrhea can also present with similar

symptoms and, on initial presentation, is often indistinguishable from inflammatory bowel disease (References 4, 6).

### Altered Motility

Diarrhea caused by altered motility is multifactorial and can involve several mechanisms, including reduction in small intestine contact time, bacterial overgrowth, and/or early emptying of the colon. Decreased exposure of material to the small intestine leads to reduced time for the normal absorption and secretion processes to occur, thus changing the composition of intestinal contents. The resulting changes in osmolarity can lead to diarrhea. Surgical resection of the gut (as in short bowel syndrome) and a medication like erythromycin or metoclopramide cause a decrease in exposure time to the small intestine. Conversely, if transit time is increased (slowing), bacterial overgrowth may occur, precipitating diarrhea. Diarrhea caused by altered motility is usually associated with sporadic and fast peristaltic waves that impair the absorption of water and prematurely move material into the colon.

## CLINICAL PRESENTATION AND DIAGNOSIS

Diarrhea is regarded as either acute or chronic and is differentiated by duration of symptoms. Signs and symptoms can vary depending on the underlying cause, and may be helpful in the diagnostic process. For example, acute diarrheal symptoms secondary to viral gastroenteritis include abrupt onset of nausea, vomiting, abdominal pain, headache, and fever lasting for 10–60 hours (see the Infectious Diarrhea chapter for more detail). Chronic diarrhea is more difficult to diagnose because of varying “normal” bowel patterns. In general, clinical symptoms of diarrhea include an increase in the frequency of stool, an increased stool volume, and a decrease in stool consistency. Because the differential diagnosis for diarrhea is lengthy (Table 1), qualifying the frequency, onset, consistency, and proposed mechanism is necessary when evaluating patients who present with diarrhea. A thorough patient history should also be completed and should include medication and supplement history, recent travel, drinking water type, and diet (e.g., consumption of raw meats; increased intake of fruits, fruit juices, sugar-free food).

**Table 1.** Common Causes of Diarrhea

Causes	Examples
Infectious	<ul style="list-style-type: none"> <li>• Viral Cytomegalovirus, adenovirus, rotavirus, norovirus</li> <li>• Bacterial <i>Salmonella, Yersinia, Escherichia coli, Shigella, Campylobacter, Clostridium difficile</i></li> <li>• Parasitic <i>Giardia, Entameba histolytica, Cryptosporidium, Microsporidia</i></li> </ul>
Toxins	<ul style="list-style-type: none"> <li>• <i>C. difficile</i> toxin</li> <li>• Enterotoxins (from enteric organisms)</li> </ul>
Exposures	<ul style="list-style-type: none"> <li>• Radiation enteritis</li> <li>• Chemotherapy</li> <li>• Laxative abuse</li> <li>• Medications (e.g., antibiotics, magnesium-containing antacids)</li> <li>• Tumor-associated increased secretion</li> </ul>
Malabsorption	<ul style="list-style-type: none"> <li>• Pancreatic insufficiency</li> <li>• Celiac disease</li> <li>• Chronic liver disease</li> <li>• Allergic enteropathy</li> <li>• Glucose galactose transport defect</li> </ul>
Inflammatory bowel disease	<ul style="list-style-type: none"> <li>• Ulcerative colitis</li> <li>• Crohn disease</li> <li>• Eosinophilic gastroenteritis</li> <li>• Allergic colitis</li> </ul>
Genetic-metabolic disorders	<ul style="list-style-type: none"> <li>• Malabsorption syndromes</li> </ul>
Chronic nonspecific diarrhea/ toddler diarrhea	<ul style="list-style-type: none"> <li>• Usually exacerbated by a low-fat, high-carbohydrate diet in infants to toddler age</li> </ul>
Overfeeding	<ul style="list-style-type: none"> <li>• Large quantity of carbohydrate-rich foods in infancy combined with decreased amylase concentration</li> </ul>

### ***Clinical and Diagnostic Evaluation Criteria***

Evaluation of stool characteristics can be helpful in determining the etiology of diarrhea. Frequency, consistency, volume, and even color of stool should be evaluated in a patient with diarrhea. A large amount of watery, foul-smelling stool containing undigested food suggests diarrhea originating from the small intestine, whereas diarrhea with red blood present suggests the colon as the origin. The physical examination is important in evaluating disease severity as well as hydration status. Often, the examination will lead to a more focused evaluation and aid in treatment approach. Pertinent findings on physical examination include abdominal tenderness and/or cramping as well as bloating. Vital signs including blood pressure, temperature, and heart rate should be evaluated. The presence of a fever may indicate an infectious etiology, whereas a decreased blood pressure could signify impending shock secondary to dehydration from diarrhea. Assessment of hydration status is an extremely important part of the evaluation in pediatric patients with diarrhea. Diarrhea can quickly lead to dehydration. In addition to vital signs, hydration status can be assessed by examining urine output (or number of wet diapers per day in infants), mucous membranes, tear production, and physical and mental status changes. A dehydrated patient would have decreased urine output or fewer wet diapers, dry mucous membranes or crying without tears, a sunken appearance around the eyes or cheeks, decreased skin turgor, weight loss, and mental status changes. Dehydration severity is discussed in detail in the Fluids and Electrolytes chapter.

Stool studies are generally not required unless the diarrhea persists beyond 24 hours or unless a specific diagnosis (e.g., malabsorption or confirmation of an infectious etiology) is needed. Symptoms including bloody stools and fever, systemic illness, severe dehydration, recent antibiotic use, or need for hospitalization all warrant stool testing. Several studies are available to assist with diagnosis. The presence of fecal leukocytes indicates an inflammatory response, either infectious or inflammatory bowel disease in origin. If positive, a stool culture may be warranted. The stool cultures and testing are completed if an infectious cause is suspected because of clinical findings and patient history. Rotavirus, for example, can be diagnosed within the same day as stool sample collection through specific kits or antibody serologic testing. Antibody serologic tests, however, are not specific and, as with rotavirus, can be time-dependent for accurate results. Together with cultures, the stool can be evaluated for the presence of ova and parasites. Testing for *Clostridium difficile* in patients with diarrhea with recent use of antibiotics or hospital-acquired diarrhea is completed by a rapid ELISA (enzyme-linked immunoassay). A stool analysis can also be evaluated for the presence of mucus, fat, osmolarity, pH, and electrolyte

content (Reference 4). Radiographic studies, endoscopy, or a biopsy may be warranted in severe or difficult diagnostic cases, including those in which inflammatory disorders or cancer may be suspected.

### **Course and Prognosis**

The underlying etiology of diarrhea is a key indicator of the duration of symptoms and clinical manifestations. Most acute cases of diarrhea are self-limiting. Acute diarrhea secondary to infectious cases may require antibiotics (see the Infectious Diarrhea chapter). Diarrhea associated with chronic medical conditions (e.g., Crohn's disease) may not be completely resolved, and only temporary symptomatic relief is achieved without treating the primary cause. Although diarrhea itself is uncomfortable, the complications of it, from severe or prolonged diarrhea, can be life threatening. Dehydration is the most common complication of diarrhea and should be managed carefully, especially in children younger than 2 years. This population is at particular risk because water constitutes a larger portion of their body composition compared with adults, together with a decreased ability for their kidneys to conserve water. In severe cases, electrolyte and fluid imbalance may lead to additional morbidities that require immediate attention, including seizures or hypovolemic shock. Malabsorption and related conditions are often linked to chronic diarrhea and should be managed accordingly. This generally involves supplementation of any electrolyte or nutrient deficiency as well as some mechanism for slowing transit time. Many times, the exact etiology of acute diarrhea is not known, but a thorough evaluation and differentiation of potential causes are important to provide adequate treatment and predict the clinical course.

### **Noninfectious Diarrhea**

#### ***Antibiotic Therapy***

Antibiotic therapy is associated with diarrhea in about 60% of all children prescribed antibiotics (Reference 5). Proposed mechanisms for antibiotic-associated diarrhea include alteration of gut flora leading to decreased carbohydrate transport and increased intestinal lactate levels. Decreased carbohydrate transport from the gut leads to increased osmolarity and increased secretion of water into the stool. Diarrhea associated with antibiotic use is described as watery, but it should not have any systemic symptoms. Once the antibiotics are discontinued, the diarrhea should resolve (Reference 7). Another consequence of antibiotic therapy that may result in diarrhea is a *C. difficile* infection. *C. difficile* is part of the normal GI flora, but when antibiotic therapy alters the normally balanced flora, the bacteria can become

pathogenic. The toxins produced by *C. difficile*, which occurs in up to 10% of patients taking antibiotics, can lead to pseudomembranous colitis (see Infectious Diarrhea chapter) (References 8–11).

### **Malnutrition**

Nutrition and diarrhea have a bidirectional relationship. Malnutrition's role in chronic diarrhea stems from the increased risk of enteral infections and relationship to malabsorptive syndromes. A lack of nutrition leads to increased infection risk because of the effect on host immune function and alterations in the protective barrier of the gut mucosa. Diarrhea can also precipitate malnutrition by decreasing the absorption of nutrients, further worsening the overall clinical effects of both (Reference 12). However, the cause of malnutrition may be multifactorial and include frequent infections, bile acid malabsorption, decreased pancreatic enzyme activity, altered motility, decreased intestinal surface area, and changes in intestinal flora. Treatment considerations for malnourished patients with diarrhea should be comprehensive and address both disease states.

### **Diet**

Infant nutrition can be a major player in diarrhea, caused by overfeeding or general developmental differences. Overfeeding, particularly in the first few weeks of life and with a high-calorie formula, can lead to diarrhea. Developmentally, neonates have a deficiency in the pancreatic enzyme amylase, thus increasing the carbohydrate content in the stool, causing diarrhea (Reference 5). Amylase is the enzyme responsible for the breakdown of carbohydrates, and as amylase function develops, increased carbohydrate load can be handled. Drinks or foods containing a large amount of sorbitol or fructose may also cause an osmotic diarrhea. Foods that are spicy, that are difficult to break down (insoluble fibers like raw vegetables and nuts), or that contain or release histamine (e.g., tomatoes, cheeses, citrus fruits, fish) may also contribute to diarrhea (Reference 5). Additionally, lactose intolerance, the inability to digest and/or metabolize lactose, may contribute to diarrhea. Lactose is a sugar found in milk and milk products, and generally, intolerance is caused by a deficiency in the enzyme lactase. Lactase is produced by the cells lining the small intestine, which breaks down lactose into the absorbable sugars glucose and galactose. Children younger than 2 years generally do not have diarrhea related to lactase deficiency because this is the period of highest production. In older children and adults, lactase production decreases, causing an increase in the incidence of lactose intolerance. The exact incidence and age of onset for lactose intolerance varies among different ethnic groups, with those having diets high in dairy

products experiencing a lower occurrence (Reference 13). This can be treated by avoiding high lactose-containing foods and taking over-the-counter lactase enzyme-containing medications. Temporary milk intolerance after an acute viral gastroenteritis can also occur. With acute gastroenteritis, the absorptive lining, which also produces lactase, is damaged, causing a transient enzyme deficiency and resulting intolerance. Short-term use of lactose-free formulas can be used in infants, but any formula changes should be discussed with the provider before changing the diet. Avoidance of high lactose-containing foods and slow reintroduction can be implemented as antibiotic therapy is discontinued (Reference 13).

Diarrhea can occur in infants younger than 6 months who are exposed to cow's milk or infant feeding formula. Breastfed infants usually have a softer stool than those receiving cow's milk, but if acute diarrheal symptoms are present in breastfed infants, infectious causes should be considered until another diagnosis is made versus discontinuing breastfeeding. Formula feeding, which is generally associated with firmer stools, may lead to diarrhea, especially with the use of high-calorie formulas or those high in sugar content. To avoid changing formulas frequently or discontinuing breastfeeding, providers will perform a thorough history to determine the cause of acute diarrhea before altering the infant's nutrition.

### **Allergic Diarrhea**

Diarrhea caused by an allergy to milk proteins is most common in infants younger than 1 year and can be resolved by switching to a soy or elemental formula. The overall incidence of milk protein allergy in infants is between 0.5% and 1% (Reference 5). Milk allergies typically resolve by 12 months, and patients can be rechallenged at that time. Of interest, a family history of atopy may increase the risk of having a protein allergy (Reference 5). Breastfeeding mothers should avoid dairy products if a milk protein allergy is confirmed. Flecks of blood in the stool of an otherwise healthy infant may be a defining symptom of milk protein intolerance. Slow introduction of dairy products into the diet and observation of diarrhea symptoms should be noted. If the sensitivity continues in older children (e.g., school-aged children and older), a protein allergy, presenting as a celiac-like disorder, may be considered. Allergies to other foods may be diagnosed by challenging the patient with the suspected offending food under close supervision. Immunoglobulin E-mediated food allergies, other than milk, generally last a lifetime and will not be outgrown, including peanut, egg, and fish allergies. Allergic responses will often include an anaphylactic-type reaction, including vomiting, diarrhea, hypotension, and pallor (Reference 5). Recently, increased awareness of gluten allergy led to increased availability of gluten-free

products. Gluten is a protein contained in wheat, rye, and barley and is implicated in intestinal damage in the autoimmune disorder known as celiac disease. It is recommended that patients with celiac disease avoid gluten-containing foods.

### *Chronic Nonspecific Diarrhea*

In healthy children, chronic nonspecific diarrhea, also known as “toddler diarrhea,” is a common reason for loose stools. A flu-like illness or recent use of antibiotics will usually precipitate symptoms. Occurring most commonly in children between 9 months and 3½ years of age, the otherwise healthy and thriving toddler may have six to eight “runny” stools per day. Usually by the time the child reaches 3½ years, no other diagnosis is made regarding the etiology, and symptoms subside (Reference 5). Although no definitive cause has been established, several associations have been reported. Low-fat, high-carbohydrate diets tend to make stools increasingly loose, which can worsen during stress or illness. Toddlers drinking a large amount of high-sugar fruit juices, parents or caregivers overfeeding or underfeeding the child, and the child’s ingestion of irritating foods (including tomatoes and citrus) are other associations. This type of diarrhea is symptomatically similar to irritable bowel syndrome in adults (Reference 5). Trying a high-fat, low-carbohydrate diet, as well as minimizing the amount of high-sugar drinks, helps relieve symptoms.

### **TREATMENT**

Although prevention of acute diarrhea secondary to infectious causes plays the biggest role in worldwide efforts to decrease mortality and morbidity, prompt treatment of diarrhea is equally important. The goals of therapy first include prevention and management of water and electrolyte imbalances to restore normal hydration status. Other goals include providing symptomatic relief, treating the underlying cause, and managing the diet or other secondary causes of diarrhea.

### **NONPHARMACOLOGIC THERAPY**

The two main components of nonpharmacologic management of diarrhea are restoring fluid and electrolyte balance and making temporary dietary modifications during the acute illness. Fasting is generally not necessary if the patient can tolerate eating—though type or amount of food ingested may need to be modified (i.e., avoid excessively fatty, spicy, or processed foods or those known to upset the stomach). Guidelines generally recommend early introduction of appropriate food and liquids during the replacement process, if patients can tolerate it (Reference 14). It is currently recommended

that for acute diarrhea, feeding should continue, except in a formula-fed infant with severe diarrhea during the initial rehydration period. It is not necessary to initiate only clear liquids or the BRAT (bananas, rice, apple-sauce, and toast) diet, which may, in fact, prolong diarrhea. This “starvation” method may prevent cellular repair and generation. A low-residue diet, or one that is easily digestible, is recommended when vomiting and diarrhea are present, unless vomiting is severe enough that nothing should be taken by mouth. Emphasis has been placed on the continuation of feeding during an acute episode of diarrhea, which is a shift in thought from restricting food because it may cause or worsen diarrhea (i.e., the ingested food is causing the diarrhea). Because most diarrhea cases are self-limiting and dehydration remains a significant risk in this age group, the benefits of feeding outweigh any risk. Treatment recommendations maintain that for breastfeeding infants with diarrhea or children with infectious acute diarrhea, feeding should continue, which has been shown to decrease morbidity and mortality (Reference 4). Older children can resume “normal” fluids and solids, but they should avoid fatty foods or those high in simple sugars (Reference 14). Maintaining nutrition also plays an important role in the management of chronic diarrhea. Proper caloric intake is important for all age groups and etiologies because feeding will assist in intestinal repair.

Water and electrolyte replacement is the cornerstone in the management of dehydration associated with diarrhea. Fluid replacement can be with oral or intravenous therapy, depending on the patient’s severity/level of dehydration. Determining the severity of dehydration and evaluating the progress of maintaining hydration are particularly important in children younger than 2 years. The combination of risk factors, including being more susceptible to dehydration because of a lack of reserve and the difficulty of determining the effectiveness of rehydration techniques, necessitates close observation and a low threshold for seeking advanced care. Careful clinical observation for signs and symptoms of dehydration and obtaining a good patient history can aid in selecting the best individualized pathway for treatment.

Severe dehydration is characterized by dry mucous membranes, loss of skin turgor, delayed capillary refill, tachycardia, and even signs of shock. Mild and moderate dehydration involves dry mucous membranes, increased thirst, sunken eyes and fontanelle, and some loss of skin turgor. Further discussion of mild, moderate, and severe dehydration is included in the Fluids and Electrolytes chapter. For mild and/or moderate dehydration, oral rehydration therapy (ORT) is preferred and is as effective as intravenous therapy in these patients (Reference 14). Patients with severe dehydration, sepsis/shock, or systemic complications need intravenous fluid resuscitation. Fluid management includes both a rehydration

and maintenance phase. In the first few hours, the goal of rehydration therapy is to rapidly restore water and electrolytes to normal concentrations. After rehydration has occurred, maintenance therapy is given to replace ongoing losses (i.e., maintain normal body composition) and provide therapy until dietary intake can be initiated (see Fluids and Electrolytes chapter). It is important to remember that the reintroduction of feeds, either breastfeeding or formula, is encouraged and supported for infants as a means of maintaining proper fluid balance.

Several commercially available ORT products are available—some are premixed solutions, and others are dry powder packets to which water must be added. The solution, consisting of glucose and salts in specific ratios to aid in intestinal absorption, is absorbed in the small intestine as a replacement for what is lost in the stool. These products vary in the amount of glucose, sodium, and other electrolytes they contain (Table 2). Products with a sodium content of 75–90 mEq/L are intended for use as rehydration solutions, whereas the sodium content of maintenance solutions is between 40 mEq/L and 60 mEq/L (References 7, 14). The rationale for the composition of these products is based on the glucose-sodium cotransport system in the GI tract. In this system, the linkage of glucose and sodium molecules allows glucose to carry sodium into the cells of the small intestine. Water then follows sodium into the bloodstream, resulting in increased absorption of both water and sodium (Reference 15). The ORT products also contain potassium and chloride to replace losses, and citrate, which converts to bicarbonate, is added to correct the acidosis associated with dehydration. For these reasons, ORT products are superior to the “clear-liquid” diets often prescribed to patients with diarrhea. Because the composition of many household “clear liquids” is

not formulated specifically for rehydration, the concentrations of electrolytes and glucose-to-sodium ratio are inappropriate, and the amount of sugar is often too high for adequate replacement of stool losses.

Specifically in developing countries where educational levels and languages may vary, the WHO and UNICEF (United Nations Children’s Fund) recommend using a single oral rehydration solution (the WHO ORS) to avoid mixing errors that would result in the administration of a solution with the incorrect concentration. The high salt content of some ORT products has raised concerns about the use of the higher-sodium solutions in well-nourished children with less severe dehydration who may not need the same level of salt replacement because it may cause hypernatremia. However, studies have shown the ORS to be quicker in the correction of dehydration and safer than intravenous fluids (References 14–18). Some available ORT products are rice-based oral solutions, which provide glucose for the cotransport system from the breakdown of complex carbohydrates in rice/cereal without increasing the osmotic gradient, as can occur with glucose-based products. Overall, oral rehydration remains safe and effective when using the approved ORT products. Fluids for rehydration in developed countries should also be carefully considered. Many fruit juices are high in sugar content and have a high osmolality with no electrolytes. Higher sugar content and osmolality solutions can cause an osmotic diarrhea, worsening dehydration status. Solutions with no electrolytes will not replace what is lost and can lead to detrimental effects related to the lower serum concentrations of these electrolytes. Examples include hypokalemia causing muscle weakness as well as hyponatremia resulting in seizures. Lower osmolar fluids that are more like the ORT products are preferred. Examples of these fluids are listed in

**Table 2.** Commonly Used Oral Rehydration Fluids and Composition

Solution	Osmolality (mOsm/L)	Glucose (g/L)	Sodium (mEq/L)	Bicarbonate (mEq/L)	Potassium (mEq/L)	Chloride (mEq/L)
Pedialyte (Ross Laboratories)	250	25	45	30	20	35
Enfalyte (Mead-Johnson)	200	30	50	34	25	45
Rehydralyte (Ross Laboratories)	305	25	75	30	20	65
WHO ORS	245	13.5	75	30	20	65
CeraLyte (CERA Products)	220	40	50–90	30	20	—

ORS = oral rehydration solution; WHO = World Health Organization.

Table 2. Overall, water, carbonated sports drinks, caffeinated drinks, and sweetened tea are not acceptable for rehydration because these beverages do not provide adequate electrolytes for replacement or because they are hyperosmolar (References 14, 15).

### Pharmacologic Therapy

Outlining the use of pharmacologic therapy as treatment for diarrhea in the pediatric population has been difficult because medications and other pharmacologic agents are used solely for supportive care in the management of diarrhea (Table 3). Different classes of medications and supplements have been used to alleviate symptoms including opiates and their derivatives, cholestyramine, psyllium (adsorbents), probiotics, bismuth subsalicylate, zinc, and vitamin A. Although each of these has been shown to provide some benefit in alleviating symptoms, guidelines are still lacking for their use in the infant and toddler population. Choosing an agent should include balancing efficacy and safety. Knowing the ways that such medications work and the related adverse effects can assist in making the proper recommendations.

Opioids, by acting on the mu receptors in the GI tract, delay GI transit time and prolong contact time. Action on these receptors also leads to the well-known adverse effect of constipation (and can lead to ileus) associated with this class. The opioids tincture of opium, paregoric

(morphine 2 mg/5 mL), and diphenoxylate have been studied in the treatment of both acute and chronic diarrhea. Because of drug abuse potential and the risk of ileus, these medications are not widely prescribed for symptomatic treatment of diarrhea. Diphenoxylate is an opioid derivative available in combination with atropine that is used in noninfectious diarrhea, particularly for chronic diarrhea. Atropine is added to the formulation to prevent abuse by causing undesirable anticholinergic effects. Children with malabsorption secondary to short bowel syndrome may benefit from combination therapy of diphenoxylate/atropine and loperamide.

Loperamide, an opioid derivative, does not cross the blood-brain barrier like other opioids and is thus void of the associated analgesic and central nervous system effects of other opioids. Loperamide acts like other opioids by delaying GI transit time and acts peripherally as an antisecretory agent, regulating chloride secretion. Because water will follow chloride ions, a decrease in water would likely help reduce diarrhea. However, its place in the therapy of acute diarrhea is limited. A recent meta-analysis of loperamide in pediatric patients found that children younger than 3 years who are malnourished, are severely dehydrated, or have bloody diarrhea are at increased risk of adverse events from loperamide, including lethargy, abdominal distention, and ileus. In addition, cases of necrotizing enterocolitis have been reported with loperamide use in children younger

**Table 3. Pediatric Dosing for Select Antidiarrheal Agents**

Loperamide	<p><b>Acute Diarrhea:</b>            2–5 years (13–20 kg): 1 mg three times/day            6–8 years (21–30 kg): 2 mg twice daily            9–12 years (&gt; 30 kg): 2 mg three times/day            After initial dosing, 0.1 mg/kg after each loose stool, but not to exceed initial daily dosing<sup>a</sup></p> <p><b>Chronic Diarrhea:</b>            0.08–0.24 mg/kg/day divided two or three times/day, maximum 2 mg/dose</p>
Paregoric	0.25–0.5 mL/kg one to four times/day
Diphenoxylate and atropine	<p><b>Initial:</b>            0.3–0.4 mg/kg/day (max 10 mg/day) in four divided doses or manufacturer’s recommended dosing:            &lt; 2 years: not recommended            2 years (11–14 kg): 1.5–3 mL four times/day            3 years (12–16 kg): 2–3 mL four times/day            4 years (14–20 kg): 2–4 mL four times/day            5 years (16–23 kg): 2.5–4.5 mL four times/day            6–8 years (17–32 kg): 2.5–5 mL four times/day            9–12 years (23–55 kg): 3.5–5 mL four times/day</p> <p><b>Maintenance:</b>            Can give 25% of initial dose</p>
Cholestyramine	240 mg/kg/day in three divided doses; titrate on the basis of indication

<sup>a</sup>Taken from Takemoto CK, Hodding JH, Kraus DM. Pediatric & Neonatal Dosage Handbook, 18th ed. Hudson, OH: Lexi-Comp, 2011 (Reference 19).

than 2 years. Therefore, loperamide should not be used routinely in this population. However, loperamide has been used in this younger population if the patient has short bowel syndrome to help with malabsorption (References 20, 21). Loperamide should not be used in most infectious diarrhea cases because impairing/slowing GI transit in patients with infectious diarrhea caused by a toxin-producing bacteria carries the risk of preventing toxins from being cleared from the GI tract. This is especially important in these cases because the toxins are largely responsible for the intestinal damage that occurs. Loperamide may have a use in chronic diarrhea, especially in patients with malabsorption problems.

Cholestyramine, a chloride and basic quaternary ammonium anion exchange binding resin, has been used in diarrheal disorders involving increased fecal bile acids or pseudomembranous colitis. Cholestyramine forms a nonabsorbable complex with bile acids in the intestines and causes the release its chloride ions during this process. The chloride ions are absorbed, allowing water to follow, thus decreasing diarrhea. Pediatric patients may be at increased risk of hyperchloremic acidosis as a result; however, studies evaluating the role of cholestyramine in children 7 months to about 2 years of age with acute and chronic diarrhea have shown that shortened courses (by about 2 days) are tolerated without significant adverse effects (Reference 17) after adequate hydration with ORT. When administering cholestyramine with other medications or supplements, medications should be given at least 1 hour before or at least 4–6 hours after cholestyramine to prevent binding and decreased absorption of other medications and with plenty of water to prevent constipation (Reference 19).

Psyllium or other adsorbents are used for symptomatic relief and are nonspecific in their action. As bulking agents, these drugs absorb liquid in the GI tract, which alters the fluid and electrolyte content and expands the stool (forms “bulk”). These agents can also absorb digestive juices, nutrients, or medications, which may reduce their bioavailability. Although psyllium can be used as a laxative, its bulk-producing properties may help create a more formed stool and can be beneficial in patients with diarrhea. Psyllium can prevent the absorption of medications, so other medications should not be taken within 3 hours of psyllium administration. Psyllium should also be taken with plenty of water because it is a bulking agent and can cause constipation, leading to obstruction (Reference 19).

The use of probiotics for diarrhea in children has recently gained momentum with the introduction of many lactobacillus products and dosage forms. Other bacterial probiotics studied in this population include *Bifidobacterium lactis* and *Streptococcus thermophilus*. *Saccharomyces boulardii* is a non-pathogenic yeast that was recently studied for its use in the treatment of diarrhea;

however, few data exist in the pediatric population. Probiotics, found in normal gut flora, have been shown to decrease or prevent diarrhea associated with antibiotic use and to benefit children at risk of infectious diarrhea related to malnutrition or pathogen exposure (References 22, 23). The mechanism of probiotics in the treatment of diarrhea is not well understood. Presumed mechanisms of benefit include enhancement of the immune system, creation of a competitive environment for microbial growth, or extension of antimicrobial action on pathogenic organisms. Despite increased use, controversy exists regarding the potential risk of seeding the organism from the gut into the bloodstream (resulting in bacteremia with lactobacillus or fungemia with *Saccharomyces*), especially in neonatal or immunocompromised populations. A meta-analysis of the use of lactobacillus for acute infectious diarrhea found a reduction in the number of stools and overall safety profile (Reference 22). This analysis predominantly included children 1–36 months of age. No studies included the neonatal or premature neonatal populations. Prebiotics, food, or supplements with nondigestible substances that facilitate microbial growth of indigenous probiotic bacteria have also been introduced as a preventive or symptomatic treatment of diarrhea. More studies are needed to assess the true benefit of probiotic and prebiotic use and evaluate the potential for adverse effects in high-risk populations (Reference 23).

The use of zinc and vitamin A has also been described in the treatment of childhood diarrhea. Zinc is an essential mineral that plays a role in immune function; it has been extensively studied in pediatric patients in developing countries (References 24, 25). These patients may be zinc-deficient secondary to malnutrition, and the extrapolation of these results to use in developed countries may not be as well-founded. The exact mechanism of zinc’s role in the treatment of diarrhea is not fully understood. Zinc may have a role in enhancing cation absorption or suppressing cation secretion. Several studies of children 1–60 months of age with either acute or persistent diarrhea show a reduction in stool frequency and overall incidence of diarrhea (Reference 26). However, controversy exists regarding the most appropriate dose and dosage form. Because of the potential concern for copper deficiency with long-term use of zinc, the WHO recommends only a 10- to 14-day course (of 10–20 mg/day) for treatment of acute diarrhea (Reference 16). Zinc, which is well tolerated, has not shown any significant adverse effects with short-term use. Copper deficiency leading to anemia has been described and should be evaluated if prolonged therapy is used.

Vitamin A supplementation has also been investigated in malnourished children of developing countries with mixed results. Of the children studied, those with a wasting syndrome responded best to vitamin A (Reference 27). As with zinc, those deficient in vitamin A may have better outcomes from supplementation, and routine use for the treatment of diarrhea is not currently recommended (Reference 27).

Bismuth subsalicylate has been used for traveler's diarrhea, for chronic infantile diarrhea, or as an adjunctive treatment for *Helicobacter pylori*-associated gastritis. Bismuth subsalicylate is thought to work by dual mechanisms. Bismuth acts by facilitating the absorption of extra water in the intestines as an antisecretory agent. When the subsalicylate is hydrolyzed into salicylic acid, it inhibits prostaglandins associated with inflammation and possible hypermotility. Bismuth subsalicylate may even have antimicrobial effects by binding toxins or because of some inherent bactericidal activity. Because all products contain salicylates, caution should be used in individuals with chickenpox or influenza, secondary to the risk of Reye syndrome.

Overall, treatment of diarrhea in the pediatric population consists of careful monitoring, prevention of dehydration, and provision of symptomatic care when appropriate. Recommending pharmacologic treatment of diarrhea should first include analyzing the etiology and age group. Medication use should be approached with caution and selected according to the clinical condition of the patient, any comorbidities, and potential for adverse effects. Hydration status remains the underlying theme of diarrhea management and thus the recommendation with the most evidence-based support. Most acute diarrhea algorithms will follow a dehydration assessment and treatment plan and suggest antidiarrheal medications only as last-line symptomatic relief. The caveat to this would be if the diarrhea were infectious in origin. Separate treatment algorithms exist for infectious diarrhea as described in the Infectious Diarrhea chapter.

## MONITORING OF THERAPY

The most important monitoring parameter with diarrhea is hydration status. Determining the degree of dehydration initially and evaluating for improvement in hydration status will help direct therapy changes in rehydration fluids. Once initial deficits are accounted for and maintenance therapy is initiated, the decision to reinstate feeds or trial of oral nutrition should be considered. Symptoms of acute diarrhea should subside within 24–72 hours. Decreased number of and more formed stools, together with decreased clinical symptoms of pain and bloating, indicate improvement and response to therapy. Daily examination of body weight with fluid

balance totals (input/output) should be monitored because this will help determine hydration status. Serum electrolytes may also need to be monitored to ensure the correction of any deficiencies. For infectious causes, a complete blood cell count, urine analysis, and blood or stool cultures are all appropriate monitoring parameters. Chronic diarrhea treatment should focus on treating/managing the underlying cause, together with any symptomatic relief measures. Careful monitoring of hydration status and signs of treatment response is the overriding principle of diarrhea management.

## CONSTIPATION

Constipation is a common problem among children and adults and is responsible for many physician, hospital, and specialty visits each year. In 2006, an estimated 5.7 million physician visits were for constipation alone (Reference 28). Even though constipation is a common and well-known condition, many different definitions have been used to describe and diagnosis it. Health care practitioners (e.g., physicians, nurses, pharmacists), researchers/epidemiologists, and patients may all describe constipation differently, with some using frequency of bowel movements (BMs) or stool characteristics and others referring to change from their own normal pattern. Even when a general definition of constipation is used—such as “the passage of bulky or hard stool at infrequent intervals”—what is “normal” for one patient may not be the same for another, leaving much to subjective interpretation. In addition, different age groups have different stooling habits as well as exposure to different diets, making it difficult to define exactly what constitutes “normal” bowel habits in the pediatric population. For example, breastfed infants are rarely constipated and often have several BMs per day, whereas older children typically have less frequent BMs per day—though the number can vary markedly, even between children of the same age (Reference 29).

### Definitions and Epidemiology

Constipation can be defined as having infrequent stools (less than 3 BMs per week), having hard stools, experiencing excessive straining, or having a feeling of incomplete evacuation. Thus, what defines constipation for each case must be individualized for the patient. Pediatric definitions, integrated into the Rome III criteria in 2006, define childhood constipation as follows:

the occurrence of two or more of the following six criteria in the previous 8 weeks: frequency of movements fewer than 3 a week; more than one episode of faecal incontinence a week; large stools in the rectum or palpable on abdominal

examination; passing of stools so large that they may obstruct the toilet; retentive posturing and withholding behaviour; and painful defecation. (Reference 30)

Constipation can be classified as “functional constipation.” This is defined as follows:

[the] occurrence of two or more of the following six criteria in the previous 2 months in a child with a developmental age of at least 4 years, who has insufficient criteria for the diagnosis of irritable bowel syndrome (including no evidence of an inflammatory, anatomic, metabolic, or neoplastic process): two or fewer defecations in the toilet a week; at least one episode of fecal incontinence a week; history of retentive posturing or excessive volitional stool retention; history of painful or hard BMs; presence of a large faecal mass in the rectum; and a history of large-diameter stools that may obstruct the toilet. Infants up to 4 years of age have to fulfill two or more criteria for at least 1 month,

according to Rome III criteria. It is important to remember that the definition of constipation is not based on frequency alone, but also on complete evacuation of the large colon and consistency. A child who has several small stools per day and is not completely evacuating the large colon is considered constipated versus a child who has large stools twice a week but evacuates the colon.

Determining the overall incidence of constipation is difficult because it is complicated to define. The prevalence of childhood constipation, both acute and chronic, has been estimated as anywhere from 0.7% to 29.6% in the general population worldwide (Reference 29). In the United States and United Kingdom, the incidence of chronic constipation is reportedly lower at 1% to 5% (Reference 29). One-half of children with a history of painful defecation develop chronic constipation and its complications, including fecal impaction and/or fecal incontinence. Ninety percent of pediatric chronic constipation cases are a result of withholding behavior (a type of functional constipation), rather than an organic or pathologic cause (Reference 28). Still, constipation comprises 25% of pediatric visits to a gastroenterologist (Reference 29).

Certain risk factors for constipation have been evaluated. One study found a higher incidence of constipation among children with a birth weight less than 750 g and in the presence of neurodevelopmental impairments (Reference 30). A low-fiber diet may also predispose a patient to constipation (Reference 31). As the number of those with childhood obesity climbs, evidence has shown a higher prevalence of constipation and fecal incontinence among these children (Reference 32).

## PATHOPHYSIOLOGY AND ETIOLOGY

Continence is maintained by muscular contractions of both the internal (involuntary) and external (voluntary) anal sphincter. When stool comes in contact with the mucosa of the lower rectum, an urge to defecate is triggered. Defecation can be controlled by tightening the external sphincter and gluteal muscles, which push the feces away from the lower rectum and eliminate the sensation to have a BM. Withholding causes the rectum to stretch (to accommodate the extra stool), resulting in a decreased ability and sensitivity to pass stool. In addition, because the fecal matter stays in the rectum, it becomes harder, making it painful to pass. This can lead to a cycle of withholding behavior and increased anxiety in the child. This description is known as functional constipation; however, constipation may also result from an organic cause. Stool patterns vary in pediatric patients, making it difficult to define what is abnormal in this population and to accurately identify the underlying cause. Therefore, each patient should be evaluated individually when diagnosing constipation.

Anatomic, dietary, and/or medication-related causes should be considered in the differential for constipation. Organic causes of constipation include neurologic (spina bifida or cerebral palsy), Hirschsprung disease, chronic intestinal pseudo-obstruction, and neuronal intestinal dysplasia. Hirschsprung disease is a condition in which the nerves (or ganglions) at the end of the colon are missing, causing the absence of peristalsis and resulting in obstruction with stool. Surgery and supportive care, including medications and maintaining an appropriate diet, are involved in the treatment of these organic causes. Cystic fibrosis and systemic lupus erythematosus have also been linked to constipation and are managed similarly with medications and diet modifications. Metabolic and endocrine disorders may also affect bowel function. Hypothyroidism, diabetes mellitus, and hypercalcemia can inhibit bowel function and should be ruled out with an appropriate workup and/or managed accordingly if present (References 31, 32).

Diet can also be a factor in causing constipation, particularly those diets low in fiber and in the presence of dehydration. In infants, breastfeeding or formula feeding is rarely associated with constipation unless there is an insufficient amount of food. Constipation in this age group should be evaluated for feeding and anatomic or neurologic etiologies. Changes in diet in older children, particularly an increase in high-fat, low-fiber diets together with decreased water consumption, can precipitate constipation.

Medications have also been implicated in causing constipation. The abuse of cathartics, or agents that induce stooling, can cause a delay in stooling and begin a cycle of daily or frequent use to maintain “normal” bowel

function. Education on the proper use of cathartics and “normal” bowel habits is an important part of constipation management. The caregiver should understand that “normal” may not include a daily BM, but as long as the colon is being emptied fully, medications are not necessary to facilitate defecation. Overuse of laxatives can cause a physical dependence and, if stopped, will result in constipation. Other medications that cause constipation, not through dependence but through effects on motility, include opioid narcotics, antihistamines, antidepressants, antacids (especially calcium-containing products), pseudoephedrine, and the chemotherapy agent vincristine, among others (Box 1). Iron supplementation, commonly used in the pediatric population with multivitamin products, may also lead to constipation. Caregivers should watch for any changes in stool habits in infants and children taking iron.

## CLINICAL PRESENTATION AND DIAGNOSIS

### Signs and Symptoms

Painful passage of stools with hard consistency is often described with constipation. In addition to discomfort when stooling, constipation is associated with symptoms such as nausea, abdominal pain, distention, and bloating and can lead to many other complications including rectal fissures, ulcers, rectal prolapse, urinary tract infections, or incontinence. Stool frequency varies with constipation; it should be evaluated more for evacuation of the large colon and change from the patient’s normal bowel patterns than for the number of stools per day or week. With functional constipation, the child may exhibit certain behaviors that aid in suppressing the urge to defecate, which include rocking back and forth, standing on tiptoes, or becoming fidgety. The withholding behavior can lead to painful stooling as well as a decreased appetite or food intake because of a full colon.

### Diagnostic Criteria

Evaluating stool history and signs/symptoms may be sufficient for diagnosis of functional constipation. The history should include changes in the stool pattern: duration of absence of BM; size, number, consistency, and frequency of stools; any rectal or abdominal pain or bleeding; soiling of underwear; having both diarrhea and hard stools; withholding behaviors; any nausea/vomiting, bloating, or decreased appetite; urinary tract symptoms; and weight loss or change in dietary habits. A complete medication and social history should also be performed.

The physical examination should involve evaluation for abdominal distention, tenderness, presence of hard stool (can be felt on palpation), and physical defects that would be consistent with an underlying cause (e.g.,

spina bifida) (Reference 31). A digital rectal examination will assist in determining whether a mass or fecal impaction is present. Fecal impaction is defined as a hard mass in the lower abdomen, a dilated rectum filled with a large amount of stool, or excessive stool in the colon as identified by abdominal radiography (Reference 31). Radiographic studies to aid in diagnosis include abdominal radiography and barium enema. Abdominal radiography is helpful to assess stool volume and rectal dilation, and a barium enema is helpful in the diagnosis of strictures, abnormal bowel shape, and even Hirschsprung disease. When a barium enema is performed, the colon is filled with a contrast agent (barium) by a rectal tube. A radiograph is taken, and the barium will block the radiograph, leaving a picture of the colon and revealing any abnormalities. Biopsies may

also need to be performed to assess for Hirschsprung disease or an inflammatory disorder (like Crohn disease). The procedure selected is related to the suspected etiology of the constipation.

Laboratory testing can help rule out potential underlying causes. Thyroid function tests can be evaluated for constipation related to hypothyroidism, magnesium levels on the basic metabolic panel rule out or confirm laxative abuse, and a urine analysis can be performed to test for a urinary tract infection.

In children younger than 1 year, constipation is less common because withholding does not occur. Diagnosis and workup in this population is geared more toward an organic cause. Although the number of stools can vary because of diet (more frequent stools with breastfeeding vs. formula), the patient history and physical examination would vary somewhat from what was previously described. A history of delayed passing of meconium, abdominal distention, bilious emesis (suggesting obstruction), and food avoidance indicate an organic cause like Hirschsprung disease. Evaluation for physical signs of congenital defects, like the presence of a sacral dimple, would point to spina bifida. Understanding age-related causes of constipation can help guide the history and physical examination.

### Course and Prognosis of Disease

Constipation, although uncomfortable, is seldom life threatening. However, significant morbidity can occur if progression to chronic constipation is left untreated. Complications of untreated constipation include impaction or obstruction, urinary retention from ureter obstruction, rectal prolapse, and encopresis. Many children with encopresis, defined as the repeated passage of feces in inappropriate places after the developmental age of 4, either have episodes at school or have to wear diaper-type undergarments well past the age-appropriate time. As a result, these patients may undergo social withdrawal, depression, and/or anxiety related to their condition. Medications used to treat depression can compound the problem because they can cause constipation. The social and economic consequences of chronic constipation, including child anxiety and missed days from school or work, should not be overlooked and necessitate the prudent management and prevention of recurrence (References 33 – 39).

Children 2–4 years of age have a higher recurrence rate of constipation than younger infants. About one-third of children with constipation continue symptoms beyond puberty (References 39). In a recent study, 25% of children with functional constipation had symptoms that persisted into adulthood (Reference 40). Several risk factors were identified including older age of onset, delay in time from diagnosis to being seen by a gastroenterologist, and lower defecation history at first presentation.

Women were also more likely to relapse than were men. This study suggested quicker follow-up with specialists, especially for those refractory to initial treatment, as a mechanism for relapse prevention (Reference 40).

## TREATMENT

### Goals of Therapy

The goal of therapy for constipation is multifactorial and should encompass prevention, alleviation of acute symptoms, and formation of a management plan to avoid recurrence. Because the etiology of constipation differs between infants and children, age should be considered in the management of constipation. The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition guidelines outline these differences in the diagnosis and treatment of constipation (Reference 41). The first step in therapy is to provide education on the pathogenesis of constipation, making sure to address the social and psychological reasons for the child's constipation. It should be recognized that constipation is not the result of defiant behavior, and this point may need to be reinforced throughout therapy. Because prevention is the ultimate goal of therapy, changes in lifestyle to facilitate prevention are necessary, including modification of diet. For children, an environment for developing and reinforcing good bowel habits can aid in prevention. Adequate time and a schedule are both key aspects of good bowel habits, but it can take some time to see results. Patience and positive reinforcement are necessary to achieve success.

Alleviating acute symptoms of constipation through both nonpharmacologic and pharmacologic therapies should be the next step in the management of constipation. Acutely, if impacted stool is present, disimpaction should occur, either through manual measures or by pharmacologic management. Disimpaction is necessary before maintenance therapy can begin. When selecting pharmacologic agents, the age of the patient, time to onset of action, and adverse effects should be considered (Reference 41). After acute symptoms are alleviated, any medications used should be weaned to prevent dependence on the medications that would inhibit the development of good bowel habits and act as negative reinforcement for the patient.

Maintenance therapy involving strategies focused on prevention should be initiated once acute alleviation of symptoms has been achieved. This generally involves both nonpharmacologic (dietary interventions and behavioral modification) and pharmacologic (laxative) therapy to ensure regular and complete evacuation of stool. When constipation is associated with medications, the dose should be decreased, if possible,

or concomitant preventive therapy should be initiated. Addressing the three main phases of constipation treatment (acute relief, maintenance therapy, and weaning) is recommended to facilitate successful outcomes.

### Nonpharmacologic Therapy

In children, nonpharmacologic therapy with both dietary changes and behavioral management contributes largely to the prevention and maintenance therapy strategies. Increased consumption of fluids and intake of fiber in addition to maintaining a balanced diet of whole grains, fruits, and vegetables should be encouraged. Decreasing the intake of constipating foods like dairy products and starches is also recommended. In infants, juices that contain sorbitol (e.g., prune, pear, and apple juice) are recommended. Fiber can be added in the form of barley malt extract (Maltsupex). In infants, 1–2 teaspoons of barley malt extract can be added to 4 oz of feedings or 2–10 mL per 240 mL of feedings (depending on the formulation) two or three times/day. Barley malt extract is a natural stool softener that may be useful for infants using a bottle because of its unpleasant odor. Corn syrup or sorbitol acts as an osmotic laxative, which can also be used in this population.

Behavioral therapy is an important component of treatment. Regular toilet habits, which include unhurried time on the toilet and maintaining a record of stool frequency, should become part of the daily schedule. Caregivers can institute a positive reinforcement system, or reward system, to record number of stools and foster a relaxed and nurturing environment for the child. Establishing normal stool habits in children through education, behavioral modifications/therapy, and regular toileting practices should be added to any treatment regimen.

One additional nonpharmacologic therapy used in the acute management of constipation is digital disimpaction, although its use is not widely agreed on in the primary care setting and its use would most likely occur if other therapies were unsuccessful.

### Pharmacologic Therapy

When selecting appropriate therapy, an underlying cause must be considered. Nonpharmacologic and pharmacologic therapy should be used in conjunction to achieve desired results. The treatment course for constipation can be lengthy. Each phase of treatment (disimpaction and maintenance) has a different duration and expectation of seeing results. For example, impaction can show results within 2–5 days, whereas maintenance therapy can require 3–12 months of treatment to sustain results. Unfortunately, around 50% of children will

not respond to initial treatment and will require refractory treatment (Reference 32). Treatment duration and outcomes among children are as different as the child and qualification of constipation.

If fecal impaction is present, disimpaction is the first goal of therapy. Disimpaction can be achieved by several methods. Method and agent chosen depend on patient age, adverse effect profile, route of administration, and severity of impaction because no guidelines or data exist favoring one agent over another. In pediatric practice, agents with the fewest adverse effects, less complicated administration, and high likelihood of adherence are used. Pharmacologic treatment options include glycerin or bisacodyl suppositories, enemas, or oral medications (e.g., mineral oil, polyethylene glycol solutions, magnesium citrate). Both oral and rectal administration can be used for disimpaction. No studies have identified that one route is superior to the other; thus, the choice depends on the child and caregiver. The oral route is less invasive, but adherence to therapy may be difficult. Alternatively, the rectal route is invasive, but it generally has a quick onset. Caution should be used with enema administration to avoid damage to the rectal wall; for this reason, it may not be the first-line option for infants.

Options are generally divided into agents that provide acute relief of impacted stool or maintenance therapy for sustained evacuation or prevention of reimpaction/re-accumulation (Table 4). To disimpact, lubricants such as mineral oil have been widely described in pediatric and adult literature. Mineral oil works by softening stool and preventing water reabsorption. In children younger than 12 years, high doses of up to 15 mL or 60 mL of mineral oil, given by the oral or rectal route, respectively, have been shown to be effective. Too high a dose results in anal leakage, and it should be titrated accordingly. However, mineral oil should not be used in infants because of the risk of aspiration and resulting lipoid pneumonia.

Osmotic laxatives have also been studied for disimpaction in children (Reference 42). Osmotic laxatives prevent the absorption of water or create an osmotic gradient in the gut to pull water into the lumen, thereby increasing the “fluidity” of the stool. Polyethylene glycol is an osmotic laxative with a good safety profile for both infants and children (Reference 43). Electrolyte disturbances should be monitored, however, because osmotic laxatives prevent the absorption of water, and electrolytes follow suit. Polyethylene glycol has also been used in hospital settings for gastric lavage if oral or enema treatment is unsuccessful in disimpaction. In gastric lavage, a nasogastric tube is placed, and the patient is given polyethylene glycol at either 25 mL/kg/hour (max 1000 mL/hour) or 20 mL/kg/hour for 4 hours/day until stools become clear (Reference 41).

**Table 4. Pharmacologic Therapy of Constipation**

Pharmacologic Agent	Dosing	Onset	Comments
Docusate salts (same dosing for sodium, calcium, potassium salts)	< 3 years: 10–40 mg/day in one to four divided doses 3–6 years: 20–60 mg/day in one to four divided doses 6–12 years: 40–150 mg/day in one to four divided doses > 12 years and adults: 50–400 mg/day in one to four divided doses	12–72 hours	Useful in prevention of constipation, not sole agent for treatment of impaction
Mineral oil	Disimpaction: 30 mL per year of age (max 240 mL) twice daily  Maintenance: Oral: 5–11 years: 5–15 mL once daily or divided > 12 years: 15–45 mL/day once or in divided doses  Rectal: 2–11 years: 30–60 mL as a single dose > 12 years: 50–150 mL as a single dose	6–8 hours	Should not be used for more than 1 week; caution with use in children < 5 years because of risk of aspiration
Polyethylene glycol (PEG)	MiraLAX oral: child < 20 kg (limited data; studied in children 18 months to 11 years for chronic constipation): 0.25–1 g/kg/day PO divided twice daily (max 17 g/day) > 20 kg: 17 g in 240 mL of water daily  GoLytely oral: maintenance: 5–10 mL/kg/day	At constipation dosing, results can be seen after 2 days to 1 week of therapy.	Contraindicated in bowel obstruction; monitor for electrolyte disturbances  In general, GoLytely is reserved for older children. Safety of long-term use has not been well established.
Lactulose	Children: 7.5 mL/day after breakfast Adults: 15–30 mL/day to a max of 60 mL/day	Within 24 hours	After discontinuation of therapy, allow 24–48 hours before normal bowel function resumes.
Sorbitol	Oral as 70% solution: Children: 1–3 mL/kg/day in divided doses Adults: 30–150 mL as single dose Enema: 120 mL as a single dose	Within 24 hours	Adjust dose on the basis of the number of daily bowel movements (lactulose and sorbitol similar).
Bisacodyl	Oral: 3–12 years: 5–10 mg or 0.3 mg/kg/day as single dose (max 30 mg/day) > 12 years: 5–15 mg/day as a single dose (max 30 mg/day)  Rectal: < 2 years: 5 mg/day as a single dose 2–11 years: 5–10 mg/day as a single dose > 12: 10 mg/day as a single dose	Oral: 6–10 hours  Rectal: 15–60 minutes	Not recommended for daily use; may cause considerable abdominal cramping
Sennosides	Syrup (8.8 mg/5 mL): 1 month to 2 years: 1.25–2.5 mL at bedtime (max 5 mL) 2–6 years: 2.5–3.75 mL at bedtime (max 3.75 mL) 6–12 years: 5–7.5 mL at bedtime (max 7.5 mL) > 12 years: 10–15 mL at bedtime (max 15 mL)  Tablet (8.6 mg): 2–6 years: ½ tablet at bedtime (max 1 tablet twice daily) 6–12: 1 tablet (max 2 tablets twice daily) > 12 years: 2 tablets (max 4 tablets twice daily)	Oral: within 6–24 hours  Rectal: evacuation occurs in 30 minutes to 2 hours	Docusate enhances the absorption of senna.

Pharmacologic Agent	Dosing	Onset	Comments
Magnesium citrate	< 6 years: 2–4 mL/kg/dose given once or in divided doses 6–12 years: 100–150 mL/dose given once or in divided doses > 12 years: 150–300 mL/dose given once or in divided doses	A few hours after oral administration	Used for acute evacuation, not impaction
Magnesium hydroxide	(All liquid milliliter doses are based on 400 mg/5 mL magnesium hydroxide, unless noted otherwise): < 2 years: 0.5 mL/kg/dose 2–5 years: 5–15 mL or 311–622 mg (1 or 2 chewable tablets) 6–11 years: 15–30 mL or 933–1244 mg (3 or 4 chewable tablets) > 12 years and adult: 30–60 mL or 1866–2488 mg (6–8 chewable tablets)	0.5–6 hours	Use with caution in patients with renal impairment.  HS or in divided doses.
Glycerin	Neonates: ½ glycerin suppository as needed Children: < 6 years: 1 infant suppository as needed > 6 years 1 adult suppository as needed	15–30 minutes	Not useful for impaction; considered a safe laxative
Phosphate soda enemas	Enema: 2–12 years: 66-mL enema × 1; may repeat × 1 dose. > 12 years and adult: 133 mL enema × 1; may repeat × 1  Oral: 5–9 years: 5 mL PO × 1 dose 10–12 years: 10 mL PO × 1 dose > 12 years and adult: 20–30 mL PO × 1 dose	Rectal: 2–5 minutes  Oral: 3–6 hours	For oral administration, mix 1:1 with water. Separate doses by 10–12 hours.  Contraindicated in renal failure. May cause electrolyte disturbances

HS = at bedtime; PO = orally.

Other osmotic agents that have been used for disimpaction in children, but that have more limited data in pediatric patients, include magnesium citrate, magnesium hydroxide, lactulose, and sorbitol. Magnesium citrate is an osmotic cathartic that is not commonly used for disimpaction, particularly in those younger than 2 years because of their susceptibility to magnesium toxicity. Toxicity can lead to electrolyte disturbances including hypermagnesemia, hypophosphatemia, and hypocalcemia and their sequelae. Magnesium hydroxide can also be used, but it is indicated more for maintenance therapy. Magnesium hydroxide induces the release of cholecystokinin, which stimulates the secretion of water and motility. Like the citrate salt, it should not be used in infants because magnesium toxicity can occur. In the presence of renal dysfunction, magnesium accumulation can occur, especially when in combination with aluminum salts; thus, it should be avoided in these patients. Magnesium salts can cause considerable cramping and gas; they are therefore less well tolerated in the pediatric population. Lactulose and sorbitol are both osmotic laxatives composed of indigestible sugars. They are generally well tolerated for long-term use, but

data are limited on their use for disimpaction. Lactulose and sorbitol cause flatulence and abdominal cramping and should be titrated to balance efficacy with these adverse effects. Sorbitol enemas have also been used for drug overdoses, but they are not routinely used for fecal impaction.

Enemas effective for fecal impaction include phosphate soda and saline enemas. However, they are generally reserved for children older than 2 years. Phosphate soda is an osmotic enema and should not be used in renal impairment because accumulation can occur. The use of soapsuds, tap water, or magnesium enemas is not recommended because of the associated toxicities, including bowel perforations, necrosis, or even water intoxication (References 29, 41).

Stimulant laxatives, including glycerin, bisacodyl, and senna, are also effective in the treatment of fecal impaction in children. Glycerin suppositories are perhaps most widely used in the neonatal and infant populations. Glycerin works through osmotic properties, but the direct rectal stimulation often produces the desired results. A stellar safety profile and variety of available dosing sizes make glycerin a good choice for infants.

However, glycerin's effectiveness may be decreased once rectal distention has occurred (References 44, 45). Bisacodyl, a stimulant, can be given orally or rectally in older children (not indicated in children younger than 2 years). It works by stimulating the nerves in the colon to cause movement as well as increase the secretion of water and chloride. Orally, it has been used for disimpaction, usually in conjunction with other therapies. Rectal use is generally not as effective because the suppository is usually inserted into the middle of the stool, rather than where it can come into contact with the mucosa, and will not have the desired action. Abdominal cramping, hypokalemia, and diarrhea have all been associated with bisacodyl use. Senna is another stimulant laxative that works by stimulating colonic nerves to produce peristalsis, or movement, in addition to preventing water and electrolyte absorption to soften stools. Senna has a quicker onset of action than bisacodyl (1–3 hours vs. 6–12 hours). Senna is often used in combination with stool softeners, mainly docusate. One unique adverse effect is the presence of melanosis coli. Melanosis coli is a benign darkening of the colon that generally improves within 4–12 months after senna discontinuation (Reference 41). As stated earlier, refractory constipation warrants further workup for an underlying disorder, including performing a barium enema or rectal biopsy. If an underlying disorder such as Hirschsprung disease is discovered, or if a patient is unsuccessfully disimpacted, surgery may be warranted to remove the area of bowel that is not functioning and/or the removal of stool. An ostomy, or surgically created opening from the intestines to the outside of the body, may be needed after surgery. Having an ostomy requires special care and diet considerations because absorption may be affected.

In general, once disimpaction occurs, maintenance therapy involves the combination of dietary and behavioral changes, together with lubricants or osmotic laxatives (or a combination of the two), if pharmacologic therapy is necessary. In infants, the maintenance stage can usually be maintained with a stool softener alone. Toddlers—stool-withholder experts—may require both stool softeners (e.g., docusate sodium) and stimulants at the beginning of the maintenance phase. Docusate works by reducing the surface tension of the oil/water interface of stool, causing increased absorption of water in the stool and ultimately softening stools (much like a soap acts on changing oil and water interfaces) (Reference 46). Docusate is available as several salts including sodium, calcium, and potassium that are considered interchangeable. Table 4 provides dosing for medications used for the treatment of constipation.

## MONITORING OF THERAPY

The ultimate goal of therapy is having a regular stool pattern and complete evacuation of stool. It should be understood that the use of laxatives is to promote comfortable evacuation, not as a medication to induce stooling. Relying on laxatives to evacuate stool can lead to laxative abuse. Therefore, incorporating all of the types of therapy previously discussed is the most appropriate approach to therapy (References 29, 32, 41).

If impaction is present, disimpaction must occur before other therapy can begin. When evaluating the effectiveness of therapy, the clinician should consider the time of onset for the agent. The type, or class, of agent selected will produce results at different times, and adequate time for these agents to work should be granted before adding or changing therapy (see Table 4). Complete evacuation can take 2–5 days. If complete evacuation is not achieved within this time, admission to the hospital for oral gastric lavage with a polyethylene glycol solution is warranted. The patient should have a complete evacuation of stool after treatment, and maintenance therapy should begin to reinforce good bowel habits and maintain evacuation to restore normal bowel tone.

During the maintenance phase, stool softeners and, periodically, stimulants, are used to ensure consistent complete evacuation and the return of normal bowel tone. This phase can take from 2 to 6 months. Stimulants and a dependence on laxatives for stooling should be evaluated by the practitioner to prevent dependence.

Weaning of therapy is the final step in the therapeutic plan. It is important to remember that “normal bowel function” is different for each patient, and a return to the patient's “normal” should be sought when evaluating the effectiveness of therapy. Weaning agents should be done gradually, and some patients may require regular use of stool softeners even after normal bowel tone returns. If the patient is taking daily medication, the medication may be weaned by going to every-other-day therapy for 1 month, followed by every 3 days for 1 month until complete evacuation occurs on a regular basis. During this phase, dietary and behavioral therapy should continue. To prevent impaction, a stimulant laxative may be administered if the child does not stool for more than 3 days. Maintaining a stool diary and reinforcement of good bowel habits may be necessary to recognize the early signs of recurrence including feeling of incomplete evacuation, return of stool-withholding behaviors, or irregular stooling. Throughout therapy, monitoring for drug-specific adverse effects and balancing that with efficacy should be considered. Introduction of medications or dietary changes that may cause constipation should also be monitored and considered if symptoms of recurrence are present. The expectation of clinicians

and caregivers alike should be that achieving therapeutic goals can take months; even with appropriate therapy and management techniques, recurrence rates have been described in up to 50% of cases (Reference 32). If the goals cannot be achieved after adequate time and therapy attempts, a specialist may be required to complete a further workup for an underlying etiology or to assist with management techniques.

## CONCLUSIONS

Diarrhea and constipation are common disease states in children. Although diarrhea is a leading cause of morbidity and mortality worldwide, rehydrating with appropriate fluids, like ORT, and monitoring hydration status have been shown to considerably affect survival (References 14–18). When treating diarrhea, if an underlying etiology can be identified, treatment should be tailored. Many times, an exact cause is unknown, but hydration management principles remain the same. Although pharmacologic therapy is not indicated as a cure for most cases of acute diarrhea, treatment with medications has or may have a place for refractory cases and for the management of chronic diarrhea. Treatment should be individualized and reassessed often. Likewise, constipation management should be individualized and guided by the underlying cause, either organic or non-organic. It is important to identify any underlying etiology because constipation is often recognized as a symptom, so treatment can be specific to the cause. Most cases are functional in origin and should be managed with diet and behavioral and pharmacologic therapy. Ultimately, the goal is to maintain complete evacuation and restoration of good bowel tone and habits. Therapy involves both an acute and maintenance approach and should be continuously monitored for changes in efficacy to step up or step down treatment. The risk of medication abuse, resulting in lack of efficacy, should also be evaluated in the treatment regimens. Understanding the cause of the patient's constipation, providing positive reinforcement of good bowel habits, and employing safe and effective use of pharmacologic therapy can help decrease the likelihood of relapse or future poor outcomes so often seen with chronic constipation. For both diarrhea and constipation, completion of a careful history, patient evaluation, and close follow-up will ensure appropriate selection and monitoring of therapy.

# CHAPTER 18

## IRRITABLE BOWEL SYNDROME

Jennifer W. Chow, Pharm.D.

### LEARNING OBJECTIVES

1. Discuss the epidemiology of irritable bowel syndrome (IBS).
2. Understand the pathophysiology of IBS.
3. Recognize the signs and symptoms of IBS.
4. Discuss the diagnosis and classifications of IBS.
5. Explain the overall management and treatments associated with IBS.
6. Discuss monitoring the efficacy and toxicity of agents used in the treatment of IBS.

### ABBREVIATIONS IN THIS CHAPTER

FGID	Functional gastrointestinal disorder
IBS	Irritable bowel syndrome
IBS-C	Constipation-predominant IBS
IBS-D	Diarrhea-predominant IBS
RAP	Recurrent abdominal pain

### INTRODUCTION/OVERVIEW

Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder (FGID) characterized by chronic abdominal pain or recurrent abdominal pain (RAP) and altered bowel habits in the absence of an organic cause. In children and adolescents, chronic abdominal pain and RAP are two of the most common concerns presented to health care practitioners (References 1, 2). Chronic abdominal pain and RAP are defined as pain without a determined cause that occurs during a 3-month period. Children with a history of RAP are at an increased risk of developing IBS in young adulthood (Reference 3). The pathophysiology of IBS is likely multifactorial. The symptoms of IBS can help diagnose and classify IBS and thus guide treatment. Treatment will be individualized to the patient's symptoms, with a goal of improving the patient's quality of life.

### EPIDEMIOLOGY

Irritable bowel syndrome is one of the most common gastrointestinal (GI) disorders for which patients seek medical treatment. Recurrent abdominal pain, or functional abdominal pain, is the main functional bowel disorder seen in children and has been linked to IBS.

Recurrent abdominal pain occurs in about 10% of children and adolescents. In a historical study of 1000 school-aged children, RAP was uncommon among children 5 years and younger. Until age 9, boys and girls are equally affected by RAP. After 9 years, girls are 1.5 times more likely to be affected, with the overall incidence peaking at 10–12 years (Reference 1). The incidence of IBS in children has not always been clearly determined. Now, however, with specific pediatric criteria for IBS, the children once classified as RAP can then be divided further into two groups. Functional abdominal pain accounts for 35% of patients with RAP, and IBS accounts for 65% of patients with RAP (Reference 4). About 6% of middle school and 14% of high school students report IBS-like symptoms. Even though in adults, IBS affects more women than men, in children boys and girls are affected equally (Reference 2).

### PATHOPHYSIOLOGY

The pathophysiology of IBS is poorly understood, although more theories are emerging. There is no single cause for IBS, but it is likely multifactorial. Irritable bowel syndrome is a biopsychosocial disorder with three primary mechanisms: altered motility, altered sensation of the intestine, and psychosocial factors. Most data on the pathophysiology of IBS are seen from studies of adults. The exact mechanism is unclear in most children who have no identifiable organic cause. Studies have suggested chronic stress, genetic factors, bacterial overgrowth, postinfectious, serotonergic disorders, and altered inflammatory response as potential causes.

Altered motility is described as a group of small bowel contractions causing abdominal pain with abnormal GI transit times. There is an increase in the frequency and irregularity of luminal contractions that can be prolonged in IBS. The intestinal transit time can be accelerated by increased contractions in patients with diarrhea-predominant IBS (IBS-D). In contrast, the transit time can be delayed with fewer high-amplitude contractions, as seen with constipation-predominant IBS (IBS-C) (Reference 5). Altered motility used to be thought to be the main contributor in IBS, but current evidence shows that visceral hypersensitivity plays a bigger role.

Children with IBS have an association with visceral hypersensitivity or altered sensation of the intestine. A distention of the lumen of the gut does not usually produce pain in control individuals but can cause pain in a

patient with IBS (Reference 6). Visceral hypersensitivity appears to be from an alteration in communication between the enteric nerves of the intestine and the gut bacteria and the central nervous system (Reference 7). Another term that has been used is *visceral hyperalgesia*. This is a heightened awareness of sensations that can be perceived as painful and not felt or even expressed as pain by other children. It has been recognized in children with IBS to have a higher association with rectal hyperalgesia. After rectal balloon distention, children with IBS perceived rectal pain at a lower threshold compared with other children. It is thought to develop from hyper-excitability neurons in the dorsal horn. This hypersensitivity of nerves in the gut is triggered by bowel distention and bloating (References 6, 8).

The psychosocial component in the pathophysiology of IBS can be an important factor. Some studies show a higher level of anxiety and depression in children with IBS compared with other children. It is often difficult to distinguish whether illness and pain-causing anxiety or anxiety and stress is the primary cause of IBS. Children who meet the criteria for IBS associate stressors with an increase in their abdominal pain (Reference 3). In addition, these children are less confident in their ability to deal with stress and less likely to use coping strategies. The psychological state of the mother is related to greater use of health care services for their children's abdominal pain. In children with RAP, an association was found with their mothers' history of anxiety and depression (References 9, 10). This may suggest a genetic component to IBS. Although no specific IBS gene has been identified, familial studies link positive family history as a predictor for IBS. A genetic predisposition to IBS in children is also observed, with an increased correlation of IBS with identical twins versus fraternal twins (References 11–14). It is unclear whether this relationship is caused by genetics or similar environmental factors.

Gut flora is also altered in patients with IBS compared with controls (Reference 15). The altered gut flora may develop after an enteric viral, bacterial, or parasitic infection (References 16–18). It can also be referred to as postinfectious IBS and may have an increased correlation in patients with a history of anxiety (Reference 19). In one study, 36% of children with a history of an acute bacterial gastroenteritis developed the abdominal pain symptoms seen with FGIDs. In this group, 87% of the children's symptoms met the criteria for IBS (Reference 20). Even after the infection has resolved, IBS symptoms can persist for many years (Reference 17).

Neurotransmitters such as cholecystokinin, substance P, and 5-hydroxytryptamine (serotonin), found in the brain and intestines, help regulate cortical centers with visceral afferent sensation and intestinal motor function. They can work on the areas of the brain

and GI system that have various effects on GI motility, emotions, and pain. Serotonin is a monoamine neurotransmitter found mainly in the GI tract. It plays an important role in gut signaling and function. Serotonin regulates GI motility, secretion, and intestinal sensation. After a meal, elevated levels of serotonin have been seen in patients with IBS-D, whereas decreased levels are seen in patients with IBS-C (References 21, 22).

Intestinal inflammation and possibly mast cells may also play a role in IBS (Reference 23). The mast cells are involved in normal immune function and release inflammatory mediators such as histamine and tryptase in response to antigen stimuli, especially in allergic diseases. Studies have found an increased number of mast cells in the GI tracts of patients with IBS. These mast cells have also been shown to be near sensory nerves, which can lead to the symptoms of abdominal pain and hypersensitivity seen with IBS (References 24–26). The role of inflammation in the etiology of IBS symptoms in children requires further study.

## CLINICAL PRESENTATION AND DIAGNOSIS OF IBS

Irritable bowel syndrome can be characterized as an FGID associated with altered bowel movements and pain (Reference 27). These alterations in bowel movements can occur with increased or decreased frequency. The pain, which is usually poorly defined, is characterized as periumbilical pain. It can last for less than 1 hour and can be unrelated to meals, activity, and stool patterns. Typically, children 3–10 years of age report “belly pain” as the most frequent location, whereas children 11–17 years of age most often report headaches in combination with abdominal and back pain (Reference 28). The diagnosis of IBS is usually symptom-based because of the lack of biochemical or physical markers. Therefore, a thorough history and physical examination are important and should include a nutritional assessment and inquiry into the psychosocial history of the child and family. Established criteria should be used in the diagnosis, while excluding organic disease (Box 1). Irritable bowel syndrome in children is usually not described before a certain age because of the inability of children to report symptoms. In general, it can be diagnosed in children 4–18 years of age.

The Committee on Childhood Gastrointestinal Disorders defines IBS as at least 12 consecutive or non-consecutive weeks in the past 12 months of abdominal pain with two of the following three features: (1) pain relieved with defecation, (2) onset associated with change in stool frequency, or (3) onset associated with change in stool appearance. The committee also include that there should be no structural or metabolic abnormalities to explain the symptoms (References 30, 31). The Manning and Rome criteria provide the standard

definitions for IBS in adults and children. The Manning criteria, introduced in 1978, includes abdominal pain relieved by defecation, more frequent stools or looser stools at the onset of pain, visible abdominal distention, passage of mucus, and sensation of incomplete evacuation. The Rome III criteria added the duration and frequency of the stools and symptoms (Table 1). In adults, the bowel patterns are then subdivided into three categories: IBS-D, IBS-C, or mixed IBS. Similar patterns are also recognized in children (References 30, 32–37) (Box 2; Table 2).

The American College of Gastroenterology (ACG) IBS Task Force recommends that, in the typical patient with IBS, routine diagnostic testing and colonoscopy not be done unless alarm symptoms are seen (Reference

38). Alarm symptoms can include the presence of blood in the stool, involuntary weight loss, decline in linear growth, significant vomiting, chronic severe diarrhea, persistent pain away from the umbilicus, unexplained fever, family history of inflammatory bowel disease, or abnormal physical examination findings (References 27, 36) (Box 3).

Typically, laboratory testing and other diagnostic testing in patients with IBS are normal. Even though they are not always done in patients with IBS, they can help exclude organic causes. A complete blood cell count with differential, C-reactive protein, and erythrocyte sedimentation rate can help confirm an infectious or inflammatory process. Stool studies are not typically done, but they can exclude bacterial, protozoan,

**Box 1.** Possible organic causes of abdominal pain.

- Constipation
- Carbohydrate malabsorption
- Pelvic inflammatory disease
- Gastroesophageal reflux disease (GERD)
- Gastrointestinal ulcers
- Lactose intolerance
- Parasitic infections
- Muscle and/or bone pain
- Urinary tract infection
- Inflammatory bowel disease (Crohn disease or ulcerative colitis)
- Menstruation
- Endometriosis

References 27, 29.

**Box 2.** IBS subtyping classifications.

Constipation-predominant IBS (IBS-C)

- ≥ 25% of bowel movements hard or lumpy stools (Bristol Stool Form Scale 1–2)
- ≤ 25% of bowel movements loose/mushy or watery stools (Bristol Stool Form Scale 6–7)

Diarrhea-predominant IBS (IBS-D)

- ≥ 25% of bowel movements loose/mushy or watery stools (Bristol Stool Form Scale 6–7)
- ≤ 25% of bowel movements hard or lumpy stools (Bristol Stool Form Scale 1–2)

Mixed IBS (IBS-M)

- ≥ 25% of bowel movements hard or lumpy stools (Bristol Stool Form Scale 1–2)
- ≥ 25% of bowel movements loose/mushy or watery stools (Bristol Stool Form Scale 6–7)

Reference 35.

IBS = irritable bowel syndrome.

**Table 1.** Manning and Rome III Criteria for IBS Diagnosis

Manning Criteria	Rome III Criteria <sup>a</sup>
Abdominal pain	Recurrent abdominal pain or discomfort <sup>b</sup>
<i>Plus two or more of the following:</i>	<i>Plus two or more of the following:</i>
Relieved by defecation	Improvement with defecation
More frequent stools at onset of pain	Onset associated with a change in frequency of stool
Looser stools at onset of pain	Onset associated with a change in form (appearance) of stool
Visible abdominal distention	
Passage of mucus	
Sensation of incomplete evacuation	

<sup>a</sup>Occurred at least 3 days/month in the past 3 months, with symptom onset at least 6 months before diagnosis.

<sup>b</sup>Discomfort means an uncomfortable sensation not described as pain.

IBS = irritable bowel syndrome.

References 32, 34.

**Table 2.** Bristol Stool Form Scale

Type	Description
1	Separate hard lumps, like nuts (hard to pass)
2	Sausage shaped but lumpy
3	Like a sausage but with cracks on its surface
4	Like a sausage or snake, smooth and soft
5	Soft blobs with clear-cut edges (passed easily)
6	Fluffy pieces with ragged edges, a mushy stool
7	Watery, no solid pieces, entirely liquid

Reference 37.

**Box 3.** Alarm symptoms.

Involuntary weight loss  
Decline in linear growth  
Presence of blood in stool  
Significant vomiting or diarrhea  
Persistent right upper or lower quadrant pain or tenderness  
Unexplained fever  
Family history of inflammatory bowel disease  
Localized fullness or mass effect  
Hepatomegaly or splenomegaly  
Tenderness over the spine  
Perianal abnormalities  
Abnormal or unexplained physical findings

References 27, 36.

or parasitic causes of abdominal pain, such as giardiasis. In addition, a complete metabolic panel that includes a liver function test and amylase or lipase can help exclude metabolic causes or pancreatitis. Depending on the clinical course, some patients will have a radiologic evaluation, such as abdominal ultrasonography or computed tomography (CT), or an upper GI series with small bowel follow-through to evaluate structure. Some patients may also require an endoscopy to further evaluate structure and to exclude organic disease.

**PROGNOSIS/MORTALITY/MORBIDITY**

Irritable bowel syndrome is not life threatening, does not progress to other diseases, and does not damage the bowel. However, IBS can cause discomfort and distress that affects a child's daily activities and quality of life. Long-term studies suggest that abdominal pain and GI upset persist into adulthood. Adults with

IBS recall having a history of childhood abdominal pain, with more physician visits and more school absences compared with other children. In addition, they report more headaches and more overall bowel symptoms (References 39–41). In a 12-year follow-up study, children with stomachaches who often used the school clinic were shown as adults also to use medical services frequently (Reference 42). The pain interferes with children's daily activities such as school, and often, the quality of life of these children is poor. They seem to have lower physical, emotional, social, and school functioning than other children and a quality of life similar to children with organic GI disease (References 4, 43).

**MANAGEMENT**

The management of IBS, which has many components, is dictated by illness severity, predominant symptoms, and patient preferences. It is important to have a positive patient and health care provider relationship. In a national survey of patients with IBS, the most desirable relationship provided a patient-centered focus; a source for information and questions, listening, and support; and hope (Reference 44). When the child's biopsychosocial and clinical needs are treated, parents report higher satisfaction rates with overall care and are more receptive to treatments (Reference 45). The primary treatment goals are to return to normal function with effective reassurance and to reduce or eliminate symptoms (Reference 27). Educating the family can play a vital role in the care of these patients. Parents need to understand that the symptoms cause pain that is not life threatening but that can interfere with the child's life. Parents should acknowledge the pain but encourage daily activities and school attendance (Reference 46).

**NONPHARMACOLOGIC MANAGEMENT**

Cognitive behavioral therapies, psychotherapy, hypnotherapy, and stress management can reduce the symptoms of IBS (Reference 38). Patients who understand their symptoms to be mainly psychological will benefit from cognitive behavioral therapies. For patients with increased anxiety or depression, these therapies seem less helpful (Reference 47). Many of these therapies affect the physical aspects of IBS as well as help give the child the ability to self-manage symptoms. The overall goals are to support families and help children identify psychological triggers, learn better independent coping and problem-solving skills, and change behavior. Cognitive behavioral therapies can include focusing on relaxation or distraction; keeping a diary of symptoms, triggers, and feelings; gradually facing avoided daily activities; and using positive and negative reinforcement (References 48, 49). The American Academy of

Pediatrics guidelines for chronic abdominal pain concluded that these therapies are useful in the short term for improving pain (Reference 27). Other studies have concluded that these approaches decrease pain in 70% to 90% of children and sometimes help reduce school absences and medication use. These studies used several interventions and involved the children in weekly therapy sessions ranging from 4 to 12 weeks (References 50–53).

## DIET

Dietary changes have been suggested in children with IBS because most patients with IBS believe that diet plays a role in their symptoms. A survey of adult patients with IBS showed that they believed they should avoid fatty foods, milk products, carbohydrates, caffeine, and high-protein foods. The patients also felt that their diet should include increasing their fiber intake and eating smaller meals. But the overall evidence for food avoidance remains unproven (References 54–56). Recommendations from the ACG IBS Task Force are not to exclude food from patients, except for purposes related to clinical trials. Patients with IBS have a higher prevalence of lactose intolerance. If the child's symptoms are consistent with those of lactose intolerance (e.g., cramping pain and bloating after milk and milk-containing foods), then eliminating lactose from the child's diet can be helpful. Children can avoid milk and milk products or use lactase enzyme replacements. Whether lactase avoidance can decrease the pain in children is unproven. A food diary is recommended to correlate foods with symptoms and to minimize dairy products at the onset or exacerbation of IBS symptoms (Reference 38). Avoiding other trigger foods (high fat or gas producing), drinks (caffeinated), and medications (nonsteroidal anti-inflammatory drugs) that can aggravate symptoms can be helpful for some patients. It may be beneficial to exclude gluten in patients with IBS-D who also have celiac disease markers, such as celiac disease-associated serum immunoglobulin G and *HLA-DQ2* allele expression. One study found that symptoms improved in 60% of patients with IBS-D with positive celiac serologies versus 12% in those with negative serologies (Reference 57).

Nutritional status should always be considered in children, especially with IBS-D. If oral intake is inadequate or if malabsorption occurs, enteral feedings or even parenteral nutrition may be considered, although it is not often needed. Sufficient calories should be provided to maintain growth and even allow catch-up weight gain. Micronutrient and vitamin supplementation should also be considered in patients with IBS, with a focus on zinc, vitamin A, folic acid, copper, and selenium (Reference 58).

## TREATMENT

### Constipation-Predominant IBS

#### *Fiber and Bulking Agents*

Although it is unproven, increasing fiber in a child's diet may improve symptoms, especially those with a constipation component. Fiber can help the stool hold onto water, promote gel formation to provide lubrication, provide bulking of the stool, and bind bile (Reference 59). Fiber can produce bowel movements that are more regular and decrease abdominal pain by softening the stool and increasing colonic transit. Fiber can be found in a well-balanced diet, including fruits and fruit juices, vegetables, and whole-grain cereals and breads. Children may also try high-fiber cookies or crackers, granola bars, or dried fruit. Fiber supplementation with soluble fiber, such as psyllium, is the first-line treatment in IBS-C. Fiber supplements are available in several forms, including powdered fiber that can be mixed in juice or made into popsicles, wafers, or chewable tablets. Fiber supplements are usually given two times/day and must be taken with a sufficient amount of water. Overall, the daily intake of water should be sufficient, with younger children drinking 2–4 glasses of water and older children drinking at least 6 glasses of water. To decrease the adverse effects of flatulence and bloating, supplementation should be a gradual process in which fiber intake is slowly increased and stool output and frequency are monitored. Supplements can improve global IBS symptoms and reduce symptom severity, but they do not improve quality of life (References 36, 60, 61) (Table 3). The additional fiber may exacerbate some symptoms in children; thus, supplements must be used with caution, especially in children who tend to withhold stools or who have chronic constipation. Fiber can increase stool bulk and cause greater distension of the rectum and colon.

#### *Laxatives*

Laxatives are commonly used to treat chronic constipation. However, whether using osmotic laxatives (e.g., polyethylene glycol [PEG], lactulose) or stimulant laxatives (e.g., bisacodyl, senna), their efficacy in IBS has not been shown. The goal of laxative therapy is to achieve one soft stool per day. This, together with behavior therapy, may take weeks, months, and sometimes years to achieve. A study of adolescents with IBS-C taking PEG alone or in combination with tegaserod showed an increase in stool frequency, but abdominal pain remained unchanged (Reference 34). In this study, the children were initially cleaned out with bisacodyl suppositories and then given PEG 17 g in 8 oz of fluid daily 1–2 hours before supper. Most laxatives seem equally efficacious, so choosing one may be based on

**Table 3.** Treatment Options for IBS-C and IBS-D

			Common Adverse Effects
<b>IBS-C</b>			
Fiber	Fruits, vegetables, whole grains Psyllium	Child's age plus 5–10 g/day Children 6–11 years: 1.25–15 g/day in two or three divided doses Children > 12 years: 2.5–30 g/day in two or three divided doses	Rectal distension Colonic distension
Laxatives			
Osmotic	Polyethylene glycol (PEG) (powder) Lactulose (syrup)	1 g/kg/day in two or three divided doses 1–3 mL/kg/day in two or three divided doses Max of 60 mL/day	Bloating Flatulence
Stimulants	Senna (syrup, granules, and tablets) Bisacodyl (tablets, suppositories)	2–6 years old: 2.5–7.5 mL/day in two divided doses 6–12 years old: 5–15 mL/day in two divided doses ≥ 2 years: 0.5–1 suppository or 5- to 10-mg tablet/dose	Abdominal cramping Discoloration of stool and urine Abdominal cramping
<b>IBS-D</b>			
Antidiarrheals	Loperamide	0.08–0.24 mg/kg/day in two or three divided doses (max of 2 mg/dose)	Abdominal distension Abdominal cramping Urinary retention

IBS-C = constipation-predominant irritable bowel syndrome; IBS-D = diarrhea-predominant irritable bowel syndrome. References 62–66.

the child's preference, cost, ease of administration, and effectiveness for the individual child. Laxative use may be limited by the adverse effects of bloating and flatulence with the osmotic laxatives and abdominal cramping with the stimulant laxatives. Stimulant laxatives are not recommended for prolonged use (Table 3).

### **Tegaserod**

Tegaserod, a selective partial agonist of the serotonin-4 receptor for serotonin, has been used in IBS-C in adults. By activating these receptors, tegaserod leads to increases in peristaltic activity and decreases in visceral hypersensitivity. In adolescents, it decreases the pain associated with IBS when used with a laxative. The global assessment scores for constipation, pain, and bloating were significantly improved without serious adverse effects (Reference 62). In 2007, tegaserod was removed from the market because of the cardiovascular risks reported in postmarketing surveillance. Currently, in the United States, tegaserod is only available under a U.S. Food and Drug Administration (FDA) emergency drug protocol for patients older than 55 years. It has been

argued that tegaserod would still be a valuable drug in children with IBS. Most adverse events were seen in adults with preexisting cardiovascular disease or risk factors. But because of the restrictions on the drug, its use in pediatric patients would warrant additional randomized controlled trials (References 62, 67).

### **Lubiprostone**

Lubiprostone is indicated for the treatment of IBS-C in women 18 years and older, but it is being evaluated in a phase IV trial of children and adolescents. The trial is an open-label study assessing the safety and efficacy of lubiprostone in functional constipation in children younger than 18 years and weighing at least 12 kg. Lubiprostone stimulates intestinal fluid secretion by serving as chloride channel activators and increasing intestinal motility. It helps facilitate the passage of stool and alleviate symptoms associated with constipation. Preliminary results showed a doubling of spontaneous bowel movements during a 4-week treatment of constipated children. Moreover, straining and pain were reduced, and stool consistency was improved. There was

also a reduction in the use of rescue medications (e.g., oral laxatives, suppositories, enemas). Lubiprostone has the potential to be a useful product for children with constipation symptoms, but again, further studies are required to confirm this (References 68, 69).

## Diarrhea-Predominant IBS

### *Antidiarrheal Agents*

Antidiarrheal agents such as loperamide improve stool characteristics. Loperamide is an opioid-receptor agonist that acts on receptors in the large intestine to slow colonic transit. Loperamide can also improve diarrhea by decreasing stool frequency and incontinence, but it has not been shown to effectively decrease IBS symptoms or abdominal pain (Reference 38) (Table 3).

## Abdominal Pain Associated with IBS

### *Antispasmodics*

Activation of cholinergic receptors in smooth muscle may be associated with abdominal pain in IBS. Pain may be caused by a smooth muscle spasm, and antispasmodics (e.g., hyoscyamine, dicyclomine, peppermint oil) are thought to be helpful. Hyoscyamine and dicyclomine have anticholinergic effects on the GI smooth muscle. In the adult population, there is consistent evidence for their use, but studies of pediatric patients with IBS are lacking. Hyoscyamine and dicyclomine have been used in children for short-term relief. However, caution should be used with prolonged use because they

can cause other anticholinergic adverse effects, such as urinary retention, constipation, tachycardia, and drowsiness. The active ingredient in peppermint oil, menthol, has calcium channel blockade properties that decrease smooth muscle spasms in the ileum and colon. A small randomized placebo-controlled trial of peppermint oil in 42 children with IBS was performed for 2 weeks. The study found that 76% of the children reported improvements in IBS symptoms with no changes in stool pattern or consistency. The ACG IBS Task Force recommends the use of any antispasmodic for short-term relief but states that long-term efficacy and safety have not been shown (References 38, 70).

### *Antidepressants*

Antidepressants have been used at low doses to improve sleep, improve bowel transit times, and decrease visceral hypersensitivity in children and adults. Through their anticholinergic effects, they are thought to reduce pain perception, improve sleep patterns, and modulate the GI tract (Table 4). Patients with comorbid depression or anxiety also show improvement. In 2004, the FDA issued a formal black box warning of antidepressant use in children and adolescents for increases in suicidal ideations and behavior. Further studies have shown no evidence of increased suicidal risk, but suicidal ideations did increase. Overall caution should be taken when prescribing antidepressants for children, together with a close monitoring of the adverse effects in the first few weeks of initiating the medication.

**Table 4.** Treatment Options for Abdominal Pain Associated with IBS

			Common Adverse Effects
Anti-spasmodics	Hyoscyamine (elixir, tablets)	2–12 years: 0.0625–0.125 mg per dose every 4 hours as needed (max 0.75 mg/day)	Constipation Dry mouth Urinary retention Tachycardia
	Dicyclomine (syrup, tablets)	5–10 mg per dose three or four times/day	
<b>Anti-depressants</b>			
Tricyclic	Amitriptyline (tablets)	< 35 kg: 10 mg at bedtime > 35 kg: 20 mg at bedtime	Sedation Weight gain
SSRIs	Citalopram (solution, tablets)	Initial 10 mg, second week 20 mg, if no improvement by fourth week, 40 mg; daily dosing	Sedation Agitation Nausea/vomiting Withdrawal symptoms with abrupt discontinuation

IBS = irritable bowel syndrome; SSRI = selective serotonin reuptake inhibitor.  
References 63, 71, 73, 74.

Tricyclic antidepressants (e.g., amitriptyline) and SSRIs (selective serotonin reuptake inhibitors) (e.g., citalopram) have been studied in children with IBS. Tricyclic antidepressants have been used in IBS-D because of their anticholinergic effects of causing constipation. In two pediatric randomized placebo-controlled trials, amitriptyline was given at 10 mg, 20 mg, or 30 mg (based on weight) for 4–8 weeks of therapy. Amitriptyline was seen to improve the overall quality of life from baseline and reduce anxiety scores in patients with IBS. Most of the patients reported feeling better but had inconsistent reports of improvement in pain, with no improvement in other IBS-related symptoms (References 71, 72).

Serotonin is an important neurotransmitter in the GI tract; SSRIs may be beneficial for IBS. More than 80% of the body's serotonin stores are found in the GI tract and are thought to regulate GI motility and visceral pain. Selective serotonin reuptake inhibitors have been used in IBS-C for their tendency to cause diarrhea, but well-controlled randomized pediatric trials are lacking. In a prospective, open-label study of children with functional RAP, citalopram was initiated at 10 mg/day and could be increased to 40 mg/day for 12 weeks. In 84% of the children, abdominal pain, anxiety, depression, and daily function improved (References 71, 73–75). Antidepressant use in children with IBS may only be beneficial in a few, particularly those with anxiety or other psychological states (Reference 36). Overall, the use of antidepressants in IBS may be promising, but their efficacy and safety must still be established in the pediatric population.

### *Anti-inflammatory Agents*

Because of the role of inflammation in IBS, anti-inflammatory agents have been studied in adults. Prednisolone, when used in a postinfectious IBS trial, did not prove helpful in the patients' symptoms (Reference 76). Another anti-inflammatory agent commonly used in inflammatory bowel disease, mesalamine, has been studied. Although it has not been shown to reduce abdominal pain and bowel habits, it causes inhibition of mast cells in the GI tract and improves overall IBS symptoms. Data are limited regarding the use and efficacy of anti-inflammatory agents in adults with IBS. Although no trials or data in pediatric IBS exist, this may be an area for study (Reference 77).

### *Probiotics*

Probiotics are live microorganisms that can provide beneficial health effects to the host. An imbalance of the normal gut flora has been linked to dysmotility and visceral hypersensitivity. Probiotics are thought to restore the bacteria balance in the gut by creating a better mucosal barrier in the intestine or changing the

inflammatory response of the intestines. Studies suggest that probiotics provide a moderate benefit in children by decreasing pain, but they do not appear to decrease the frequency of pain (References 78–80). Nor has the specific strain of probiotic been determined. Most studies use *Lactobacillus* strains, but inactive *Escherichia coli* bacteria have also been used with some success. With *E. coli* strains, patients seem to tolerate the probiotic without adverse events (intestinal flatus), and it reduces IBS symptoms. The consensus of physicians and parents is that the probiotic is beneficial. In this study, therapy duration for adults averaged about 40 days for all types of IBS (References 81, 82).

## MONITORING OF THERAPY

Overall monitoring of therapy in patients with IBS is related to their quality of life. Most of the treatments discussed should be tailored to the individual patient's symptoms. Dietary changes can be made to improve symptoms, but this should be done carefully to ensure the patient continues to obtain sufficient calories for growth. It is important that the child's growth parameters, such as height and weight, be monitored to ensure proper growth. The medications to treat IBS-C and IBS-D should be used to regulate stools to one soft stool per day. Patients should be monitored for any adverse effects of increasing abdominal distension or abdominal pain. Antidepressants are the other medication that should be closely followed, especially at the initiation of therapy. Patients should be monitored for suicidal ideations at the beginning of treatment and then for improvement in anxiety or depression. Again, with all the therapies for IBS, daily function and quality of life should improve.

## CONCLUSIONS

Irritable bowel syndrome in pediatric patients greatly affects quality of life, both for the patient and the family. It is associated with an increased health care and economic burden. The pathophysiology of IBS is poorly understood and likely multifactorial. Emerging theories are leading to better treatments. Finding the optimal treatment for patients with IBS can sometimes be challenging, especially given the complexity of the disease. Overall, treatment for IBS must be patient-centered and individualized to each patient's perception of pain and symptoms.

# CHAPTER 19

## FLUIDS AND ELECTROLYTES

Weng Man Lam, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. Describe the composition of body fluids, electrolytes, and regulation of osmolality in the human body.
2. Demonstrate an understanding of fluid and electrolyte maintenance requirements in pediatrics.
3. Identify clinical signs and symptoms of the various stages of dehydration.
4. Describe clinical manifestations and medical management for hyponatremic, isonatremic, and hypernatremic dehydration in pediatrics.
5. Design an individualized treatment plan for hyponatremic, isonatremic, and hypernatremic dehydration based on specific characteristics of the patient and the degree of dehydration.

### ABBREVIATIONS IN THIS CHAPTER

ADH	Antidiuretic hormone
ECF	Extracellular fluid
ICF	Intracellular fluid
ORT	Oral rehydration therapy
SIADH	Syndrome of inappropriate antidiuretic hormone secretion
TBW	Total body water

### INTRODUCTION

#### Composition of Body Fluids

In the human body, water is the largest compartment compared with the other nutritional components including protein, fat, and carbohydrate. As humans age, total body water (TBW) as a percentage of body weight slowly decreases as described in Figure 1 (see Pediatric Pharmacokinetics chapter). The fetus has the highest TBW content, which gradually decreases to about 75% for a full-term infant. During the first year of life, the TBW will decrease to about 60% and remain steady at this percentage until puberty. In general, the TBW is 60% in men and 50% in women (Reference 1). This discrepancy occurs because, during puberty, a female's fat content increases more than that of men, and men tend to have more muscle mass than women. This affects the TBW of men and women because the fat content has a lower water content, and the muscle content has a higher water content (Reference 2).

Water is distributed between two main compartments: intracellular fluid (ICF) and extracellular fluid (ECF). In the adult, the ICF is composed of two-thirds of the TBW, and the ECF is one-third of the TBW, which is further divided into three-fourths interstitial fluid and one-fourth plasma (Reference 1). The fetus and newborn infant's ECF volume is larger than the ICF volume, but it decreases with age. By 1 year of age, the ratio of ECF and ICF approaches the adult level because of the postnatal diuresis at birth and the continued expansion of the ICF compartment caused by cellular growth (References 2–4). The interstitial fluid, which is about 15% of the body weight, will increase in the presence of pathologic conditions such as heart failure, liver failure, nephrotic syndrome, and hypoalbuminemia (Reference 2). The plasma is about 5% of the total body weight. It is estimated that the plasma in neonates is 85–100 mL/kg compared with 60–70 mL/kg of body weight in adolescents and adults (Reference 3). The plasma volume can be affected by different pathologic conditions including dehydration, anemia, polycythemia, heart failure, abnormal plasma osmolality, and hypoalbuminemia.

Figure 1. Total body water, intracellular fluid, and extracellular fluid as a percentage of body weight and a function of age. Used with permission from Winters RW. Water and electrolyte regulation. In: Winters RW, ed. The Body Fluids in Pediatrics. Boston: Little, Brown, 1973.

## Electrolyte Composition

The composition of solutes is different in the ICF versus the ECF. In the ICF, potassium is the predominant cation, and phosphate is the predominant anion (Reference 1). The activity of the Na, K-ATPase pump (sodium pump) in plasma membranes is responsible for the low-sodium and high-potassium intracellular concentrations. In the ECF (plasma and interstitial fluid), sodium and chloride are the dominant cations and anions, respectively. Sodium excretion, which can affect the ECF volume, occurs mainly through urine, sweat, and feces. The intake and output of chloride usually parallels that of sodium, and the kidney plays a major role in regulating the reabsorption of filtered chloride. Table 1 describes the approximate electrolyte composition of ECF and ICF.

**Table 1.** Approximate Electrolyte Composition of the ECF and ICF

	ECF (mEq/L)	ICF (mEq/L)
Na <sup>+</sup>	135–145	10–20
K <sup>+</sup>	3.5–5	120–150
Cl <sup>-</sup>	95–105	0–3
HCO <sub>3</sub> <sup>-</sup>	22–30	10
Phosphate	2	110–120

ECF = extracellular fluid; ICF = intracellular fluid. Information from reference 1.

## Regulation of Osmolality

Osmolality represents the number of osmoles (solute) per kilogram (Osm/kg). The solution of higher osmolality represents more solute and less water per unit volume. However, solutions of lower osmolality have less solute and more water. Water is the primary factor in maintaining osmotic balance because it moves freely across the cell membrane between the ECF and ICF. If there is any disturbance affecting the osmolality balance between the body fluid compartments, water will respond to changes in the osmotic shifts (References 2, 3). For example, in a child with a diagnosis of diabetic ketoacidosis, the high blood glucose present in the body causes an increase in the osmolality of the ECF. This results in a shift in water from the ICF to the ECF to maintain the osmotic equilibrium.

Normal serum osmolality is about 285–295 mOsm/kg. Plasma osmolality is calculated by the following formula, where BUN is blood urea nitrogen:

$$\text{Serum osmolality: } 2 \left[ \text{Na} + \frac{\text{glucose in mg/dL}}{18} + \frac{\text{BUN in mg/dL}}{2.8} \right]$$

Antidiuretic hormone (ADH) plays a significant role in plasma osmolality, with responses detectable with as little as a 1% change in osmolality (Reference 2). Osmoreceptors in the hypothalamus sense changes in plasma osmolality. An increase in osmolality leads to the secretion of ADH. The circulating ADH binds to V2 receptors in the collecting duct cells of the kidney, causing an insertion of water channels (aquaporins-2) into the renal collecting ducts. Thus, ADH increases the permeability of water for reabsorption, resulting in an increase in urine concentration and a decrease in water excretion. Therefore, urine osmolality acts as an important tool in assessing water homeostasis. Urine osmolality, excluding that in neonates, ranges from 50 to 1,200 mOsm/kg (Reference 1). The high value indicates maximally concentrated urine, and the low value indicates very dilute urine. In a dehydrated patient with normal kidney function, a small volume of highly concentrated urine will be produced because the body is trying to retain water; therefore, the urine osmolality has a high value.

## FLUID AND ELECTROLYTE MAINTENANCE REQUIREMENTS

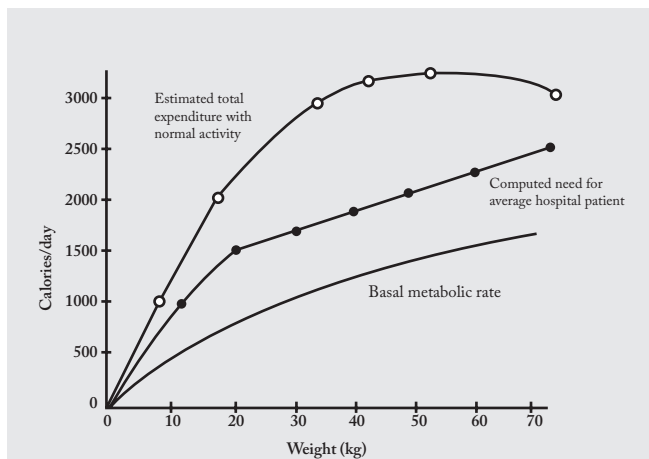

Maintenance fluid and electrolytes are required because of normal losses from body basal metabolism. In general, body basal metabolism is divided into two by-products, solute and heat, that are eliminated to maintain homeostasis (References 5, 6). Soluble waste by-products from metabolism are excreted in the urine, which is also known as urinary water loss (References 6, 7). Heat is described as an “insensible water loss” and is a function of basal energy expenditure (Reference 7). Examples of insensible water losses include the evaporation of water from the skin surface, the elimination of warmed water vapor from the upper respiratory tract during exhalation, and sweating.

In a 1957 study, the caloric requirements of a child were estimated to allow a determination of maintenance fluid requirements using weight alone. A comparison of energy expenditure from the basal metabolic rate and the normal activity state is described in Figure 2. The lower line defines the basal metabolic rate at various weights, and the upper line defines the estimated total expenditure with normal activity for various weights (Reference 7). The middle line expresses the calculated energy expenditure for the average hospitalized patient at bed rest. The graph shows that, compared with body weight, the metabolic rate is higher (on a calorie per kilogram basis) in the newborn period compared with adulthood. Furthermore, this shows that the metabolic rate per unit of body weight declines with increasing age. Adolescents and adults generate less heat and solute from basal metabolism than children and infants; therefore, they need less fluid and electrolytes per unit

of body weight. Likewise, children generate less heat and solute from basal metabolism than infants or neonates and therefore require less fluid and electrolytes per unit of body weight (Reference 6).

These principles dictate how fluid requirements are calculated. Several methods (surface area method, basal calorie method, Holliday-Segar method) have been proposed to correlate maintenance requirements to body weight. All three of these methods work when used appropriately; however, the Holliday-Segar method is commonly used because the formula is easy to apply and remember. The surface area method requires an equation or table to determine the patient's body surface area, as well as the patient's height and weight. The basal calorie method requires a table and information such as weight, height, age, and activity level. This method also involves the most calculations compared with the other two methods (Reference 6).

Therefore, the Holliday-Segar method is commonly used to calculate the 24-hour maintenance fluid requirements in children (Table 2). In general, infants become

**Figure 2.** The comparison of energy expenditure in basal and ideal states.

Used with permission from Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics* 1957;19:823–32.

dehydrated faster than older patients (adolescents); infants therefore have a higher maintenance fluid requirement on a milliliter per kilogram basis. For example, an adolescent can tolerate 12–18 hours without any oral intake when preparing for a surgical procedure, but an infant requires intravenous maintenance fluids within 4–6 hours after the last feeding for a morning surgical procedure to avoid developing dehydration. It is very important to recognize the patient populations in need of maintenance fluids versus those who can tolerate an extended period without any fluids (Reference 2).

A premature neonate and a newborn are more susceptible to insensible losses than are infants. A premature neonate has about 5 times more body surface area in relation to weight (and a newborn 3 times more), resulting in a higher fluid loss (Reference 4). Moreover, it is also important to realize that extremely low-birth-weight neonates and very low-birth-weight neonates require more fluids than a term neonate or infant. For fluid intake, neonates weighing less than 1500 g require 140–190 mL/kg of body weight per day, and neonates weighing more than 1500 g require 140–160 mL/kg body weight per day (Reference 8). Once the neonate's weight reaches 3 kg, the Holliday-Segar method is preferred.

The goal of providing maintenance fluids is to prevent dehydration, electrolyte disorders, ketoacidosis, and protein degradation. Maintenance fluids typically consist of water, glucose, sodium, and potassium. Each component of maintenance fluid plays a role in replacing the fluid and electrolyte losses needed by an average individual with normal ICF and ECF volumes over a 24-hour period (Reference 5).

Maintenance water is designed to provide enough water that the kidney does not need to dilute or concentrate the urine to maintain the fluid balance in the body (Reference 2). The amount of glucose administered to the patient is only sufficient to prevent ketoacidosis and protein degradation. The electrolytes (sodium, potassium, chloride) are present in the maintenance fluid to replace normal losses from urine and stool. For most patients, a few days without any other electrolyte supplements like calcium, phosphorous, magnesium, or bicarbonate is not problematic; therefore, they are not routinely added to the maintenance fluid therapy. The

**Table 2.** Holliday-Segar Method

Weight (kg)	24-Hour Maintenance Water Requirement for Infants, Children, and Adolescents	Maintenance Water Rate
≤ 10	100 mL/kg	4 mL/kg/hour
11–20	1,000 mL + 50 mL/kg for each kg > 10 kg	40 mL/hour + 2 mL/kg/hour × (wt – 10 kg)
> 20	1,500 mL + 20 mL/kg for each kg > 20 kg	60 mL/hour + 1 mL/kg/hour × (wt – 20 kg)

wt = weight.

Information from reference 7.

daily maintenance requirement for sodium is 2–3 mEq/kg/24 hours, potassium is 1–3 mEq/kg/24 hours, and chloride is 2 mEq/kg/24 hours in children (References 2, 9). Potassium is not required for patients with acute and chronic renal failure or in conditions in which potassium retention is present.

Maintenance fluids do not provide adequate calories, protein, fat, minerals, or vitamins for normal consumption in children. However, it is not problematic for a patient to receive maintenance fluids, without additional calories or nutrition, for a few days. Nevertheless, it is important to monitor the patient's weight while on maintenance fluid therapy because he or she may lose 0.5% to 1% of weight each day while on this therapy alone (Reference 2).

Intravenous fluids safe to administer parenterally on the basis of their osmolality are shown in Table 3. The solution is selected on the basis of the clinical status of the patient. In general, hypotonic fluids offer an adequate amount of water and electrolytes to match the maintenance requirements in children. The most hypotonic (lowest osmolality) intravenous solution that can be safely used is 0.45% isotonic sodium chloride (osmolality = 154 mOsm/L) (Reference 1). Any solution with an osmolality less than 154 mOsm/L is not recommended because cell lysing causes the release of potassium to the extracellular space, resulting in hyperkalemia and potentially cardiac arrhythmias and death (Reference 1). Solutions without dextrose (example: 0.45% sodium chloride solution with electrolytes) are administered to patients presenting with diabetic ketoacidosis. For patients who are taking nothing by mouth or who are pre- or post surgery, the common fluid used is 5% dextrose in 0.2% to 0.45% sodium chloride with or without potassium chloride (KCl). Neonates are a little different from children because they tend to have a

difficult time excreting sodium. Therefore, fluids such as 5% or 10% dextrose in water are used to deliver isotonic fluids without an excessive sodium load while delivering the maintenance water requirements.

## DEHYDRATION

### Introduction

Dehydration is a physiologic disturbance caused by the reduction or translocation of body fluids, and if severe, it can be considered a type of hypovolemic shock (Reference 10). Dehydration is one of the leading causes of morbidity and mortality in children throughout the world. Infants have the highest morbidity and mortality from dehydration because they have a larger water content, a higher metabolic turnover rate of water, renal immaturity, and an inability to independently meet their own needs. In the early process of dehydration, most of the water loss is from the ECF.

In the United States, the main cause of dehydration in children is diarrhea. Other causes of dehydration are gastroenteritis, febrile illness, stomatitis, diabetic ketoacidosis, heat prostration, and burns over 25% of the total body surface area (Reference 10). In many cases, dehydration can be managed with an oral rehydration solution, to be discussed in the following section. In more severe cases, intravenous therapy is required, especially when the patient cannot tolerate oral intake or is in hypovolemic shock (References 10–12).

### Clinical Evaluation of Dehydration and Severity of Dehydration

The first step in managing a child with dehydration is to assess the severity of dehydration. Dehydration is classified as mild, moderate, and severe on the basis of the percentage of body weight loss (Table 4). This estimation is calculated as a percentage of the total amount of

**Table 3.** Intravenous Fluid Comparison

Solution	Osmolality (mOsm/L)	Sodium (mEq/L)	Chloride (mEq/L)	Dextrose (mOsm/L)
Lactated Ringer's solution	273	130	109	None
0.9% isotonic NaCl (normal saline)	308	154	154	None
0.45% NaCl	154	77	77	None
5% dextrose in water	252	None	None	278
5% dextrose + 0.33% NaCl	378	50	50	278
5% dextrose + 0.225% NaCl	329	38.5	38.5	278
5% dextrose + 0.45% NaCl	432	77	77	278

Information modified from reference 1.  
NaCl = sodium chloride.

body weight loss based on pre-illness weight and current (illness) weight (see algorithm in Figure 3). Because infants have a higher percentage of body weight as water, the total percentages of body weight loss are higher compared with those of older children in moderate and severe dehydration (Reference 5). The history provided by the parents or caregivers is also beneficial because it may help describe the child's fluid loss and its origin (examples in Box 1) (Reference 10).

### Physical Examination and Laboratory Assessment

Vital signs will help evaluate the severity of dehydration. The first vital sign change in mild dehydration is tachycardia. The respiratory rate of a patient with mild to moderate dehydration is generally normal. As the severity of dehydration worsens, the respiratory rate may increase. Severe hypotension is a sign of severe dehydration.

The skin is also a reliable organ to assess for signs of peripheral perfusion. Assessment of skin temperature, turgor, and capillary refill is useful in dehydration. For example, cool peripheral extremities are an early sign of poor perfusion, meaning there is inadequate blood flow to the peripheral part of the body. Skin turgor is measured by pinching the skin into folds (tenting) and then promptly releasing it. If there is a delay in the return of skin to its original state, then there is a decrease in skin elasticity caused by water loss. Capillary refill time is defined as the amount of time needed for

vascular reperfusion after blanching pressure is applied to the nail bed (References 13, 14). If there is a delay of 2–3 seconds, moderate dehydration is indicated. However, if the capillary refill time is greater than 3 seconds, severe fluid loss and impending shock could be indicated (Reference 10).

A serum electrolyte panel may not be as helpful in predicting the degree of dehydration. Patients presenting with altered mental status, moderate to severe dehydration, or clinical signs of hypokalemia or hypernatremia or infants younger than 6 months warrant obtaining an electrolyte panel (References 12, 15). The serum sodium concentration determines the type of dehydration: hypernatremic dehydration, isonatremic dehydration, or hyponatremic dehydration. The measurement of blood urea nitrogen (BUN) or serum urea concentration is usually a marker of prerenal uremia and dehydration. Studies have shown a trend for urea concentration to increase with the degree of dehydration (References 16–20). Normally, the BUN/serum creatinine ratio is 10:15 to 1; therefore, an elevated BUN/serum creatinine ratio may imply that the patient is dehydrated.

### MANAGEMENT OF DEHYDRATION

The severity of dehydration dictates the urgency of the situation (e.g., whether oral or intravenous therapy is required) and the volume of fluid needed to replace the loss. For a patient who can tolerate oral intake, oral rehydration therapy (ORT) is recommended.

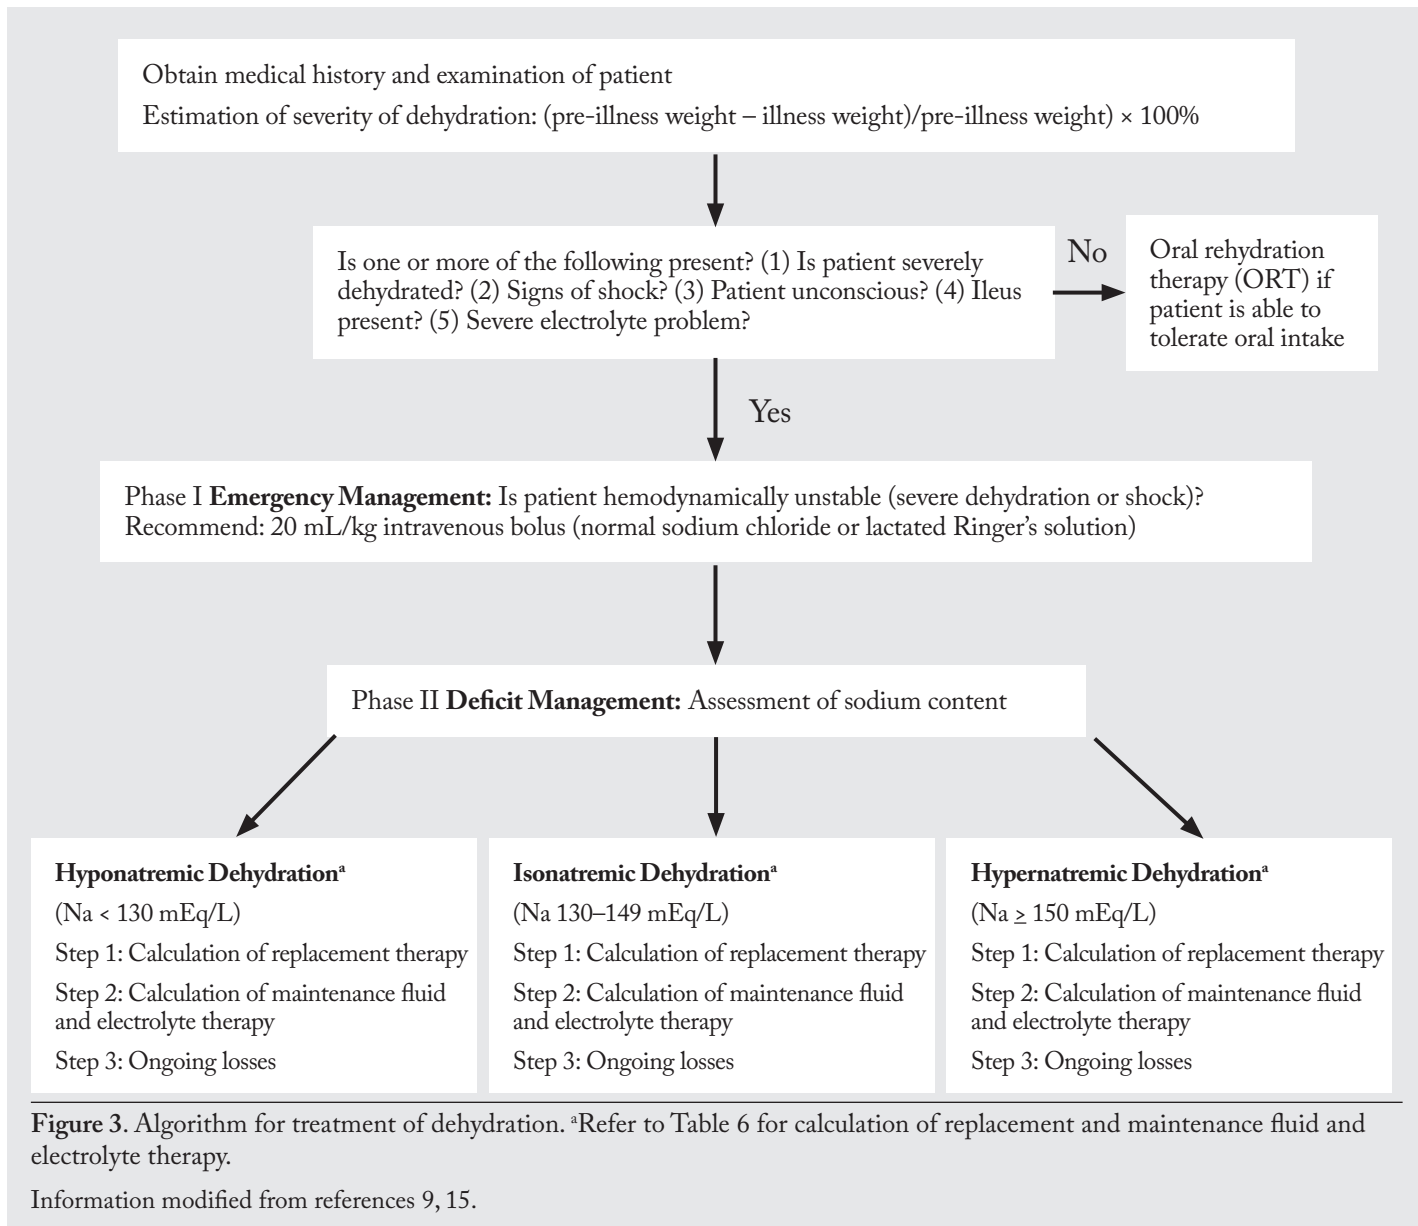

**Table 4.** Signs and Symptoms Related to Severity of Dehydration

	Mild	Moderate	Severe
<b>Infants</b>	1% to 5% <sup>a</sup>	6% to 9% <sup>a</sup>	> 10% (≥ 15% = shock) <sup>a</sup>
<b>Older Children</b>	1% to 3% <sup>a</sup>	4% to 6% <sup>a</sup>	> 6% (≥ 9% = shock) <sup>a</sup>
Pulse	Normal, increased	Tachycardia	Rapid and weak pulse
Systolic blood pressure	Normal	Normal, low	Decreased, very low
Urine output	Decreased	Little or low UOP < 1 mL/kg/hour	Oliguria << 1 mL/kg/hour
Buccal mucosa	Slightly dry	Dry	Parched
Ant fontanelle	Normal	Sunken	Very sunken
Eyes	Normal	Sunken	Very sunken
Skin turgor/capillary refill	Normal	Delayed Cool and pale	Very delayed Cool and mottled
Skin (infants < 12 months of age)	Normal	Cool	Acrocyanosis
Tears	Normal	Decreased	No tears
Mental status	Normal	Normal to listless	Normal to lethargic or comatose
Thirst	Drinks normally; might refuse liquids	Thirsty; eager to drink	Drinks poorly; unable to drink

<sup>a</sup>The percentage is the amount of body weight loss based on the pre-illness weight and the current (illness) weight.

UOP = urinary output.

### Oral Rehydration Therapy

Oral rehydration therapy is the preferred treatment of fluid and electrolyte losses caused by diarrhea in children with mild and moderate dehydration. Several studies have shown the safety and efficacy of ORT. In addition, ORT has several potential advantages over intravenous therapy. Oral replacement therapy is less expensive, more convenient, and less traumatic to the child, and it can be given in a variety of settings such as in a physician's office, in an emergency department, or at home. The ORT solutions have successfully rehydrated more than 90% of dehydrated children and have lower complication rates than intravenous therapy (References 21, 22). In studies comparing ORT with intravenous therapy, the frequency of stools, duration of diarrhea, and rate of weight gain are similar (References 15, 22–30).

All the commercially available rehydration fluids (e.g., Pedialyte) are acceptable for ORT. They contain 2–3 g/dL of glucose; 45–90 mEq/L sodium; 30 mEq/L lactate, citrate, or acetate; and 20–25 mEq/L of potassium (Reference 9). The list of commonly used oral rehydration fluids and their composition can be found in the Constipation and Diarrhea chapter. Rehydration with solutions such as apple juice, ginger ale, sodas, sports drinks, milk, and chicken broth is discouraged because they contain low electrolyte concentrations and high carbohydrate content, and they are hypertonic (osmolality ranges from 260 to 700 mOsm/L) (References 15, 29). The high carbohydrate content may worsen diarrhea. In addition, the sodium content is generally too low, which is an important electrolyte that is lost during diarrhea and vomiting.

**Box 1.** Examples of information obtained from parent or caregiver.

Volume, type, and frequency of the fluid intake  
Amount of urine output  
Frequency of stool output and stool consistency  
Frequency and volume of emesis

Presence of fever  
Presence of sweating  
Hyperventilation  
Changes in diet<sup>a</sup>  
Infant formula

Information modified from reference 10.

<sup>a</sup>Diluted juices or water can be associated with hyponatremic dehydration, and excess salt intake or low liquid intake can be associated with hypernatremic dehydration.

Correction of mild dehydration includes giving 50 mL of ORT per kilogram plus replacement of any continuing losses during a 4-hour period. The continuing losses from stools and emesis can be accomplished by giving 10 mL of ORT per kilogram for every stool or emesis. The patient is evaluated every 2 hours for his or her progress with ORT and his or her hydration status. As soon as the patient is rehydrated, breastfeeding, formula, milk, or other recommended foods should be resumed, as should continued replacement of ongoing losses with an appropriate ORT solution (Reference 15).

For moderate dehydration, it is recommended to administer 100 mL of ORT per kilogram and to replace continuing losses during a 4-hour period. The hydration status of the patient is assessed on an hourly basis and is best accomplished in a supervised setting such as the emergency department, urgent care facility, or physician's office. Once rehydration is completed, feeding should be resumed as previously described. Controversy still lies in determining which foods are best for refeeding children. Certain foods, including complex carbohydrates (rice, wheat, potatoes, bread, and cereals), lean meats, yogurt, fruits, and vegetables, have been shown to be better tolerated in children (Reference 15).

## Intravenous Therapy

The management of moderate to severe dehydration in children requires acute intervention to ensure adequate tissue perfusion. The care plan for correcting a child's dehydration requires monitoring the patient's clinical status such as vital signs during treatment, modifying the therapy as needed given the clinical situation, and assessing the electrolytes often. All children who are severely dehydrated and in a state of shock or near shock, as well as those who have severe electrolyte abnormalities, require intravenous fluid therapy. Children who are moderately dehydrated and unable to retain oral liquids because of persistent vomiting should receive intravenous therapy. In addition, intravenous therapy should be given to children who are unconscious, have an ileus, or have severe electrolyte abnormalities (References 9, 15).

Intravenous replacement therapy is generally divided into two phases: phase I emergency management and phase II deficit management, which includes a combination of deficit replacement, maintenance therapy, and ongoing losses. The overall goals of therapy are (1) restoration of skin turgor and weight, (2) recovery of alertness, (3) tolerance of oral intake of food, and (4) correction of serum chemistry levels (Reference 5). Figure 3 provides an algorithm for the treatment of dehydration. The serum sodium concentration determines the type of dehydration: hypernatremic dehydration (serum sodium 150 mEq/L or greater), isotatremic dehydration (serum sodium between 130 mEq/L and 149 mEq/L), and hyponatremic dehydration (serum sodium less than 130 mEq/L).

### *Phase I – Emergency Management*

Volume depletion reduces the blood volume needed to adequately perfuse tissues. If not treated in a timely manner, organ damage may occur. With persistent hypovolemia, shock and death may result. For a hemodynamically unstable patient (severe dehydration or shock), one or more boluses of intravenous fluids are recommended. A common recommendation is to give 20 mL/kg of 0.9% sodium chloride or lactated Ringer's solution in the first 30 minutes. If the patient continues to be unstable after a few boluses, 40 mL/kg may be required as a bolus (Reference 9). The main goals for the correction phase are to ensure a return of adequate intravascular volume and to avoid tissue damage.

### *Phase II – Deficit Management*

Intravenous rehydration therapy is indicated for phase II deficit management. Selecting the appropriate intravenous therapy (focusing on the sodium content of the fluid) depends on the patient's serum sodium. Patients may present with hyponatremia, isotatremia, or hypernatremia. Steps for calculating the deficit replacement

therapy and maintenance therapy of fluids and electrolytes are outlined in the discussion of specific types of dehydration (refer to the following sections of the chapter). In general, deficit replacement therapy replaces any current existing water and electrolyte deficits (i.e., sodium and water deficits). The calculated maintenance therapy volume also accounts for expected ongoing losses of water and electrolytes from a normal physiologic process.

Replacement therapy is also designed to replace any abnormal ongoing fluid and electrolyte losses. Measuring or estimating the electrolyte content of these losses and replacing them is preferred. Examples of measured losses include continued diarrhea or vomiting and aspirates from a nasogastric tube attached to suction. Other examples of estimated losses from various body fluids include gastric, pancreatic, small bowel, and bile fluids. The electrolyte composition of various body fluids is listed in Table 5 (Reference 6). Table 6 details the calculations necessary to determine the amount and type of fluids in the treatment of moderate to severe dehydration.

**Table 5.** Electrolyte Composition of Various Body Fluids

Fluid	Sodium (mEq/L)	Potassium (mEq/L)	Chloride (mEq/L)
Gastric	20–80	5–20	100–150
Pancreatic	120–140	5–15	90–120
Small bowel	100–140	5–15	90–130
Bile	120–140	5–15	80–120
Ileostomy	45–135	3–15	20–115
Diarrhea	10–90	10–80	10–110
Burns	140	5	110
Sweat	10–30	3–10	10–35

Information modified from references 9, 31.

## DISORDERS OF SODIUM HOMEOSTASIS

### Hyponatremia

Hyponatremia is defined as a serum sodium concentration less than 130 mEq/L. The pathogenesis of hyponatremia is usually a combination of sodium loss and water retention to compensate for volume depletion. The body's primary defense against developing hyponatremia is the kidney's ability to dilute the urine and excrete free water (Reference 6). It is important to determine the patient's volume status: euvolesmia, hypovolemia, or hypervolemia. This will help distinguish between hyponatremia caused by low sodium and hyponatremia caused by an increase in TBW, resulting in a relative dilution of the ECF compartment (Reference 31). Hyponatremia can also be linked to renal or nonrenal causes. If the kidney

is working properly, normal renal retention of sodium occurs. Thus, the urinary sodium concentration will be low (less than 10 mEq/L). However, if the kidney is the cause of sodium loss, the urine will have a sodium concentration greater than 20 mEq/L. This reflects a defect in renal sodium retention by the kidney to maintain normal homeostasis. Therefore, assessing the renal function of the patient also may play a role in the management of hyponatremia (Reference 2). Causes of hyponatremia in children are listed in Table 7.

Hypovolemic hyponatremia usually occurs in three clinical situations: a net loss of sodium in excess of water, inadequate sodium intake, and movement of sodium into cells (Reference 31). Two common causes of hypovolemic hyponatremia are acute gastroenteritis and administration of loop diuretics (furosemide, bumetanide). Patients with acute gastroenteritis experience diarrhea, which may lead to intravascular volume depletion. To compensate for the loss of water, ADH and arginine vasopressin are released. Antidiuretic hormone enhances water reabsorption in the proximal tubule, resulting in renal water retention in the collecting duct. Arginine vasopressin acts on the kidney through the V2 receptors, which leads to the reabsorption of water by the collecting ducts of the kidney, thus decreasing urine formation (Reference 1). Arginine vasopressin also binds to V1 receptors on vascular smooth muscle to cause vasoconstriction and release of prostaglandin, which results in an increase in arterial pressure. Furthermore, ADH plays a central role in thirst control, which drives the patient to consume water to replace any losses (Reference 2).

Loop diuretics (furosemide, bumetanide) cause hypovolemic hyponatremia by inhibiting the Na<sup>+</sup>/K<sup>+</sup>/Cl<sup>-</sup> (sodium/potassium/chloride) cotransporter of the luminal membrane in the ascending limb of the loop of Henle, resulting in a decreased reabsorption of sodium, potassium, and chloride ions. Because the use of diuretics affects the reabsorption of sodium ions, hyponatremia will result.

Euvolemic hyponatremia commonly occurs in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Common etiologies include renal, adrenal, or thyroid insufficiency, congestive heart failure, nephrotic syndrome, or medication use such as diuretics (Reference 32). In SIADH, the secretion of ADH is inhibited by neither low-sodium osmolality nor expanded intravascular volume. As a result, children with SIADH are unable to excrete water, which causes a dilution of serum sodium and hyponatremia. Retained water causes an expansion of extracellular volume, resulting in the kidney's increase in sodium excretion in an effort to decrease the intravascular volume to normal. In this clinical situation, the patient

**Table 6.** Treatment Summary for Dehydration

	Hyponatremic Dehydration ( $< 130$ mEq/L)	Isonatremic Dehydration ( $130$ – $149$ mEq/L)	Hypernatremic Dehydration ( $\geq 150$ mEq/L)
<b>Step 1:</b> Calculation of the replacement therapy			
Fluid deficit	Fluid deficit (L) = % dehydration $\times$ weight (kg)	Fluid deficit (L) = % dehydration $\times$ weight (kg)	TFD = % dehydration $\times$ weight (kg) SFD = TFD – FWD
Free water deficit <sup>a</sup>	Not applicable	Not applicable	FWD = $4$ mL $\times$ (actual sodium – desired sodium mEq/L) $\times$ body weight (kg)
Sodium deficit <sup>b</sup>	Fluid deficit (L) $\times 0.6$ (L/kg) $\times$ normal serum sodium concentration ( $140$ mEq/L)	Fluid deficit (L) $\times 0.6$ (L/kg) $\times$ normal serum sodium concentration ( $135$ mEq/L)	SFD (L) $\times 0.6$ (L/kg) $\times$ normal serum sodium concentration ( $140$ mEq/L)
Excess sodium deficit	(Desired serum sodium [ $135$ mEq/L] – actual serum sodium) $\times 0.6$ (L/kg) $\times$ body weight (kg)	Not applicable	Not applicable
Potassium deficit <sup>c</sup>	Fluid deficit (L) $\times 0.4$ (L/kg) $\times 120$ mEq/L	Fluid deficit (L) $\times 0.4$ (L/kg) $\times 120$ mEq/L	SFD (L) $\times 0.4$ (L/kg) $\times 120$ mEq/L
<b>Step 2:</b> Calculation of maintenance fluid and electrolyte therapy			
Holliday-Segar method (Table 2)			
<b>Step 3:</b> Ongoing losses: Refer to Table 5 for the electrolyte composition of various body fluids.			

FWD = Free water deficit; SFD = Solute fluid deficit; TFD = Total fluid deficit.

<sup>a</sup>Pure water deficit is part of the TFD.

<sup>b</sup> $0.6$  L/kg means sodium distribution factor as fraction of body weight.

<sup>c</sup> $0.4$  L/kg means potassium distribution factor as fraction of body weight;  $120$  mEq/L is the normal value of intracellular potassium concentration.

Information from references 1,2, 9.

**Table 7.** Causes of Hypernatremia and Hyponatremia

Hypernatremia	Hyponatremia
Improperly mixed formula	Hyperglycemia
Excess sodium bicarbonate	Mannitol
Ingestion of seawater or sodium chloride	Gastrointestinal (emesis, diarrhea)
Intentional salt poisoning	Skin (sweating or burns)
Intravenous hypertonic sodium chloride	Third space losses
Hyperaldosteronism	Urinary tract obstruction and/or urinary tract infection
Nephrogenic diabetes	Thiazide or loop diuretics
Central diabetes insipidus	Cerebral salt wasting
Increased sensible losses	Diluted formula
Diarrhea	Syndrome of inappropriate antidiuretic hormone
Emesis/nasogastric suction	Hypothyroidism
Burns	Water intoxication
Excessive sweating	Nephrotic syndrome
Osmotic diuretics (e.g., mannitol)	Congestive heart failure

Information modified from reference 2.

will present in a hyponatremic state. Fluid restriction is the mainstay of therapy for SIADH. Patients should only receive between 50% and 75% of their maintenance needs (Reference 31).

Another cause of euvolemic hyponatremia in postoperative patients is the administration of maintenance fluids that are low in sodium (hypotonic fluids). When the patient is experiencing stress related to an acute illness, or surgical procedures or trauma, the body will respond by initiating a neurohormonal cascade, maintaining and retaining free water. If the patient receives a low-sodium maintenance fluid and the body fails to maintain the free water balance, hyponatremia can result. Other factors contributing to postoperative hyponatremia include a combination of ADH release, subclinical volume depletion, pain, nausea, and stress (References 31, 32).

Hyponatremic encephalopathy is a serious complication of euvolemic hyponatremia that can result in death or permanent neurologic injury. It is estimated that more than 50% of hospitalized children with a serum sodium concentration of less than 125 mEq/L will develop hyponatremic encephalopathy. Often, this is associated with SIADH or occurs during the postoperative period. Therefore, monitoring the neurologic status of patients plays a role in preventing this complication (References 31, 32).

Finally, hypervolemic hyponatremia occurs when the net water retention exceeds the sodium retention. This clinical situation will be seen in patients with edema-forming states such as congestive heart failure, cirrhosis, and nephrotic syndrome (Reference 31).

### ***Clinical Manifestations of Hyponatremia***

Hyponatremic dehydration produces more substantial intravascular volume depletion because of the shift of water from the ECF into the ICF. The decreased content of sodium in the ECF results in decreased osmolality of ECF. Physiologically, the water will move from the ECF to the ICF to maintain osmotic equilibrium. The increase in water content within the cells will cause the cells to swell. Because the brain is a fixed space in the skull, there is an increase in intracranial pressure as the brain cells swell. This brain swelling is the main cause of the neurologic symptoms that occur with hyponatremia. Symptoms suggesting neurologic complications include anorexia, nausea, emesis, malaise, lethargy, confusion, agitation, headache, seizures, coma, and decreased reflexes. As the sodium falls below 125 mEq/L, the patient may experience nausea and malaise. If the sodium continues to fall below 120 mEq/L, the patient may also develop seizures. Seizures associated with hyponatremia are more refractory to treatment with an antiepileptic and require an increase in serum osmolality to correct the underlying problem (References 1, 2).

### ***Correction of Hyponatremia***

The approach to treating hyponatremia in children involves identifying the underlying cause of hyponatremia and administering oral or intravenous therapy to correct the dehydration and hyponatremia. For mild to moderate dehydration, ORT may be used unless the child has persistent vomiting (Reference 1). If intravenous therapy is required, it is very important to avoid rapid correction of hyponatremia in children. Rapid correction of hyponatremia may cause central pontine myelinolysis, an irreversible neurologic injury. Classic features of central pontine myelinolysis include mutism, dysarthria, spastic quadriplegia, pseudobulbar, and ataxia (References 32, 33). The general recommendation is to avoid correcting the serum sodium concentration by more than 12 mEq/L during the course of 24 hours. The cornerstone of therapy is to replace the sodium and water deficits by applying the formula list included in Table 6. An aggressive initial correction is indicated for the first 3–4 hours of management, with a goal not to exceed a rise in serum sodium of 2 mEq/L per hour. The chemistry panel should be evaluated every 6 hours to determine the progress of sodium and water correction. Intravenous hypertonic sodium chloride (3% hypertonic sodium chloride solution) may be used to rapidly increase the serum sodium in children with active symptoms (e.g., seizures). Hypertonic sodium chloride solution affects serum osmolality, which leads to a decrease in brain edema. Each 4 mL/kg of 3% sodium chloride increases the serum sodium by about 1 mEq/L (Reference 9). It is recommended that hypertonic sodium chloride solution be administered through a central line because of its high osmolality (i.e., 1027 mOsm/L). If the solution is to be administered peripherally, it should be slowly infused to minimize venous irritation and avoid infiltration. Refer to example 1 for a patient case of hyponatremia dehydration.

### ***Isonatremia (Isotonic)***

Isonatremic dehydration is defined as a serum sodium concentration between 130 mEq/L and 149 mEq/L. Isonatremic dehydration occurs when the degree of water and sodium losses is equal in both ICF and ECF. This is the most common type of dehydration in children, and the treatment plan is less complicated than that involved in hyponatremic and hypernatremic dehydration (see treatment formula, listed in Table 6).

### ***Correction of Isonatremia***

In emergency phase I for a hemodynamically unstable patient, the treatment objective is to expand the ECF volume, thereby preventing circulatory collapse. Acutely, an isotonic fluid (0.9% sodium chloride or

### Example 1. Hyponatremic dehydration case.

A 12-month-old male infant presents to the emergency department with the chief concern of diarrhea and cannot tolerate any oral intake. The infant has a normal blood pressure of 85/40 mm Hg.

Today's weight: 7.5 kg; pre-illness weight: 8 kg; serum sodium content: 129 mEq/L

Estimation of severity:  $[(\text{pre-illness weight} - \text{illness weight})/\text{pre-illness weight}] \times 100 = (8 \text{ kg} - 7.5 \text{ kg}/8 \text{ kg}) \times 100 = 6\% \text{ dehydrated} = \text{moderate dehydration}$

Is one or more of the following present? (1) Is patient severely dehydrated? (2) Signs of shock? (3) Patient unconscious? (4) Ileus present? (5) Severe electrolyte problem? No

Phase I Emergency Management: No

Phase II Deficit Management: Assessment of sodium content = patient serum sodium content: **129 mEq/L**

#### Step 1: Calculation of the replacement therapy

Fluid deficit (L) = % dehydration  $\times$  weight (kg) =  $6\% \times 8 \text{ kg} \times 1,000 \text{ mL/kg} = 480 \text{ mL}$

Sodium deficit = fluid deficit (L)  $\times 0.6 \times$  normal serum sodium concentration (140 mEq/L) =  $0.48 \text{ L} \times 0.6 \text{ L/kg} \times 140 \text{ mEq/L} = 40.3 \text{ mEq} = 40 \text{ mEq}$

Excess sodium deficit = (desired serum sodium (135) – actual serum sodium)  $\times 0.6 \text{ (L/kg)} \times$  body weight (kg) =  $(135 - 129 \text{ mEq/L}) \times 0.6 \text{ L/kg} \times 8 \text{ kg} = 28.8 \text{ mEq} = 29 \text{ mEq}$

Potassium deficit = fluid deficit (L)  $\times 0.4 \text{ (L/kg)} \times 120 \text{ mEq/L} = 0.48 \text{ L} \times 0.4 \text{ L/kg} \times 120 \text{ mEq/L} = 23 \text{ mEq}$

#### Step 2: Calculation of maintenance fluid and electrolyte therapy: Holliday-Segar method

Fluid requirements:  $100 \text{ mL/kg/day} \times 8 \text{ kg} = 800 \text{ mL}$

Sodium requirements:  $3 \text{ mEq/kg/day} = 24 \text{ mEq}$

Potassium requirements:  $2 \text{ mEq/kg/day} = 16 \text{ mEq}$

#### Step 3: Ongoing losses if necessary

	Water	Sodium	Potassium
Deficit	480 mL	40 mEq + 29 mEq	23 mEq
Maintenance	800 mL	24 mEq	16 mEq
<b>Total</b>	<b>1280 mL</b>	<b>93 mEq</b>	<b>39 mEq</b>
First 8 hours = 1/2 remaining deficit + 1/3 daily maintenance			
1/2 remaining deficit	240 mL	34.5 mEq	11.5 mEq
1/3 daily maintenance	267 mL	8 mEq	5 mEq
Total	507 mL	42.5 mEq	16.5 mEq
Next 16 hours = 1/2 remaining deficit + 2/3 daily maintenance			
1/2 remaining deficit	240 mL	34.5 mEq	11.5 mEq
2/3 daily maintenance	533 mL	16 mEq	11 mEq
Total	773 mL	50.5 mEq	22.5 mEq

#### Fluid Selection

First 8 hours = 5% dextrose + 0.45% NaCl<sup>a</sup> + 20 mEq/L KCl running at 63 mL/hour

Next 16 hours = 5% dextrose + 0.45% NaCl<sup>b</sup> + 30 mEq/L KCl running at 48 mL/hour

<sup>a</sup>Sodium:  $77 \text{ mEq/L} \times 507 \text{ mL} \times 1\text{L}/1000 \text{ mL} = 39 \text{ mEq} \rightarrow$  selection of 0.45% NaCl solution is close to goal of 42.5 mEq.

<sup>b</sup>Sodium:  $77 \text{ mEq/L} \times 773 \text{ mL} \times 1\text{L}/1000 \text{ mL} = 60 \text{ mEq} \rightarrow$  selection of 0.45% NaCl solution is close to goal of 50.5 mEq.

**Example 2. Hyponatremia dehydration case.**

A 12-month-old male infant presents to the emergency department with a 3-day history of being ill. After the physical examination, the baby is assessed to be severely dehydrated with a capillary refill of 4 seconds, and his skin is cool and mottled. The infant has a low blood pressure of 70/30 mm Hg.

Today's weight: 7.2 kg; pre-illness weight: 8 kg; serum sodium content: 151 mEq/L

Estimation of severity:  $[(\text{pre-illness weight} - \text{illness weight})/\text{pre-illness weight}] \times 100 = (8 - 7.2 \text{ kg})/8 \text{ kg} \times 100 = 10\% \text{ dehydrated} = \text{severe dehydration}$

Is one or more of the following present? (1) Is patient severely dehydrated? (2) Signs of shock? (3) Patient unconscious? (4) Ileus present? (5) Severe electrolyte problem? **Yes, patient is severely dehydrated with hypotension.**

**Phase I Emergency Management**

Calculation:  $20 \text{ mL/kg} = 20 \text{ mL} \times 8 \text{ kg} = 160 \text{ mL of } 0.9\% \text{ sodium chloride therapy}$

**Phase II Deficit Management: Assessment of sodium content = patient serum sodium content: 151 mEq/L**

**Step 1: Calculation of the replacement therapy (round with the nearest number)**

Total fluid deficit (TFD) (L) = % dehydration  $\times$  weight (kg) =  $10\% \times 8 \text{ kg} \times 1,000 \text{ mL/kg} = 800 \text{ mL}$

Free water deficit (FWD) =  $4 \text{ mL} \times (\text{actual sodium} - \text{desired sodium mEq/L}) \times \text{body weight (kg)}$

$4 \text{ mL} \times (151 - 145) \times 8 \text{ kg} = 192 \text{ mL}$

Solute fluid deficit (SFD) = TFD - FWD =  $800 \text{ mL} - 192 \text{ mL} = 608 \text{ mL} = 0.6 \text{ L}$

Sodium deficit = SFD (L)  $\times 0.6 \text{ (L/kg)} \times \text{normal serum sodium concentration (140 mEq/L)} = 0.6 \text{ L} \times 0.6 \text{ L/kg} \times 140 \text{ mEq/L} = 50.4 \text{ mEq} = 50 \text{ mEq}$

Potassium deficit = SFD (L)  $\times 0.4 \text{ (L/kg)} \times 120 \text{ mEq/L} = 0.6 \text{ L} \times 0.4 \text{ L/kg} \times 120 \text{ mEq/L} = 28.8 \text{ mEq} = 29 \text{ mEq}$

**Step 2: Calculation of maintenance fluid and electrolyte therapy: Holliday-Segar method**

Fluid requirements:  $100 \text{ mL/kg/day} \times 8 \text{ kg} = 800 \text{ mL}$

Sodium requirements:  $3 \text{ mEq/kg/day} = 24 \text{ mEq}$

Potassium requirements:  $2 \text{ mEq/kg/day} = 16 \text{ mEq}$

**Step 3: Ongoing losses if necessary**

	<b>Water</b>	<b>Sodium</b>	<b>Potassium</b>
Deficit	800 mL + 192 mL	50 mEq	29 mEq
Maintenance	800 mL	24 mEq	16 mEq
<b>Total</b>	<b>1,792 mL</b>	<b>74 mEq</b>	<b>45 mEq</b>
First 8 hours = 1/2 remaining deficit + 1/3 daily maintenance			
1/2 remaining deficit	496 mL	25 mEq	14.5 mEq
1/3 daily maintenance	267 mL	8 mEq	5 mEq
Total	763 mL	33 mEq	19.5 mEq
Next 16 hours = 1/2 remaining deficit + 2/3 daily maintenance			
1/2 remaining deficit	496 mL	25 mEq	14.5 mEq
2/3 daily maintenance	533 mL	16 mEq	11 mEq
Total	1,029 mL	41 mEq	25.5 mEq

Note: The acute phase is usually excluded from the 24-hour calculations.

**Fluid selection**

First 8 hours = 5% dextrose + 0.225% NaCl<sup>a</sup> + 20 mEq/L KCl at a rate of 95 mL/hour

Next 16 hours = 5% dextrose + 0.225% NaCl<sup>b</sup> + 30 mEq/L KCl at a rate of 64 mL/hour

<sup>a</sup>Sodium:  $38.5 \text{ mEq/L} \times 763 \text{ mL} \times 1\text{L}/1000 \text{ mL} = 29 \text{ mEq} \rightarrow$  selection of 0.225% NaCl solution is close to goal of 33 mEq.

<sup>b</sup>Sodium:  $38.5 \text{ mEq/L} \times 1029 \text{ mL} \times 1\text{L}/1000 \text{ mL} = 39.6 \text{ mEq} \rightarrow$  selection of 0.225% NaCl solution is close to goal of 41 mEq.

lactated Ringer's solution) is given as a bolus of 20 mL/kg over 30 minutes and repeated if necessary. As previously stated, the deficit management, phase II, requires a calculation of both fluid and sodium deficit to determine the type and amount of fluids needed. In addition, maintenance fluids and ongoing losses must be included in the overall plan. In general, the treatment plan involves providing one-half of the remaining deficit plus one-third of the daily maintenance requirement during the first 8 hours, followed by the other one-half of the remaining deficit plus two-thirds of the daily maintenance during the next 16 hours. Commonly used maintenance solutions are 5% dextrose in 0.2% to 0.45% sodium chloride containing 20 mEq/L KCl. As previously mentioned, these solutions are used because they contain a combination of water, glucose, sodium, and potassium, which are the essential elements of maintenance fluid therapy. In the presence of metabolic acidosis, potassium acetate may be used instead of KCl (Reference 34). The acetate portion of potassium acetate will convert to bicarbonate in the liver and help neutralize the acidotic state.

### Hyponatremia

Hyponatremic dehydration is defined as a serum sodium concentration of 150 mEq/L or greater. The body has two defense mechanisms to protect against hyponatremia: the ability to produce concentrated urine and a powerful thirst mechanism (Reference 34). When assessing hyponatremia, it is important to distinguish between hyponatremia caused by (1) excessive sodium, (2) a water deficit, or (3) a combination of water and sodium deficit (Reference 2). In children, it is most likely related to an excess of free water loss because of increased insensible losses from fever, sweating, or gastroenteritis. Causes of hyponatremia in children are listed in Table 7.

An example of the combination of water deficit and sodium deficit is an infant or child presenting with gastroenteritis and mild hyponatremia. However, most children with gastroenteritis do not develop hyponatremia because of their supplemental intake of fluids such as water, juice, or formula, which compensates for the water deficit. If a child develops hyponatremia, it is most likely related to his or her inadequate intake of water, or lack of access to water, or anorexia (Reference 2).

Excessive sodium administration (also defined as sodium gain greater than water gain) in nonhospitalized patients may stem from improperly mixed formula, consumption of baking soda, intentional salt poisoning, and ingestion of seawater.

The classic causes of hyponatremia from inadequate water administration (water deficit) are nephrogenic diabetes and central diabetes insipidus (References 2, 34, 35). Diabetes insipidus is defined as complete or partial failure of ADH secretion (central diabetes insipidus) or renal response to ADH (nephrogenic insipidus), resulting in the

excretion of hypotonic urine (Reference 31). Hyponatremia will occur if patients do not have access to water or cannot drink an adequate amount of water because of neurologic impairment, emesis, or anorexia (Reference 2). Patients with central diabetes insipidus may have a history of head trauma, central nervous infections, or tumors. However, cases of nephrogenic insipidus may be congenital or acquired (Reference 31).

### Clinical Manifestations of Hyponatremia

In the hyponatremic state, the ECF is hyperosmolar because of a high serum sodium content. This state promotes water movement from the ICF to the ECF to maintain the osmotic balance. Children may appear less ill because the increased intravascular volume helps maintain their blood pressure and urine output. Only when children become more symptomatic and dehydrated do they seek medical attention (Reference 2). As a result, this treatment is delayed, and these children experience increased morbidity and mortality compared with patients who present with hyponatremia. The mortality rate of hyponatremia is 15% in children.

Hyponatremia can also cause serious neurologic damage. The movement of water from the brain cells to the ECF causes brain cell shrinkage (decrease in brain volume), tearing of blood vessels within the brain (hemorrhages), or cerebral contraction (Reference 2). Seizures and coma are possible sequelae of the brain hemorrhage. Overall, brain cell volume can be decreased as much as 10% to 15% in the presence of hyponatremia (Reference 32).

Children presenting with mild hyponatremia appear less ill than do children with isotonic dehydration. Children presenting with hyponatremia may have fever, hypertonicity, and hyperreflexia. In severely ill children, cerebral bleeding may develop. For patients with excessive sodium intoxication, signs of volume overload such as pulmonary edema may be present (Reference 2). On neurologic examination, these children may have increased tone, nuchal rigidity, and brisk reflexes. Other symptoms include myoclonus, asterixis, and chorea. Tonic-clonic and absence seizures have also been described.

### Correction of Hyponatremia

The objectives for correcting hyponatremia are to prevent cerebral edema, identify the underlying causes, limit further water loss, and replace the water deficit (Reference 1). It takes 48–72 hours for idiogenic osmoles in the brain to adapt to changes in the sodium concentration during the treatment plan; therefore, the free water deficit should not be replaced too rapidly. Rapid lowering of the extracellular osmolality will result in water movement from the ECF into the brain cells, causing cerebral edema. Cerebral edema may lead to

seizures, permanent neurologic damage, or death. Hypernatremic dehydration can be treated successfully, but it is difficult to manage and should be approached with caution. Therefore, the prevention of any neurologic sequelae is important to emphasize (Reference 35).

The goal of therapy in children is to slowly correct volume deficit while correcting the serum sodium concentration by no more than 12 mEq/L during the course of 24 hours. The general first step is to restore intravascular volume (e.g., administer 0.9% sodium chloride 20 mL/kg within 20–30 minutes). Lactated Ringer's solution is avoided because it is a more hypotonic solution (osmolality = 273 mOsm/L; sodium content = 130 mEq/L), which may lead to a rapid correction of the serum sodium concentration. The correction time varies depending on the initial sodium concentration. If the initial sodium concentration is 150–157 mEq/L, 158–170 mEq/L, 171–183 mEq/L, or 184–196 mEq/L, the time required for correction is 24 hours, 48 hours, 72 hours, and 84 hours, respectively (Reference 2). It is advisable to monitor the serum sodium concentration every 4–6 hours in the initial phases of sodium concentration, thus helping to ensure that the sodium level falls slowly and gradually (Reference 36). Typical fluids used for replacement include 5% dextrose in 0.45% sodium chloride or 5% dextrose in 0.2% sodium chloride (both with 20 mEq/L KCl unless contraindicated). Total volume deficit and free water deficit must be calculated to determine the correct infusion rate and the tonicity of the fluid needed (Table 6) (References 35, 36). Refer to example 2 for a patient case. As a pharmacist, you should discontinue any medications with high sodium content and avoid using fluids with high sodium content such as 0.9% sodium chloride. If such precautions are not taken, the correction time of the high initial serum sodium concentration may be affected, or the risk of the patient's developing neurologic complications may be increased.

## CONCLUSIONS

The Holliday-Segar formula remains the most popular and universally accepted method for calculating the daily maintenance fluid needs of pediatric patients. Dehydration is one of the leading causes of morbidity and mortality in children throughout the world. It commonly occurs if a child loses a large amount of fluid from diarrhea or vomiting. In assessing the patient who is dehydrated, two factors play a role: (1) the degree of dehydration and (2) the type of dehydration. For mildly and moderately dehydrated children, ORT is still the mainstay of therapy unless the patient cannot tolerate oral intake, is unconscious, or is in a state of shock. In children with severe dehydration, the key point is to calculate the fluid and electrolyte needs for deficit

replacement therapy, maintenance therapy, and ongoing losses. For the hemodynamically unstable patient (severe dehydration or shock), one bolus or more is the initial step to restore an adequate intravascular volume and avoid tissue damage. Depending on the type of dehydration, the correction times are important to prevent any neurologic complications. Overall, the patient must be monitored closely, and adjustment of the fluid therapy must be directed by the laboratory values from the chemistry panel, physical examination (to check whether the signs of dehydration have improved), weight, and urine output.

# CHAPTER 20

## PARENTERAL AND ENTERAL NUTRITION

*Catherine M. Crill, Pharm.D., FCCP, BCPS, BCNSP;  
and Johanna L. Norman, Pharm.D., BCPS*

### LEARNING OBJECTIVES

1. Discuss methods to assess adequate nutrition and weight gain in preterm and term infants, children, and adolescents.
2. Determine whether a pediatric patient is a candidate for specialized nutrition support (enteral or parenteral nutrition [EN, PN] therapy).
3. Formulate an EN regimen for a pediatric patient given the patient's age, disease state, and clinical status.
4. Formulate a PN regimen for a pediatric patient given the patient's age, type of intravenous access, disease state, and clinical status.
5. Identify common complications associated with EN and PN in pediatric patients.

### LIST OF ABBREVIATIONS

EN	Enteral nutrition
GI	Gastrointestinal
IVFE	Intravenous fat emulsion
MCT	Medium-chain triglyceride
PN	Parenteral nutrition
PNALD	Parenteral nutrition–associated liver disease
TNA	Total nutrient admixture

### INTRODUCTION

The importance of optimal nutrition across the pediatric age spectrum cannot be underestimated. Neonates and infants, particularly those who are born prematurely, and hospitalized pediatric patients are at particular risk of adverse effects from suboptimal nutrition. Pharmacists with skills in pediatric nutrition support play a key role on the health care team in ensuring that the nutritional needs of pediatric patients are met safely and effectively. This chapter reviews nutrition assessment, requirements, and indications for specialized nutrition support in pediatric patients and outlines specific details related to the optimal provision of enteral nutrition (EN) and parenteral nutrition (PN) therapy in pediatric patients.

### NUTRITION ASSESSMENT

Adequate growth should be routinely monitored in healthy and hospitalized infants and children by measuring weight, length or height, and head circumference. These measurements are then used to plot development on growth curves, whereby growth is expressed as an expected percentile for age (based on population standards). Several growth charts are available; the appropriate chart to use varies on the basis of age and sex, and in infants, whether the infant is human milk or formula fed (see the Introduction to Pediatrics chapter) (References 1, 2). Growth charts are used to determine whether infants and children are growing appropriately and are critical in identifying patients with failure to thrive across the pediatric age spectrum. Growth charts using body mass index are useful in identifying children and adolescents at risk of overnutrition or obesity, the prevalence of which has increased significantly during the past few decades (References 3, 4). Of note, growth percentiles may increase or decrease in infants, whereas children should generally follow their own growth curves over time. Standard growth charts can be used for preterm infants, provided corrections for gestational age are made for weight until 24 months, length until 40 months, and for head circumference until 18 months postnatal age (Reference 5). Alternatively, the Fenton growth chart may be used for preterm infants from 22 to 50 weeks' gestational age (Reference 6).

Compared with adults, pediatric patients have greater nutrient needs per kilogram and reduced reserves (Reference 7). Significant development related to nutrition occurs during the third trimester and the immediate postnatal period. The maximal period of growth and maturation of the gastrointestinal (GI) tract occurs throughout the third trimester. Nutritive sucking, necessary for oral feeding, is fully developed at 32–34 weeks' gestation. Gastric capacity is limited at birth, causing neonates to feed more frequently than older infants. Feeding issues, including gastroesophageal reflux, are common in infants and particularly preterm infants. Infants may also present with failure to thrive in which they are not gaining weight according to normal growth curves. This can be the result of inadequate intake or improper reconstitution of formula, or it can be indicative of a pathophysiologic condition such as cystic fibrosis, hypothyroidism, or pyloric stenosis.

Infants have greater total body water per weight than older children or adults, and the percentage of extracellular fluid is even greater in preterm infants. During the first few days after birth, there is contraction of the extracellular fluid and a significant diuresis that is accompanied by a decrease in weight. This weight should be regained within the first to second week of life. Weight gain velocity is greatest during the first few months of life. Term infants should gain about 20–30 g/day, leading to a doubling of their birth weight by about 4 months of age (Reference 8). Growth then slows such that infants triple their birth weight by the end of the first year of life (Reference 9). Preterm infants may grow even faster. An infant's length normally increases by 50% during the first year (Reference 8). From 2 to 10 years, children gain about 2–3 kg/year and grow 2.5–3.5 inches/year (Reference 9). Other methods of nutrition assessment in pediatric patients include anthropometric measurements (arm circumference and tricep skinfold thickness), visceral protein (albumin, transferrin, prealbumin or transthyretin, retinol-binding protein) measurement, and urine studies for nitrogen balance. With respect to visceral protein status, note that concentrations can also be influenced by other factors including hydration status, metabolic stress, organ dysfunction, and other disease states (Reference 10).

## SPECIALIZED NUTRITION SUPPORT

### Indications

In general, specialized nutrition support, to include EN and PN, is necessary in patients who are malnourished or at risk of being malnourished (Reference 11). Enteral nutrition, or the delivery of nutrition by tube to the GI tract, is indicated in premature neonates younger than 32–34 weeks' gestation because the suck-swallow reflex has not fully developed, in infants too sick to breast- or bottle-feed, in patients who are mechanically ventilated, and in any pediatric patient whose needs cannot be met by the oral route (Reference 11). Parenteral nutrition, or the delivery of nutrition directly to the bloodstream through a peripheral or central venous catheter, is indicated in pediatric patients when nutritional needs cannot be met by EN or when the GI tract is not functioning. Common examples of indications for PN in infants include prematurity, small bowel resection resulting in short bowel syndrome, abdominal wall defects (gastroschisis and omphalocele), necrotizing enterocolitis, intestinal atresias or webs, malrotation/volvulus, Hirschsprung disease, imperforate anus, diaphragmatic hernia, tracheoesophageal fistula, and meconium aspiration. Other disease states or conditions in which PN therapy may be indicated include critical illness, trauma, extracorporeal membrane oxygenation, appendicitis, pancreatitis, chylothorax, failure to thrive,

chronic malabsorption/diarrhea, organ failure, and exacerbations of inflammatory bowel disease. In patients unable to meet nutritional requirements with EN therapy, PN should be initiated within 24 hours in preterm neonates and within 5–7 days in older pediatric patients (References 11, 12).

### Fluid and Caloric Requirements

When initiating EN or PN support, fluid and caloric needs should be assessed. Table 1 outlines fluid and caloric needs across the pediatric age spectrum (Reference 13). Increased fluid requirements exist with prematurity because of increased losses from evaporation through the skin, immature renal conservation, and the use of radiant warmers and phototherapy. Excess fluid provision may be detrimental with specific disease states such as bronchopulmonary dysplasia, intraventricular hemorrhage, patent ductus arteriosus, congestive heart failure, and liver or renal failure (see Fluid and Electrolytes chapter). Caloric requirements may be increased because of critical illness and disease states such as congenital heart disease or bronchopulmonary dysplasia, or they may be decreased because of developmental delay or immobility. Caloric provision should be reassessed in pediatric patients not gaining appropriate weight or gaining weight too rapidly.

## ENTERAL NUTRITION

Enteral nutrition may be provided through nasogastric, gastric, or jejunal tube. It may be given by bolus administration or by intermittent, continuous, or cyclic enteral infusion.

### What to Feed

Exclusive breastfeeding is recommended by the American Academy of Pediatrics for the first 6 months of life, with support for continued breastfeeding for the first year and beyond. Expressed human milk should be given whenever possible in patients who are receiving their nutrition enterally. In addition, donor breast milk is available through the Human Milk Banking Association of North America (Reference 14). Advantages of human milk feeding include decreased upper respiratory infections (particularly otitis media), urinary tract infections, necrotizing enterocolitis, meningitis, diarrhea, sepsis, sudden infant death syndrome, diabetes, cancer, asthma, and obesity. Although there is a risk of jaundice and kernicterus because of the inhibitors of glucuronyl transferase (responsible for bilirubin conjugation) present in breast milk, this potential risk does not outweigh the benefits of human milk feeding in most patients.

**Table 1.** Fluid, Caloric, Macronutrient, and Electrolyte Daily Requirements Across Pediatric Ages (References 11, 13, 18, 31)

Requirement	< 1500 g	1500–2000 g	2–10 kg	> 10–20 kg	> 20 kg
Fluid	130–150 mL/kg	110–130 mL/kg	100 mL/kg	1000 mL + 50 mL/kg > 10 kg	1500 mL + 20 mL/kg > 20 kg
Calories	Preterm neonate 90–120 kcal/kg	1–12 months 80–105 kcal/kg	1–7 years 75–90 kcal/kg	7–12 years 50–75 kcal/kg	12–18 years 30–60 kcal/kg
Protein	Preterm neonate 3–4 g/kg	1–12 months 2–3 g/kg	1–10 years 1–2 g/kg	11–17 years 0.8–1.5 g/kg	
Fat	1–3 g/kg	1–3 g/kg	1–3 g/kg	1–3 g/kg	
	<b>Preterm Neonate</b>	<b>Infants/Children</b>	<b>Adolescents</b>		
Sodium	2–5 mEq/kg	2–4 mEq/kg	1–2 mEq/kg		
Potassium	2–4 mEq/kg	2–4 mEq/kg	1–2 mEq/kg		
Calcium	2–4 mEq/kg	0.5–4 mEq/kg	10–20 mEq		
Phosphorus	1–2 mmol/kg	0.5–2 mmol/kg	10–40 mmol		
Magnesium	0.3–0.5 mEq/kg	0.3–0.5 mEq/kg	10–30 mEq		
Acetate/Chloride	Variable	Variable	Variable		

Infant formulas are available for feeding infants whose mothers are unable to breastfeed or provide expressed human milk. Enteral formulas for administration to children are also commercially available. Formulas come as ready-to-feed products, dry powders, and concentrated liquids. Caregivers should be educated on the proper technique for formula reconstitution and storage.

Most standard infant formulas provide 20 kcal/oz (0.67 kcal/mL) of formula; however, some may be available as 22 kcal/oz (0.73 kcal/mL) and 24 kcal/oz (0.8 kcal/mL). The caloric density of a formula may be increased further by concentrating a powdered formula or using protein-, carbohydrate-, or fat-source modular additives. Standard child formulas are typically available as 30 kcal/oz (1 kcal/mL). See Table 2 for examples of standard and therapeutic preterm and term infant formulas and standard and therapeutic child formulas that are commercially available, their indications for use, and their caloric density. Figure 1 outlines examples of calculations for EN feeding regimens based on patient age, caloric goal, and caloric density of formula.

### Drug-Nutrient Considerations

Patients with enteral feeding tubes often need to receive medications through the tube. However, several factors need to be considered when drugs designed for oral administration are delivered in this manner. Only certain drug formulations should be given through an enteral tube. Although some parenteral formulations have been given enterally, this practice is generally not

recommended because these formulations are meant for parenteral administration. Enteric-coated and modified-release products should be avoided because they cannot be crushed. Immediate-release solid dosage forms may be given after being ground and mixed with water. Liquid formulations can also be used, but not all are appropriate for administration through a tube. Suspensions may be too viscous and require dilution, or they may have granules with modified-release properties. Additives and electrolytes in liquid formulations may also increase their osmolality.

The site of absorption and action of the drug should also be considered. Some drugs have absorption throughout the GI tract, but others have specific sites of absorption that the tube may bypass, depending on the location of the distal tip. Still other medications, such as proton pump inhibitors, may be acid labile and rendered ineffective by the lower pH of the GI tract. Finally, patients with enteral feeding tubes may have undergone bowel resection, so it is important to know the length and location of the patient's functional bowel.

To avoid interactions, medications should not be added directly to an enteral feeding formula (Reference 15). Even when the formula and medications are given separately, there is still a potential for interactions that can affect the compatibility or stability of the drug or nutrient. If the volume can be tolerated, flushing between each medication will help prevent drug interactions and occlusion of the feeding tube. Caution should be exercised when mixing several medications for administration

**Table 2. Commercially Available Enteral Formulas for Infants and Children**

Formula Type	Brand Name <sup>a</sup>	Indication	Kilocalories (per oz)
<b>Premature Infant Formulas</b>			
Premature	Similac Special Care Enfamil Premature	Initial formula for low-birth-weight and premature infants	20–30
Transitional premature	Similac Expert Care NeoSure Enfamil EnfaCare	Transitional formula for older premature infants or after discharge home	22
<b>Infant Formulas</b>			
Cow's milk-based	Good Start Enfamil Premium Infant Similac Advance Similac Organic	Healthy, term infants	20–24
Lactose-free	Enfamil Gentlease Similac Sensitive	Lactose intolerance	20
Soy protein-based	Similac Soy Isomil Enfamil ProSobee Good Start Soy Plus	Lactose intolerance or galactosemia	20
Protein hydrolysate	Similac Expert Care Alimentum Nutramigen Pregestimil	Allergy or sensitivity to cow's milk or soy protein, impaired digestion or absorption	20
Free amino acid	EleCare Nutramigen AA Neocate Infant	Allergy or sensitivity to cow's milk or soy protein, impaired digestion or absorption	20
Low-fat, high MCT	Enfaport	Chylothorax or chylous ascites	30
Low iron	Similac PM 60/40	Renal insufficiency	20
Rice starch/ cereal added	Enfamil AR Similac Sensitive for Spit-Up	Gastroesophageal reflux	20
<b>Infant/Toddler or Children's Formulas</b>			
Cow's milk-based	Good Start 2 Similac Go and Grow Milk-Based Enfagrow Premium PediaSure	Healthy older infants, toddlers, and children	20–30
Lactose-free	Nutren Junior Boost Kid Essentials	Lactose intolerance	30
Fiber-containing	Nutren Junior Fiber PediaSure with Fiber	Many potential indications (e.g., constipation)	30
Soy protein-based	Enfagrow Soy Good Start 2 Soy PLUS Similac Go and Grow Soy-Based	Lactose intolerance or galactosemia	20
Protein hydrolysate	Peptamen Junior Vital jr. Pepdite Junior	Allergy or sensitivity to cow's milk or soy protein, impaired digestion or absorption	30
Free amino acid	EleCare Neocate Junior Vivonex Pediatric E028 Splash	Allergy or sensitivity to cow's milk or soy protein, impaired digestion or absorption	24–30
Low-fat, high MCT	Portagen	Impaired digestion or absorption of long-chain fats, chylothorax or chylous ascites	30
High calorie	Boost Kid Essentials 1.5	Increased caloric needs	45

<sup>a</sup>Brand names listed are examples and not a complete list of products in each category.

MCT = medium-chain triglyceride.

through a tube because the stability and compatibility of drugs are unknown when tablets are crushed together or liquid formulations are mixed. Complete information regarding the potential for interactions between drugs and EN formulations was recently reviewed (Reference 16). Table 3 summarizes the most important medications with respect to drug-nutrient interactions.

### EN Complications

Complications associated with EN include mechanical complications (feeding tube occlusion and malposition), GI symptoms (nausea, vomiting, diarrhea, cramping, aspiration, or constipation), feeding tube site infections, tubing misconnections, and aversion to oral feeding (particularly in enterally fed infants).

## PARENTERAL NUTRITION

Parenteral nutrition is a formulation composed of dextrose, amino acids, water, minerals, electrolytes, vitamins, and trace elements that is infused intravenously into the systemic circulation. Intravenous fat emulsion (IVFE) is typically given as a separate infusion in pediatric patients. Parenteral nutrition may be given through peripheral or central venous access. When giving peripheral PN, the osmolarity of the PN solution should be limited to 900 mOsm/L or less, and care should be taken to assess the catheter site regularly for signs of infiltration. Central PN requires the placement of a central catheter (i.e., a peripherally inserted central catheter or tunneled central venous catheter). When PN is initiated in infants and children, it is typically given by continuous infusion over 24 hours. In older infants and children who will be receiving long-term PN, the PN solution may be cycled over a defined period (e.g., a 12-hour PN infusion overnight).

### Formula Considerations

Parenteral nutrition solutions may be formulated as a 2-in-1 admixture, in which the dextrose and amino acid solution infuses separately from the IVFE, or as a total nutrient admixture (TNA), in which all components (dextrose, amino acids, IVFE, and additives) are provided in a single solution. The use of TNAs in pediatric patients has disadvantages, including lower calcium and phosphorous solubility, inability to use a 0.2-micron filter because of the large particle size of IVFE, and inability to visualize particulates if they exist. For these reasons, the use of TNAs is not recommended in neonates and infants (Reference 18).

### Components

#### *Protein*

Protein is provided as crystalline amino acids in PN formulations. The standard commercial solutions provide essential, semi-essential, and nonessential amino acids.

Pediatric-specific amino acid products (e.g., Aminosyn-PF, Premasol, TrophAmine) were designed to mimic plasma amino acid concentrations of postprandial breastfed infants. These products have lower amounts of methionine, phenylalanine, and glycine, together with supplemental taurine, glutamate, and aspartate. Pediatric-specific amino acid products also have a lower pH, which imparts greater calcium and phosphorus solubility. All amino acid solutions contain varying amounts of electrolytes that should be considered part of the patient's overall electrolyte provision from PN.

Immaturity of the transsulfuration pathway, specifically hepatic cystathionase activity, during infancy prevents optimal conversion of methionine to cysteine. Thus, cysteine becomes a conditionally essential nutrient because it is further metabolized to taurine, which is essential for retinal development, neurodevelopment, and many other critical functions. Addition of 40 mg of cysteine per gram of amino acid has been shown to further normalize plasma amino acid patterns (specifically taurine concentrations) of parenterally fed infants (Reference 19). The addition of cysteine also lowers solution pH, thus enhancing calcium and phosphorus solubility (Reference 20).

Each gram of protein provides 4 kcal when oxidized for energy; however, controversy exists regarding whether protein calories should be considered in the caloric content of the PN regimen. The argument is that if adequate energy substrate is provided as dextrose and lipids, amino acids should be used for protein synthesis only, not oxidized for energy (Reference 21).

Early initiation of protein is recommended in extremely low- and very low-birth-weight preterm neonates, starting on the first day of life, to decrease protein losses and restore positive protein balances (References 22–24). Preterm neonates have the highest protein needs per kilogram to maintain growth rates similar to what occurs in utero; this protein requirement decreases with age (Reference 25). In infants, 55% of protein intake is used for growth and 45% for maintenance. As the growth rate slows, the balance changes so that only 10% of protein is used for growth by 4 years of age (Reference 26).

#### *Carbohydrates*

Dextrose serves as the main source of energy in PN, and it is commercially available as dextrose monohydrate in concentrations ranging from 5% to 70%. Final concentrations in PN formulations normally vary from 10% (or lower initially in preterm infants) to 35%, depending on the patient's age, nutritional needs, intravenous access, and condition. For example, dextrose should be limited to 12.5% or less in patients with peripheral access (Reference 27).

Each gram of dextrose yields 3.4 kcal when oxidized. Glucose oxidation rates in infants (10–14 mg/kg/minute) are greater than in older children or adults (5 mg/kg/minute) (References 28–30). When the dextrose infusion rate

## Enteral Nutrition Calculations

### Calculate caloric content of formulas:

20 kcal/oz of formula (standard infant formula) = 20 kcal/30 mL = 0.67 kcal/mL

30 kcal/oz of formula (standard pediatric formula) = 30 kcal/30 mL = 1 kcal/mL

### Examples of enteral feeding requirements:

- For a 3-kg infant, give 100 kcal/kg or 300 kcal.
- For a 6.5-kg infant, give 100 kcal/kg or 650 kcal.
- For a 19-kg child, give 100 kcal/kg for the first 10 kg, followed by 50 kcal/kg for the next 9 kg (i.e., for each kilogram between 10 and 20 kg): 1000 kcal + 450 kcal = 1450 kcal.

### Examples of volume of formula needed and regimen to provide estimated daily caloric needs:

- For a 3-kg infant receiving standard infant formula (20 kcal/oz):

Desired daily calories = 300 kcal

$300 \text{ kcal} \times 30 \text{ mL}/20 \text{ kcal} = 450 \text{ mL}$  (150 mL/kg)

- Check to make sure it is calculated correctly:  $450 \text{ mL} \times 0.67 \text{ kcal/mL} = 301.5 \text{ kcal}$  (about 300 kcal).  
*Thus, this infant requires about 2 oz (60 mL) of formula every 3 hours to approximate calorie needs.*

- For a 6.5-kg infant receiving standard infant formula (20 kcal/oz):

Desired daily calories = 650 kcal

$650 \text{ kcal} \times 30 \text{ mL}/20 \text{ kcal} = 975 \text{ mL}$  (150 mL/kg)

- Check to make sure it is calculated correctly:  $975 \text{ mL} \times 0.67 \text{ kcal/mL} = 653 \text{ kcal}$  (about 650 kcal).  
*Thus, this infant requires about 6.5 oz (or 195 mL) of formula every 4 hours during the day (with the infant sleeping through the night – so only five feedings per day) to approximate calorie needs.*

- For a 19-kg child receiving standard pediatric formula (30 kcal/oz or 1 kcal/mL):

Desired daily calories = 1450 kcal = 1450 mL

*Thus, this child requires about six cans of formula (240 mL per can) per day. This can be given by mouth or by tube intermittently during the day. Alternatively, it can be given continuously at a rate of 60 mL/hour per tube, or the child can receive an increased amount (milliliters) per hour over less than 24 hours to give the patient time off the tube feeding/pumps. This calculation assumes that all caloric needs are being provided with the pediatric formula and the child is not receiving any additional calories from an oral diet.*

Figure 1. Examples of enteral nutrition calculations.

is greater than the glucose oxidation rate, glycogenesis and fat deposition occur (Reference 29). Excess dextrose can lead not only to hyperglycemia, but also to hypertriglyceridemia, excess carbon dioxide production, and hepatic steatosis (Reference 29). Of note, the administration of exogenous insulin will lower the blood glucose, but it will not alter the glucose oxidative capacity.

Preterm infants are more likely to have glucose intolerance, which may result in hyperglycemia or hypertriglyceridemia. Dextrose should be advanced more slowly by about 2–3 g/kg/day in these patients. In older infants, dextrose can usually be advanced by 5 g/kg/day (References 12, 31). Other risk factors for hyperglycemia in pediatric patients include corticosteroid or catecholamine vasopressor therapy, diabetes, pancreatitis, or stress (organ failure, sepsis, or surgery) (Reference 29). Although neonates may develop significant hyperglycemia after surgery, it resolves more quickly in them, with glucose returning to preoperative levels within 12 hours postsurgery (Reference 32).

## Intravenous Fat Emulsion

Intravenous fat emulsions provide a concentrated source of calories, prevent or treat essential fatty acid deficiency, and extend the life of peripheral intravenous lines. Commercially available products in the United States are soybean oil based, composed primarily of the long-chain fats, linoleic acid (omega-6 fatty acid) and linolenic acid (omega-3 fatty acid). The 20% IVFE product is preferred for use in pediatric patients because of the lower phospholipid-to-triglyceride ratio, which improves triglyceride clearance (References 18, 31, 33). The amount of linoleic acid necessary to prevent essential fatty acid deficiency can be supplied by providing 2% to 4% of the nonprotein calories, or 0.5–1 g/kg/day, from the IVFE (References 33, 34). Although 1 g of fat provides 9 kcal, the egg phospholipids that are used as emulsifying agents and the glycerol that is added to make the IVFE isotonic also provide calories, thereby

**Table 3.** Select Potential Drug–Nutrient Interactions with Enteral Nutrition (References 16, 17)

Drug or Class	Interaction	Recommendation
Amiodarone	An increased dose may be required when given nasoduodenally.	Administer consistently with respect to timing of enteral feeds. Monitor closely.
Carbamazepine	Adsorption to enteral tube feeds may occur.	Dilute the suspension 1:1 with water and flush after administration. Monitor closely.
Digoxin	Reduced absorption may be possible with fiber-containing enteral feeds.	Administer consistently with respect to timing of enteral feeds. Administer 1 hour before or 2 hours after feeds with high fiber or pectin. Monitor closely.
Fluoroquinolones	Reduced absorption may occur because of chelation with cations and/or interactions with the protein content in enteral feeds.	An increased dose of ciprofloxacin and levofloxacin may be needed. Hold enteral feeds 1 hour before and 2 hours after ciprofloxacin administration. Monitor closely.
Itraconazole	Reduced plasma concentrations may occur, even when separated from enteral feeds by 2 hours. An increased dose leads to increased GI adverse effects.	Do not administer with enteral feeds.
Levothyroxine	Reduced absorption may occur when not in a fasting state.	An increased dose may be needed. Monitor closely.
Phenytoin	Reduced plasma concentrations may occur.	An increased dose may be needed. Separate administration by 2 hours. Monitor closely.
Proton pump inhibitors	Denatured proteins may clog small-bore feeding tubes if diluted with juice (pantoprazole). Increased viscosity from xanthan gum may clog small-bore tubes (esomeprazole and omeprazole).	Pantoprazole is not ideal for feeding tube administration. Flush the tube well after administering esomeprazole or omeprazole.
Sevelamer	High viscosity may clog feeding tubes.	Flush feeding tube well before and after administration
Sucalfate	May complex with protein and clog feeding tubes.	Do not administer by small-bore (i.e., ≤ 12F) feeding tubes.
Warfarin	Warfarin resistance may occur because of the vitamin K content of feeds and/or binding to protein in feeds (more recent data).	Hold enteral feeds 1 hour before and after administration. Monitor the INR closely.

GI = gastrointestinal; INR = international normalized ratio.

increasing the caloric content of the 20% IVFE to 2 kcal/mL. Patients with severe allergic reactions to eggs should not receive IVFE products.

Lipid clearance is reduced in premature neonates, and rapid infusion is more likely to result in hypertriglyceridemia. Clearance is further impaired if premature neonates are receiving steroids, are stressed, or have organ dysfunction (Reference 35). Serum triglyceride monitoring is recommended when administering IVFE. A longer infusion time of 24 hours has been shown to improve IVFE tolerance and is recommended in preterm infants (References 33–35). Rapid lipid infusions have also been associated with impaired oxygenation in neonates. Soybean oil–based IVFE carry a boxed warning regarding preterm infant deaths attributed to pulmonary fat accumulation (Reference 36).

Soybean oil–based IVFE have proinflammatory effects secondary to eicosanoid production from omega-6 polyunsaturated fatty acids, and they have been thought

to contribute to the development of PN-associated liver disease (PNALD). Although only soybean oil–based IVFE are available in the United States, products composed of fish oil, olive oil, medium-chain triglycerides (MCTs), and combinations of these fat sources are available in Europe. Intravenous fat emulsion products containing fish oil (with less-inflammatory omega-3 fatty acids) have been shown to improve and potentially prevent PNALD (References 37, 38).

Figure 2 gives an example of initiating a PN solution in an infant, including caloric calculations.

### *Electrolytes*

Electrolytes added to PN solutions include sodium, potassium, calcium, phosphorus, magnesium, chloride, and acetate. Requirements vary on the basis of age, disease state, organ function, and concomitant drugs. On the basis of intravenous access, certain electrolytes should be limited. For example, potassium given through a

peripheral line should not exceed 40 mEq/L. Specifics on fluid and electrolyte management can be found in the Fluid and Electrolytes chapter. See Table 1 for typical electrolyte doses per day across pediatric ages (Reference 18). Electrolyte losses from sources other than urine, such as diarrhea or stoma output, should also be replaced.

The in utero provision of calcium and phosphorus during the third trimester approximates 120–150 mg/kg/day of elemental calcium and 70–85 mg/kg/day of elemental phosphorus (References 39–42). Supplementation of similar doses through PN is impossible without exceeding solubility limits and causing calcium phosphate precipitation. Despite the inability to supplement with similar in utero mineral doses, the highest retention of both minerals and sufficient bone mineralization has occurred in infants and children on PN when the minerals are given in a 1.7:1 calcium-to-phosphorus (milligram to milligram) ratio (References 43–45). This ratio is typically provided throughout the first year of life. Mineral requirements decrease as children age. In older children, an equimolar provision of calcium and phosphorus is optimal. It is important for severely malnourished patients to receive sufficient phosphorus to avoid the refeeding syndrome (see the Complications section for a more detailed discussion).

Acetate is provided in PN to help maintain the acid-base balance. Although bicarbonate is not compatible with PN, acetate is converted to bicarbonate in vivo. Premature neonates may be more prone to developing metabolic acidosis caused by reduced renal absorption of bicarbonate, lower pH of pediatric amino acid products, and addition of L-cysteine to pediatric amino acid-containing PN solutions. Consequently, they often need acetate added as a sodium or potassium salt.

### *Vitamins and Trace Elements*

Vitamins are required cofactors in many metabolic processes. They include lipid-soluble vitamins (A, D, E, and K) and water-soluble vitamins (ascorbic acid and the B-complex vitamins), and both types should be provided in PN. Commercially available multivitamin products are available for use in PN solutions. Infants and young children should receive a pediatric multivitamin product, whereas children/adolescents older than 11 years should receive an adult multivitamin product. Iron is not included in commercially available multivitamin products, so it may need to be supplemented in patients on long-term PN.

Chromium, copper, zinc, manganese, and selenium are commonly added to PN solutions to prevent deficiencies. Although pediatric multitrace element products exist for use in PN solutions, they result in the underdosing of zinc in neonates and infants, who thus require additional zinc supplementation. In addition,

zinc is important for immune function and wound healing, and supplemental zinc may be needed if abnormal fluid losses are occurring from wounds or increased stooling (Reference 46). Trace element contamination also occurs, primarily with chromium and manganese, in many components of PN, so they are not routinely added. Chromium, selenium, and zinc, which are eliminated renally, may accumulate in patients with renal insufficiency. Likewise, copper and manganese, which are eliminated through the biliary system, accumulate in patients with liver disease. Manganese accumulates in patients with or without liver disease who receive long-term PN, which has been associated with concerns for neurotoxicity. Although iodine supplementation is not needed in patients on short-term PN, deficiency may occur in patients receiving long-term therapy (Reference 47). Given these concerns, some pediatric practitioners individually dose trace elements rather than use the multitrace products. This practice allows the adjustment of trace elements in specific disease states or conditions or for the exclusion of trace elements, such as chromium and manganese, because of contamination.

### *PN Additives*

Neonates have a reduced biosynthetic capacity for carnitine, a nutrient required for transporting long-chain fatty acids into the mitochondria for energy production. Because PN does not contain carnitine, neonates, particularly preterm neonates, will become deficient while receiving exclusive carnitine-free PN. Thus, carnitine supplementation in neonates expected to receive PN for more than 1 week will prevent deficiency and augment their capacity for fatty acid oxidation (Reference 48). Other pediatric patients who may benefit from carnitine supplementation include those with hypertriglyceridemia while receiving IVFE, as well as patients with short bowel syndrome, diffuse inflammatory bowel disease, or malabsorption syndromes who are receiving a portion of their calories parenterally (Reference 48).

Parenteral nutrition is not preferred as a drug vehicle because of the risk of interactions with the various components of the admixture; however, several medications can be safely added during compounding. Histamine-2 ( $H_2$ )-receptor antagonists are often used in patients who are critically ill and in those with short bowel syndrome. Ranitidine, famotidine, and cimetidine have been shown to be compatible with most PN admixtures (Reference 49). These medications should be used judiciously, however, because they have been associated with an increased incidence of necrotizing enterocolitis in infants, possibly caused by reduced inhibition of bacterial growth with higher gastric pH (Reference 50). Insulin may also be added to PN solutions to facilitate glucose metabolism, but only regular

## Parenteral Nutrition Calculations

### Estimate fluid and caloric needs:

For a 3-kg infant, give 300 mL/day parenterally and 300 kcal/day.

### Calculate rate of infusion:

$300 \text{ mL/day} \div 24 \text{ hr/day} = 12.5 \text{ mL/hr}$

### Carbohydrate (dextrose):

Adjust dose in grams per kilogram.

Advance 2.5–3 g/kg in small, preterm infants.

Advance 5 g/kg in term infants and young children.

In general, advance by 5% per day in older children/adolescents.

### Protein:

Begin with your desired protein dose on day 1 (no need to titrate up protein as you do with dextrose and fats).

Include 40 mg cysteine per gram of protein when giving pediatric amino acid products (i.e., Aminosyn PF, Premasol, TrophAmine).

### Intravenous fat emulsion (IVFE):

Begin at 0.5–1 g/kg/day and advance by 0.25–1 g/kg/day until at desired daily dose.

### Total calories:

Add kilocalories per day from dextrose, protein, and IVFE.

Divide total by patient weight for kilocalories per kilogram per day.

### Total volume:

Add up milliliters per day from dextrose/amino acid solution and IVFE.

Divide total by patient weight for milliliters per kilogram per day.

### Calculating dextrose calories:

Dextrose (g)  $\times$  3.4 kcal/g

300 mL of dextrose 10% = 300 mL  $\times$  10 g/100 mL = 30 g of dextrose  $\times$  3.4 kcal/g = 102 kcal/3 kg = 34 kcal/kg/day

### Calculating protein calories:

Protein (g)  $\times$  4 kcal/g

2.5 g/kg/day  $\times$  4 kcal/g = 10 kcal/kg/day

### Calculating IVFE calories:

20% fat emulsion provides 2 kcal/mL.

Need to calculate volume of fat emulsion per day:

1 g/kg/day  $\times$  3 kg = 3 g/day; 3 g  $\div$  20 g/100 mL (i.e., 20% emulsion) = 15 mL; 15 mL/24 hr = 0.625 mL/hr

Round rate to 0.6 mL/hr  $\times$  24 hr/day = 14.4 mL; 14.4 mL/day  $\times$  2 kcal/mL = 28.8 kcal/day or 9.6 kcal/kg/day

### Final calculations:

3-kg infant receiving PN (10% dextrose and 2.5 g/kg/day protein) at 12.5 mL/hr and 20% IVFE at 0.6 mL/hr:

Dextrose	34 kcal/kg
Amino acids	10 kcal/kg
IVFE	9.6 kcal/kg
Total	53.6 kcal/kg

Continue to advance dextrose and lipid calories to get to “goal” of 100 kcal/kg/day.

Figure 2. Examples of parenteral nutrition calculations.

hr = hour.

human insulin should be used. Modified insulin formulations should not be added. Low-dose heparin may also be added to most PN solutions to help prevent thrombosis of the catheter; however, the addition of heparin to IVFE can result in disruption of the emulsion (Reference 51). Iron dextran is the only parenteral iron formulation compatible with PN, but it is incompatible with IVFE (Reference 52).

Table 4 summarizes potential drug-nutrient interactions with commonly used PN additives.

### Complications

Although PN is a lifesaving therapy for infants and children who cannot tolerate or absorb EN, it is associated with significant technical, metabolic, and infectious complications.

Technical complications may result with catheters when they are placed or later during their use. Catheters may move or be accidentally removed, or the lumen of the catheter may become occluded with a clot or biofilm. Fibrinolytic agents such as alteplase may be used to dissolve the fibrin and restore the patency of the catheter. Components of the PN solution such as calcium and phosphate may precipitate, causing an occlusion.

Although hyperglycemia and hypoglycemia may both occur, hyperglycemia is seen more often. It frequently occurs after surgery, when given with concomitant glucocorticoids, when dextrose is advanced too quickly, and in neonates. Hyperglycemia may impair the immune system and make the patient more susceptible to infectious complications (Reference 29). The most serious risk associated with hyperglycemia is the development of a hyperosmolar hyperglycemic state. Blood glucose should be monitored carefully, particularly when PN is initiated, when dextrose is advanced, or in patients who are at increased risk of hyperglycemia because of concomitant medications or their clinical condition. Hypoglycemia may occur if PN is abruptly discontinued.

Hypertriglyceridemia may occur in infants who receive excessive glucose or secondary to the inadequate clearance of IVFE. Clearance of the IVFE is improved if it is given over 24 hours. Elevated triglycerides may be the result of poor clearance of exogenous chylomicrons or caused by the mobilization of endogenous fat in response to inadequate caloric intake. Assessment of the serum sample is useful; if the IVFE is not being adequately cleared from the circulation, the serum sample will be lipemic.

Acid-base disorders are also common in patients receiving PN and may be caused by the underlying condition or, less commonly, by the PN formulation. The acetate and chloride components of PN should be adjusted to prevent or treat metabolic acid-base anomalies.

The refeeding syndrome is a potentially life-threatening complication. It is usually seen in patients who were very undernourished, causing their bodies to mobilize free fatty acids and ketone bodies for energy. If dextrose is started aggressively after a period of undernutrition, hypophosphatemia, hyperinsulinemia (or increased insulin secretion), and other electrolyte abnormalities may develop as energy metabolism is shifted to an anabolic state. Elevated insulin levels may cause fluid retention, which can result in cardiac decompensation in these patients. To prevent the refeeding syndrome, it is imperative to monitor glucose and other electrolytes in patients who were severely undernourished and to slowly advance dextrose. The risk may also be reduced in undernourished patients by providing additional phosphorus and potassium above the recommended daily allowance when PN is started (Reference 35).

Parenteral nutrition-associated liver disease, defined as a direct bilirubin equal to 2 mg/dL or more, is a common complication that may develop in 40% to 60% of children receiving long-term PN (Reference 53). In infants, PNALD normally manifests as cholestasis that can progress to liver failure and even death. In older children and adults, hepatic steatosis is more often seen. Risk factors include prematurity, sepsis, lack of enteral feeding, duration of PN, length of bowel remaining, and excessive calories (Reference 53). Components of PN have also been associated with the development of PNALD, including the amino acid composition and soybean oil-based IVFE. Fish oil-based IVFE has been shown to reverse PNALD and may help prevent the disease (References 37, 38). Other treatments include administering ursodiol, cycling PN, restricting the IVFE dose, preventing sepsis, providing trophic feeds, and preventing bacterial overgrowth with the use of antibiotics or probiotics (References 38, 53). The condition is normally reversible if EN can be advanced and PN discontinued before irreversible liver damage occurs; however, patients may require liver transplantation if the disease progresses.

Metabolic bone disease is also a multifactorial process that is more common in infants on long-term PN. It usually presents as osteopenia in preterm infants, but fractures and rickets can also occur (Reference 54). Preterm infants are at the greatest risk because they missed the third trimester when the highest calcium and phosphorus accretion normally occurs. Metabolic bone disease may be related to insufficient provision of calcium and phosphorus, increased renal excretion of calcium, or aluminum contamination in the PN solution. To reduce the incidence of metabolic bone disease in infants, calcium and phosphorus should be maximized to amounts that can be safely administered by PN, as well as given in the appropriate ratio; supplemental vitamin D may also be necessary.

Patients receiving PN therapy are at increased risk of infection because of the presence of an intravenous catheter. The most common organisms are coagulase-negative *Staphylococcus*, *Staphylococcus aureus*, *Enterococcus*, and *Candida* spp. (Reference 55). Organisms can be introduced from the skin, from the hub of the catheter, or by hematogenous spread from another location in the body. Catheter-related bloodstream infections begin with infection at the catheter site. In addition to systemic antibiotic therapy, treatment may include catheter removal. However, if the child depends on PN for hydration and nutrition, he or she will continue to require central venous access. Lock therapy may also be used in an effort to salvage the catheter (Reference 56). This may include the placement of an antibiotic or ethanol into the catheter lumen, where it is allowed to dwell for a time, after which the solution is flushed through the catheter or withdrawn. The use of antibiotic or ethanol lock therapy requires the patient to be cycled off PN and not receiving other systemic medications through the catheter for the duration of the dwell time. Thus, the dwell time can vary from a few hours per day to the entire time the catheter is not in use for PN or other medication administration. If lock therapy is being used for treatment of catheter-related bloodstream infection, it is commonly given daily, whereas lock therapy for prevention of catheter-related bloodstream infection is

given less frequently (1–3 times/week). In patients with multi-lumen catheters, lock therapy should be alternated between all the lumens of the catheter for optimal results.

#### SAFETY CONSIDERATIONS IN NUTRITION SUPPORT

Specialized nutrition support has been associated with several safety issues in which serious harm and/or death have occurred. Commonly reported errors with EN that have resulted in patient death include the contamination of EN formulations and enteral feeding misconnections. Enteral nutrition contamination may occur at any point in the compounding, reconstitution, handling, and administration processes. Enteral feeding misconnections have occurred when feeding formulations for enteral delivery have been infused into non-enteral sites, such as a central venous catheter. The American Society of Parenteral and Enteral Nutrition has published EN guidelines that address these safety issues and give recommendations for preventing EN-related errors (Reference 15).

Parenteral nutrition is a complex formulation of macro- and micronutrients and additives. Parenteral nutrition has been associated with several errors that have resulted in serious patient harm and death, including calcium phosphate precipitation, contamination of PN formulation, over- or underdosing of dextrose,

**Table 4.** Select Potential Drug–Nutrient Interactions with PN (References 16, 20, 51, 52)

Drug or Class	Interaction	Recommendation
Albumin	Glycosylation of albumin may occur when it is exposed to dextrose. Clogging of 0.2-micron filters may occur. Creaming of TNAs may occur.	Do not add to PN formulations.
Heparin	Lipid instability may occur in the presence of high concentrations of heparin.	Add low-dose heparin to lipid-free PN formulations only.
Histamine-2 receptor antagonists	No effect on stability or effectiveness has been shown to occur.	Histamine-2 receptor antagonists may be added to PN formulations (lipid-free or TNA).
Hydrochloric acid	Cracking of TNAs may occur.	Add to lipid-free PN formulations only.
Insulin	No effect on stability or effectiveness of regular human insulin has been shown to occur. Other insulins are not compatible.	Add regular human insulin to PN formulations only.
Iron dextran	Lipid instability may occur when iron dextran is added.	Add to lipid-free PN formulations only.
Octreotide	Octreotide may be listed as physically compatible, but glycosylation may occur when it is exposed to dextrose that leads to inactive metabolites.	Do not add to PN formulations.
Sodium bicarbonate	Sodium bicarbonate combines with calcium to form a calcium carbonate precipitate.	Do not add to PN formulations.

PN = parenteral nutrition; TNA = total nutrient admixture.

omission of dextrose, iron overload, trace element overdoses, overdose of electrolytes, and heparin overdoses. Errors that have resulted in patient harm have occurred throughout the PN process (PN ordering, order entry/verification, PN compounding and labeling, and PN handling and administration). The American Society of Parenteral and Enteral Nutrition has published guidelines with recommendations for the safe provision of PN formulations (Reference 18).

Pharmacists in many different practice sites, including home care, institutional pharmacy, and clinical pharmacy, play an integral role in providing specialized nutrition support to patients. Many clinical pharmacists who specialize in nutrition support are directly responsible for ordering PN formulations. Parenteral nutrition solutions are typically compounded in the pharmacy, whereas EN formulations may or may not be dispensed from the pharmacy. Pharmacists are thus responsible for PN order review and verification before compounding. Pharmacy departments responsible for preparing EN and PN formulations should be aware of the safety issues associated with specialized nutrition support, remain current with recommended standards and guidelines for nutrition support, and institute safeguards within their practices to ensure the safe and effective administration of EN and PN to their patients.

## CONCLUSIONS

Specialized nutrition support has been lifesaving for many pediatric disease states. Pharmacists practicing in nutrition support should be able to adequately assess nutrition status, understand the appropriate indications for EN and PN use in patients, order and compound EN and PN formulations, avoid drug-nutrient interactions, monitor patients for complications associated with therapy, and ensure the effective and safe use of nutrition therapy in patients.

# CHAPTER 21

## PEDIATRIC OBESITY

Sandra Benavides, Pharm.D.

### LEARNING OBJECTIVES

1. Illustrate the pathophysiology of pediatric obesity.
2. Describe risk factors associated with pediatric obesity.
3. Understand the diagnosis and classification of overweight and obesity in pediatric patients.
4. Discuss treatment goals and strategies for the management of obesity in pediatric patients.
5. List the benefits and limitations of current pharmacologic therapy for the treatment of obesity in pediatric patients.

### ABBREVIATIONS IN THIS CHAPTER

AAP	American Academy of Pediatrics
BMI	Body mass index
CDC	Centers for Disease Control and Prevention
LAGB	Laparoscopic adjustable gastric band
RYGB	Roux-en-Y gastric bypass
SGA	Small for gestational age

### INTRODUCTION

Pediatric obesity has reached epidemic proportions in the United States. The consequences are leading to increases in chronic health conditions that previously had only occurred in adults. Obesity can lead to many negative health outcomes in children and adolescents and substantially increases the risk of morbidity and mortality in adulthood.

### EPIDEMIOLOGY

The prevalence of obesity in this population has been increasing since the 1960s, as illustrated in Figure 1. The most dramatic increase, however, was between the 1980s and 2000s, when obesity rates tripled in the pediatric population. The most recent estimates of obesity in children and adolescents range from 15% to 27%, as illustrated in Figure 2. Although the rates are high, they appear to have stabilized (Reference 3). Rates for specific sex, racial, and ethnic groups vary as depicted in Figure 3.

Figure 1. Rising prevalence of obesity in children and adolescents in the United States between 1963 and 2008 (Reference 1).

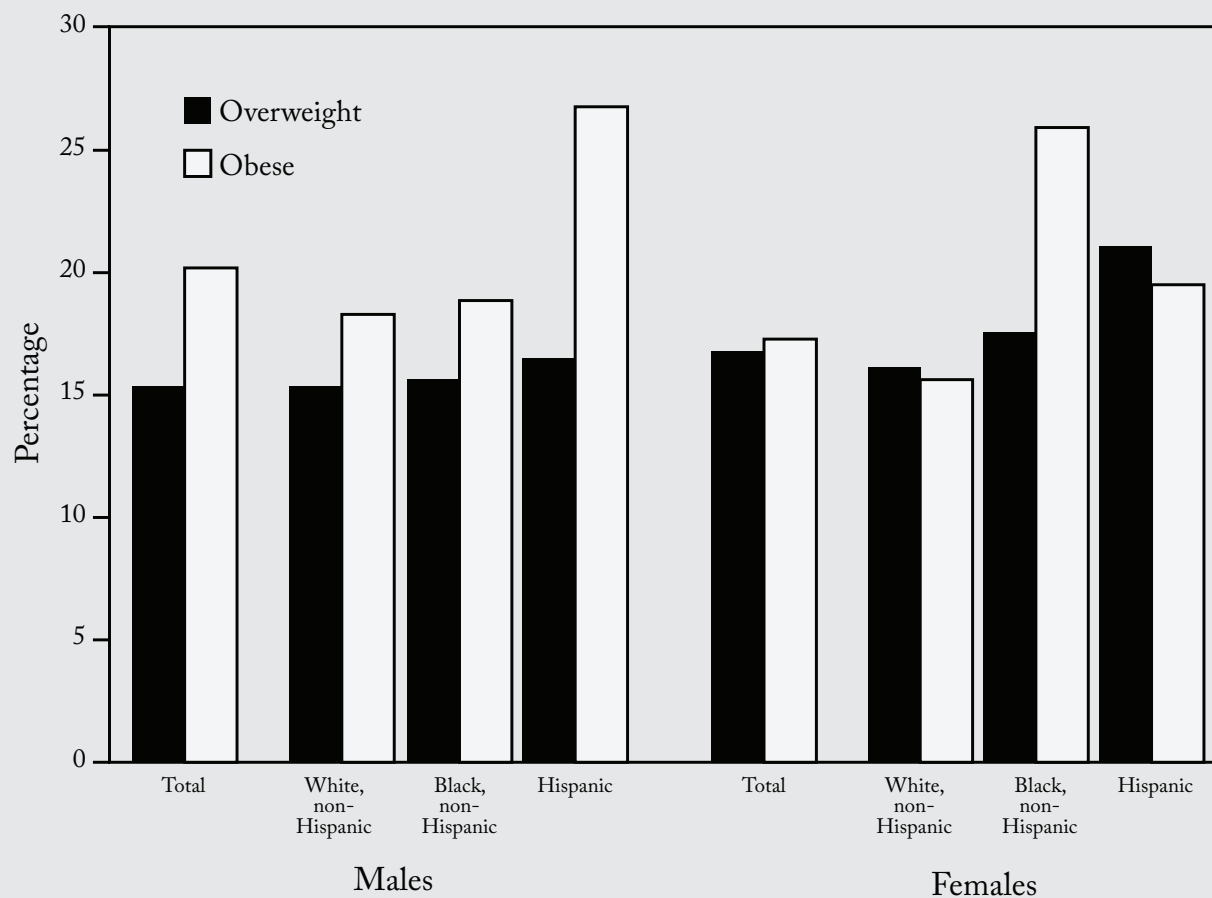

Figure 2. Prevalence of overweight and obesity in children and adolescents for 2007–2008 (Reference 2).

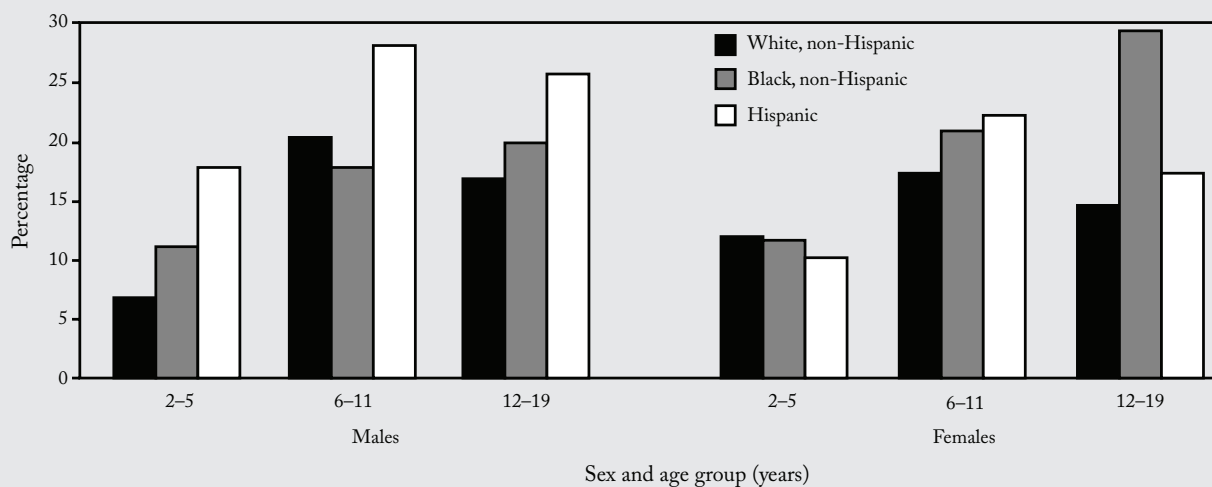

Figure 3. Prevalence of obesity among children and adolescents by sex, age group, and race/ethnicity in the United States for 2007–2008 (Reference 1).

The number of overweight children has also increased since the 1960s. More than 30% of children and adolescents between 2 and 19 years are considered overweight. Although the rates are lower for 2- to 5-year-old children at 21%, the prevalence of overweight children between 6–11 years and 12–19 years is 36% and 34%, respectively (Reference 3).

## ETIOLOGY

Obesity results from a mismatch between energy consumed and energy expended. Although a genetic component may be causative in some individuals, the present epidemic of obesity is thought to be secondary to environmental factors, including increased consumption of high-caloric, energy-dense foods; decreased physical activity; and increased television and video game time.

### Pathophysiology

The leptin-signaling pathway is the main biologic pathway responsible for maintaining energy balance in the body (References 4, 5). Several hormones and cytokines have been described in this pathway, as illustrated in Figure 4. Specific mutations in any part of the pathway can result in obesity. For example, deficient or low levels of leptin cause an increase in food consumption and decreased energy use, which may result in obesity. Other mutations that have been associated with obesity in children include pro-opiomelanocortin, cocaine-amphetamine-related transcript, brain-derived neurotrophic factor, and prohormone convertase 1 as well as in receptors for leptin, melanocortins, or brain-derived neurotrophic factor (Reference 4). However, these mutations account for only 3% to 4% of children and adolescents who are obese (Reference 5).

Obesity can also be a consequence of treatment of medical conditions (i.e., drug induced). Children with hypothyroidism, growth hormone deficiency, Cushing syndrome, or a history of trauma to the hypothalamus may present as overweight or obese. Syndromes associated with obesity include Prader-Willi, Bardet-Biedl, Alström, and Smith-Magenis. All of these disorders should be considered when evaluating an obese pediatric patient. Medications known to increase weight are listed in Table 1. If weight gain is identified in children or adolescents taking these medications, alternative drug therapy should be considered.

### Risk Factors

Pediatric obesity has been associated with several risk factors such as intrauterine exposure to gestational diabetes, diet, decreased energy expenditure, increased television viewing, race/ethnicity, socioeconomic status, and rural residence. Critical times for the development

of persistent obesity include prenatal/neonatal and early infancy, the period of adiposity rebound during the early childhood years, and adolescence.

Factors that affect obesity in childhood and adolescence during the prenatal period include maternal pre-pregnancy body mass index (BMI), gestational weight gain, maternal smoking while pregnant, and gestational diabetes. Infants born to mothers who are obese before pregnancy tend to be large for gestational age, have increased adipose tissue at birth, and be at increased risk of obesity in childhood and adolescence (Reference 6). As important as the mother's BMI before conception is the amount of weight gain during the pregnancy. Studies have reported that excessive weight gain during pregnancy is associated with obesity in children at age 3 years, 7 years, and in adolescence (References 7–9). Infants born to mothers with gestational diabetes are generally larger babies, have increased adipose tissue at birth, and have an increased risk of obesity and type 2 diabetes mellitus in adolescence (Reference 10).

Neonates born small for gestational age (SGA) are also at risk of subsequent obesity. The prenatal period is considered critical in “programming” the fetus's future metabolic, nutritional, and developmental status. The “programming” is based on the “thrifty phenotype” hypothesis in which the body learns to store excess fat and decrease energy expenditure when there is a perceived deficiency (Reference 11). Although these infants are born SGA, they often have rapid growth in early infancy. These infants appear to have an increased disposition for obesity, insulin resistance, and cardiovascular disease later in life (References 12, 13). Malnutrition and maternal smoking during pregnancy have been related to SGA births.

Breastfeeding is believed to have protective effects against childhood obesity. Infants who are breastfed for at least 1–3 months have a decreased risk of being obese (Reference 14). However, many of the studies that report the benefits of breastfeeding to prevent obesity are observational, and when confounding factors such as socioeconomic status and maternal BMI are considered, the benefits of breastfeeding are minimal (References 15, 16).

In infants, the BMI increases in the first year of life and peaks at around 1 year of age. After the peak, the BMI will slowly decline before it begins to increase, as depicted in the Centers for Disease Control and Prevention (CDC) BMI growth charts in Figure 5. The point at which the BMI begins to increase again is called the adiposity rebound. On average, adiposity rebound occurs in children between 5 and 7 years of age. However, if adiposity rebound occurs earlier than this (e.g., 2–3 years), the child is at an increased risk of obesity (Reference 18). Dietary factors known to increase the risk of obesity such as the overconsumption of high-calorie,

Figure 4. Leptin-signaling pathway.

energy-dense foods and sweetened beverages may cause an early adiposity rebound (Reference 19). The overconsumption of these foods, coupled with large portion sizes at any age, also contributes to obesity in pediatrics.

Factors that have been associated with increased obesity in pediatrics are decreases in physical activity and increases in television viewing and video/computer use. Studies have shown a relationship between obesity in children and television watching and video game playing (Reference 20). As such, the American Academy of Pediatrics (AAP) recommends no television viewing or video game playing for children younger than 2 years and no more than 2 hours/day for those older than 2 years (Reference 21). The time spent on

viewing/gaming may also replace the time spent on physical activity, which can further increase the risk of becoming obese. Children with sleeping problems (reported as having difficulty falling asleep and awaking several times a night between 6 months and 5 years of age) are also at an increased risk of obesity in early adulthood (Reference 22).

The most recent National Health and Nutrition Examination Survey reported that non-Hispanic white children and adolescents have an increased prevalence of obesity in relation to decreased socioeconomic status (Reference 23). However, most obese children do not live at or below poverty level. The obesity rates also decreased in the non-Hispanic white population

**Table 1. Medications Associated with Weight Gain**

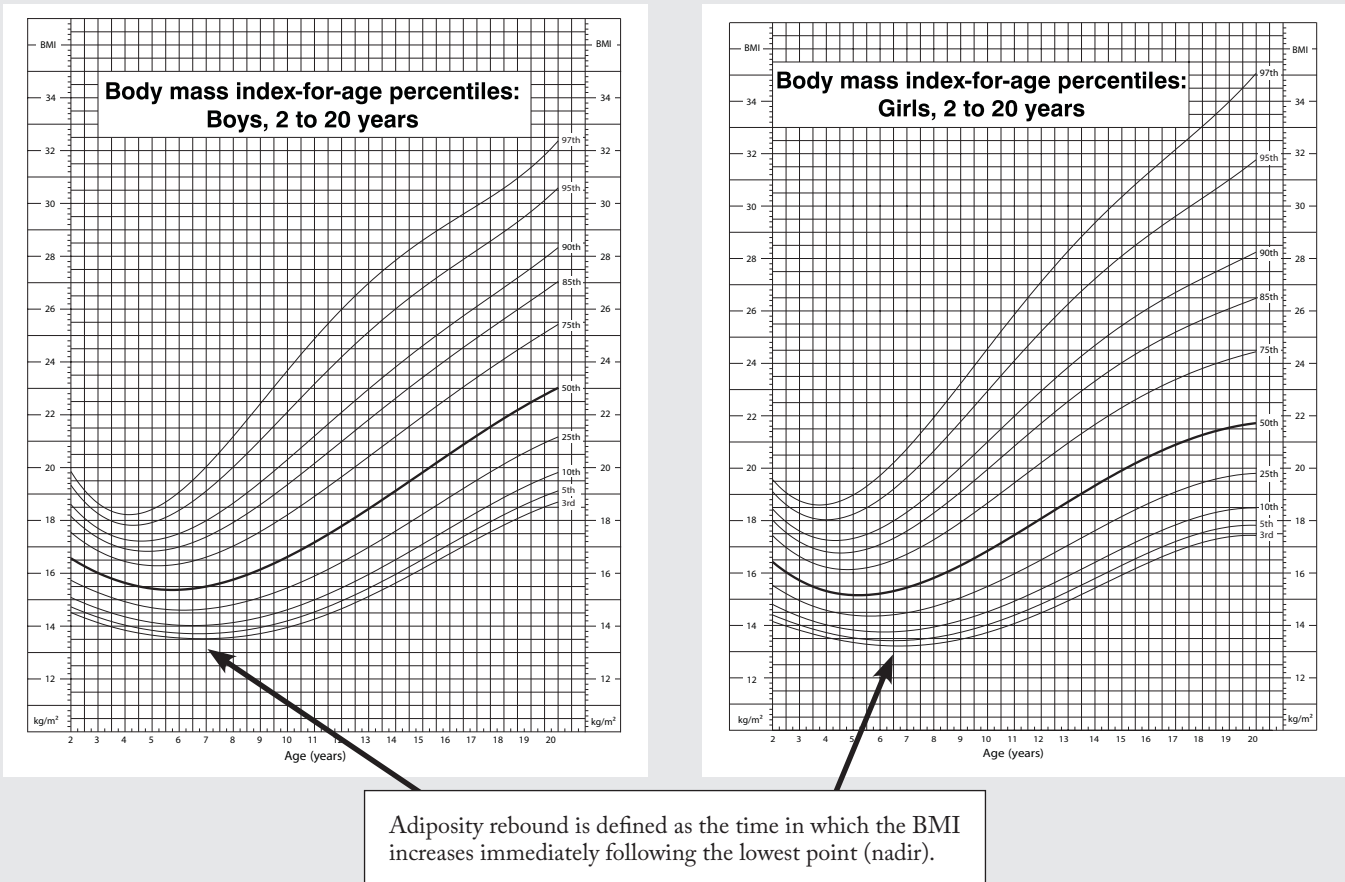

Class	Examples
Anticonvulsants	Valproic acid, gabapentin, carbamazepine
Antihistamines	Diphenhydramine, cyproheptadine
Antihypertensive agents	Clonidine, propranolol, nifedipine
Atypical antipsychotics	Olanzapine, risperidone
Glucocorticoids	Prednisolone, prednisone
Hormonal contraceptives	Depot medroxyprogesterone
Insulin	Regular insulin, insulin aspart, glargine
Insulin secretagogues	Glyburide, glipizide
Mood stabilizers	Lithium
Tricyclic antidepressants	Amitriptyline, imipramine, nortriptyline

References 4, 5.

as the head of household level of education increased (Reference 23). With respect to race and ethnicity as risk factors for obesity, African American females and Mexican-American males appear to have had the largest increases in BMI since the 1970s (Reference 24) and the highest prevalence of obesity in the United States (Reference 3). Although urban residence is attributed to increased obesity rates worldwide, children and adolescents living in rural areas of the United States tend to be more obese compared with those living in urban areas (Reference 25).

### CLINICAL PRESENTATION AND DIAGNOSIS

The identification of obesity is determined on the basis of an increased amount of adipose tissue that can result in adverse health outcomes (e.g., cardiovascular disease). Although excess adipose tissue has been correlated with health risks, specifically cardiovascular disease (Reference 26), the exact amounts necessary to cause disease have not been described. In addition, there is no easy method to quantify the amount of excess adipose tissue in a pediatric patient. For that reason, weight, adjusted

**Figure 5.** Centers for Disease Control and Prevention body mass index growth charts (Reference 17).

for height, is used as a measure of body fat. The accepted and recommended tool to assess body fat is the BMI, which is defined as weight (in kilograms) divided by the square of height (in meters) [BMI = kg/m<sup>2</sup>]. In adults, specific absolute BMI values have been determined to define obesity. In pediatric patients, however, the BMI distribution changes with age, and an absolute BMI would not be appropriate to classify children as obese. For that reason, specific percentile cutoff points, as illustrated in Table 2, have been established to define obesity in children and adolescents. Of note, BMI percentiles are not available and are therefore not included in the CDC growth charts for children younger than 2 years. In this age group, infants and toddlers above the 95th percentile for weight-for-height are considered overweight, but no obesity classification exists. Because of the increase in children and adolescents who are extremely overweight, the “severe obesity” category has been established and defined as a cutoff point greater than the 99th percentile. However, the standard CDC growth charts do not designate the 99th percentile. Table 3 defines the specific cutoff points for the 99th percentile for specific ages and sex for children older than 5 years because data for children younger than 5 years are not available. The term *overweight* defines a child or adolescent who has a higher weight for height and sex, but the weight may be not be caused by excess adipose tissue. These children must be further evaluated for risk factors for future obesity.

All children and adolescents identified as either overweight or obese should be further evaluated for medical and behavioral risks of obesity and subsequent disease. Assessments should include: the child’s history and physical examination, the child’s growth history based on a CDC growth chart, the child’s family history (including parental obesity), and the child’s activity level, dietary habits, and sedentary time (Reference 27). A complete history will aid in identifying modifiable lifestyle factors. Although no specific laboratory analyses are required for diagnosing obesity, a lipid panel, fasting glucose concentration (or fasting insulin level), and baseline alanine aminotransferase and aspartate aminotransferase should be obtained (Reference 4) to assess whether complications of obesity are present. Underlying endocrine and genetic defects or syndromes must be considered when giving a child or adolescent a diagnosis of obesity.

Alternative methods of quantifying adiposity in pediatrics have been described. Direct measurement of adipose tissue using dual-energy x-ray absorptiometry, densitometry, air displacement plethysmography, or bioelectrical impedance can provide a more accurate measure of adipose tissue, but these measurements are not practical in the clinical setting. Other indirect measures of adiposity include waist circumference or skinfold

**Table 2.** Weight Classifications in Children and Adolescents 2–18 Years of Age

Weight Category	Criteria
Overweight	BMI-for-age between the 85th and 95th percentile
Obese	BMI-for-age greater than the 95th percentile
Severely obese	BMI-for-age greater than the 99th percentile

BMI = body mass index.  
Reference 27.

**Table 3.** Cutoff Points for the 99th Percentile BMI for Age and Sex for Children and Adolescents Older than 5 Years

Age (years)	99th Percentile BMI Cutoff Point (kg/m <sup>2</sup> )	
	Male	Female
5	20.1	21.5
6	21.6	23.0
7	23.6	24.6
8	25.6	26.4
9	27.6	28.2
10	29.3	29.9
11	30.7	31.5
12	31.8	33.1
13	32.6	34.6
14	33.2	36.0
15	33.6	37.5
16	33.9	39.1
17	34.4	40.8

measurement. Waist circumference references are available for children; however, the use of waist circumference has not been shown to increase the identification of obesity in children and adolescents over using BMI (Reference 28). Although the use of skinfold thickness helps identify obesity, the additional benefits are minimal compared with using BMI, and the measurements are more cumbersome to perform (Reference 29).

## COMPLICATIONS

Childhood obesity has been related to increased morbidity and early mortality in adulthood (References 30, 31). In obesity, almost all body systems are affected. Table 4 lists complications associated with obesity. During the initial evaluation of an obese pediatric patient, it is important to determine the presence of any comorbidities for early intervention and treatment when necessary.

## PREVENTION

Preventive strategies in childhood obesity begin in the prenatal period. Pregnant women should be advised to obtain adequate prenatal care, ensure proper nutrition, and stop smoking to minimize the risk of intrauterine growth restriction. In addition, although the data are limited, it is recommended to breastfeed infants for at least 6 months to potentially decrease the risk of obesity. The AAP has several obesity-preventive strategies with respect to healthy eating and physical activity (Reference 27). These strategies are listed in Figure 6.

The American Heart Association also recommends increasing fruits and vegetables to decrease the consumption of energy-dense foods (e.g., fast food, snacks). They also recommend limiting high-calorie beverages, refined carbohydrates, excess dietary fat, and large portion sizes (Reference 33). In children younger than 2 years, it is important to provide healthy meals and snacks and to limit sugar-sweetened beverages and energy-dense foods (Reference 27).

To date, no medications and/or supplements have been studied or approved for use in healthy-weight children and adolescents for the prevention of obesity.

## TREATMENT

The treatment goal in obesity is to develop a healthy lifestyle and improve future health status (Reference 27). A recent study found that children and adolescents who are obese but lose the weight before the onset of adulthood have the same risk of type 2 diabetes mellitus, hypertension, hyperlipidemia, and atherosclerosis as children and adolescents who have never been obese (Reference 34). Such findings underscore the importance of a healthy weight in the pediatric population. However, in pediatric patients, attaining this goal may not always encompass weight loss, but rather, maintenance of growth velocity or current weight. In addition, because the stigma of being “obese” in children can cause poor self-esteem and lead to eating disorders, caution is warranted in the development of treatment plans. The AAP has detailed interventions and goals for treating obesity in children and adolescents based on age and the BMI category, as shown in Table 5.

**Table 4.** Complications of Obesity in Children and Adolescents

Body System	Complication
Cardiovascular	Atherosclerosis Dyslipidemia Hypertension
Central nervous system	Pseudotumor cerebri
Endocrine	Insulin resistance Polycystic ovary syndrome Pubertal advancement Type 2 diabetes mellitus
Gastrointestinal	Gallbladder disease Gastroesophageal reflux disease Nonalcoholic steatohepatitis
Mental health	Anxiety Decreased quality of life Depression Eating disorders Low self-esteem Social isolation
Orthopedic	Osteoarthritis Slipped capital femoral epiphysis
Pulmonary	Asthma Exercise intolerance Obstructive sleep apnea

## Therapy Goals

Specific weight goals for the treatment of obesity differ on the basis of age, initial BMI category, and presence of health risks upon diagnosis, as indicated in Table 5. Because children are growing and developing, weight loss is not always a target of therapy. Goals may include weight velocity maintenance (i.e., weight gain at a stable rate), weight maintenance, slow weight gain, gradual weight loss (defined as a loss of no more than 1 lb/month), or weight loss (defined as a loss of no more than 2 lb/week). Children and adolescents who present with risks of comorbid conditions or those with a BMI above the 99th percentile have more aggressive goals. Health risks include increases in blood pressure, evidence of insulin resistance, abnormal lipid panel, and strong family history of obesity, type 2 diabetes mellitus, or cardiovascular disease. In children younger than 2 years, there is no specific weight goal regardless of the weight-for-height percentile (Reference 27).

1. Eat a well-balanced diet with regards to fat, carbohydrates, and protein as recommended by the U.S. Department of Agriculture (USDA).
2. Consume the USDA-recommended numbers of fruit and vegetables for each specific age group.
3. Eat a diet rich in calcium.
4. Eat a high fiber diet.
5. Eat breakfast every day.
6. Limit the amount of sugar-sweetened drinks including sodas, sports drinks, and sweetened fruit juice.
7. Limit the consumption of energy-dense foods.
8. Limit the number of times a family eats at restaurants, especially fast food restaurants.
9. Eat meals together as a family at the dinner table.
10. Pay particular attention to nutrition labels with regards to portion sizes in an effort to avoid large portion sizes.
11. Limit television viewing to less than 2 hours per day for children greater than 2 years of age. Children less than 2 years of age should not view any television.
12. Ensure physical activity for at least 1 hour per day.
13. Involve the entire family in healthy lifestyle modifications.

**Figure 6.** American Academy of Pediatrics obesity-preventive strategies (Reference 27).

**Table 5.** Interventions for Weight Loss and Weight Goals Based on Age and BMI Categories

Age (years)	BMI Category	Weight Goal	Initial Intervention	Highest Intervention
< 2	Weight-for-height $\geq$ 95th percentile	N/A	Prevention counseling	Prevention counseling
2–5	85th–94th percentile with no health risks	Weight velocity maintenance	Prevention counseling	Prevention counseling
	85th–94th percentile with health risks	Weight maintenance <b>OR</b> slow weight gain	Stage 1	Stage 2
	$\geq$ 95th percentile	Weight maintenance <b>OR</b> Gradual weight loss (if BMI > 21 kg/m <sup>2</sup> )	Stage 1	Stage 3
6–11	85th–94th percentile with no health risks	Weight velocity maintenance	Prevention counseling	Prevention counseling
	85th–94th percentile with health risks	Weight maintenance	Stage 1	Stage 2
	95th–99th percentile	Gradual weight loss	Stage 1	Stage 3
	> 99th percentile	Weight loss	Stage 1 (2 or 3 if family motivated)	Stage 4
12–18	85th–94th percentile with no health risks	Weight velocity maintenance; after linear growth is complete weight maintenance	Prevention counseling	Prevention counseling
	85th–94th percentile with health risks	Weight maintenance <b>OR</b> Gradual weight loss	Stage 1	Stage 2
	95th–99th percentile	Weight loss	Stage 1	Stage 4
	> 99th percentile	Weight loss	Stage 1 (2 or 3 if patient and family motivated)	Stage 4

Specific health risks include increased blood pressure, evidence of insulin resistance, dyslipidemia or strong family history of obesity, type 2 diabetes mellitus, or cardiovascular disease. Stage 1 = Prevention Plus; Stage 2 = Structured Weight Management; Stage 3 = Comprehensive Multidisciplinary Intervention; Stage 4 = Tertiary Care Intervention.

BMI = body mass index; N/A = not applicable.

## Treatment Stages

The AAP has developed five stages of intervention for the treatment of obesity in children, beginning with prevention counseling and subsequent treatment stages 1–4 (Reference 27). Prevention counseling includes the preventive strategies listed in Figure 6. Stage 1 is also known as the “Prevention Plus” stage. This stage incorporates the prevention counseling strategies with more frequent monitoring. In this treatment stage, it is recommended to allow the child to regulate his or her food intake and not to establish a “diet” or restriction of food. In implementing this stage, it is important to work with the entire family to determine goals that are reasonable for the family. For example, increasing physical activity to 1 hour/day may not be feasible, whereas starting at 15 minutes and slowly adding time may be more realistic. Also important to consider are the cultural values, financial status, work and school schedule, and motivation of the family. This stage of treatment lasts 3–6 months, and it is reevaluated if goals for the child are not being met.

Stage 2 treatment, “Structured Weight Management,” incorporates many of the same healthy lifestyle strategies as stage 1, but it differs by providing more structure. In this stage, a planned diet, including daily meals and snacks, and planned physical activity are included. The meals are planned in accordance with the USDA (U.S. Department of Agriculture) Dietary Reference Intake recommendations, which limit eating and drinking (other than water) in between meal and snack time. Food intake and physical activity are monitored more closely with food recalls and logs of physical activity. The child or adolescent is monitored and reevaluated monthly in this stage of treatment and, if necessary, moves to a different treatment stage. Dietitians, physical therapists, exercise therapists, or clinicians with additional training in these areas are typically involved in the care of these patients.

Stage 3 treatment, referred to as Comprehensive Multidisciplinary Intervention, continues to follow the structure of stage 2, but it becomes more intense in both goal setting and monitoring. Diet and physical activity are set for the child or adolescent with weight loss as a goal. In this stage, a multidisciplinary approach with input from a social worker, psychologist, dietitian, exercise specialist, and physician is recommended. For optimal results, patients are initially monitored weekly for 8–12 weeks and then monthly. Commercial programs (e.g., Weight Watchers) may be suitable at this treatment stage; however, the program should be reviewed to ensure healthy strategies are used.

The highest level of treatment, Tertiary Care Intervention (stage 4), involves more intense interventions such as medications, very low-calorie diets, and weight-loss surgery. This treatment stage is reserved for those

who are severely obese, those whose previous stages of treatment have failed, and those that are motivated and committed to the treatment. In addition, this stage requires the child or adolescent to have the maturity to understand the risks associated with medication and surgery. The details of medication use and surgical options for treatment will be discussed later in the chapter.

Treatment recommendations differ for children younger than 2 years. It is important to assess parental status for risk of future obesity. An infant of two obese parents is at high risk of being obese later in life, even if the infant is less than the 95th percentile in weight-for-height. It is not recommended to restrict caloric intake in this age group regardless of weight-for-height. Instead, parents should be counseled on obesity-preventive strategies. Such strategies (listed in Figure 6) include breastfeeding the infant from birth to at least 1 year of age and avoidance of sugar-sweetened beverages and high-fat, energy-dense foods (e.g., chips, French fries). For children between 12 and 24 months, additional nutritional strategies include limiting the amount of milk consumed because more than 24 oz/day may cause the child not to eat other healthy foods. At this age, it is important not to restrict food intake, but to provide the toddler with healthy meal and snack options. It is advised to provide three meals a day at a table with the family. Young children will typically eat two additional snacks per day.

## Pharmacotherapy

Orlistat (Xenical) is presently the only medication approved for the treatment of obesity in the pediatric population. Previously, sibutramine (Meridia) was approved for use in adolescents older than 16 years; however, it was removed from the U.S. market in 2010 because of the increased risk of nonfatal myocardial infarctions and strokes associated with its use (Reference 35). The use of metformin (Glucophage) has shown some positive results in decreasing weight; however, it is not currently approved or recommended for use in this population. There are no nonprescription medications or supplements recommended for use in the pediatric population for the treatment of obesity.

### *Orlistat (Xenical)*

Orlistat reversibly inhibits pancreatic lipases in the stomach and small intestine. The inhibition of the enzymes prevents the digestion of dietary fat (in the form of triglycerides) to absorbable free fatty acids and monoglycerides. As a result, orlistat inhibits around 30% of ingested dietary fat, leading to decreased caloric intake and weight loss. Orlistat is minimally absorbed as it

exerts its action in the gastrointestinal tract. It is metabolized primarily in the gastrointestinal wall, with 97% excreted in the feces. The elimination half-life of the drug is between 1 and 2 hours (Reference 36).

The efficacy of orlistat has been evaluated in pediatric patients 8–18 years of age. Clinical trials have shown a decrease in BMI ranging from 0.5 to 4.1 kg/m<sup>2</sup> with a dose of 120 mg three times/day (References 37–41) in combination with lifestyle modifications. About 30% of patients in clinical trials lost >5% of body weight, whereas 15% lost >10% of body weight. One study evaluating the long-term efficacy of orlistat found that the BMI decreased by 0.55 kg/m<sup>2</sup> in the orlistat-treated group and increased by 0.31 kg/m<sup>2</sup> in the placebo group after 1 year (Reference 37). However, although there was an overall decrease in BMI, participants in both treatment arms gained weight throughout the year. Clinical trials, however, had drop-out rates from 20% to 35% due to adverse drug reactions. The most commonly reported adverse drug effects included mild to moderate gastrointestinal upset in almost all the patients. These included nausea, fatty/oily stool, oily spotting, oily evacuation, fecal urgency, frequent stools, diarrhea, abdominal pain, fecal incontinence, and flatulence (with and without discharge). Other serious adverse effects reported included systemic cholelithiasis leading to a cholecystectomy in one patient (Reference 37).

Orlistat appears to decrease the absorption of fat-soluble vitamins, resulting in decreases in serum levels of vitamin D (Reference 42). All pediatric patients taking orlistat should supplement with a multivitamin containing vitamin A (5,000 IU), vitamin D (400 IU), vitamin E (300 IU), and vitamin K (25 mcg). The vitamin is best administered at least 2 hours before or after the administration of orlistat. In patients on anticoagulation therapy with warfarin, the decrease in vitamin K absorption may cause an increase in the INR (international normalized ratio). Close monitoring is warranted for patients concomitantly taking orlistat and warfarin. Orlistat also decreases the absorption of levothyroxine and cyclosporine. It is advised to separate orlistat and levothyroxine by at least 4 hours. It is not recommended to use orlistat if the patient is taking cyclosporine. However, if the two drugs are used concomitantly, they must be separated by at least 2 hours, and careful monitoring of cyclosporine levels is critical.

The recommended dose of orlistat in children older than 12 years is 120 mg orally three times/day with meals. The dose is taken during the meal or up to 1 hour after the meal. It is not recommended to exceed three doses/day. Patients should also be advised to limit fat intake to a maximum of 30% of total caloric intake and to divide between the three meals. If a meal does not

contain fat, it is not necessary to take the medication. Although orlistat is available as an over-the-counter medication (Alli), the manufacturer does not recommend its use in anyone younger than 18 years.

### ***Metformin (Glucophage)***

Metformin has been evaluated for weight loss in obese children and adolescents (9–18 years of age) with and without insulin resistance. Metformin decreases hepatic glucose production and intestinal absorption of glucose and improves insulin sensitivity. On administration, about 50% to 60% is systemically absorbed. It is not bound to plasma proteins. Metformin is excreted unchanged in the urine by tubular secretion. The elimination half-life of metformin is about 17 hours (Reference 43).

Small, short-term studies of metformin for weight loss have found decreases in weight ranging from 4.4 to 6.1 kg (References 44, 45) and decreases in BMI of 0.16–0.5 kg/m<sup>2</sup> (References 46, 47). However, of note, these studies were short (maximum of 6 months), had a limited number of subjects, and did not always show a significant difference over placebo. Further studies are necessary to evaluate the role of metformin in weight loss of obese children and adolescents.

Commonly reported adverse effects of metformin in the studies included nausea, dizziness, and loose stools. No reports of serious adverse reactions, such as lactic acidosis, were reported. In addition, no studies monitoring serum creatinine and liver function enzymes reported any abnormalities. Minimal clinically significant drug interactions exist with metformin. However, metformin must be discontinued before administering intravenous iodinated contrast materials and not reinitiated until 48 hours after the procedure and adequate renal function is restored. Adolescents should also be cautioned regarding acute or chronic alcohol use because alcohol can increase the risk of lactic acidosis.

The doses used for weight loss ranged from 500 to 1000 mg orally twice daily. In the study using 1 g twice daily, the dose was titrated up during a 3-week period. Metformin should be given with meals.

### **Surgical Therapy**

The last line of therapy for obesity is surgical intervention. However, before electing for weight-loss surgery in pediatric patients, the matter must be given careful consideration. Some factors to consider include BMI, comorbidities, physical and emotional maturity, and ability to adhere to the lifestyle modifications required after surgery.

In general, pediatric patients considered for weight-loss surgery include those with a BMI greater than 30 kg/m<sup>2</sup> with a serious comorbidity such as type 2 diabetes mellitus, moderate or severe obstructive sleep apnea,

pseudotumor cerebri, or severe steatohepatitis. Many of these comorbidities have been reported to improve or completely resolve after weight-loss surgery (References 48, 49). Other candidates for weight-loss surgery include children and adolescents with a BMI greater than 40 kg/m<sup>2</sup> with or without comorbidities (Reference 50).

Two types of weight-loss surgery have been successfully performed in pediatric patients: the Roux-en-Y gastric bypass (RYGB) and the laparoscopic adjustable gastric band (LAGB) procedure. The RYGB involves the creation of a 15- to 30-mL gastric pouch to bypass the small intestine (Reference 51). This form of weight-loss surgery is restrictive and decreases the amount of nutrients absorbed. In adolescents, the RYGB can lead to a weight loss of 18–22 BMI units (Reference 49) with weight loss efficacy rates reported at about 60% in adolescents (Reference 48). To date, no in-hospital deaths immediately after the surgery have been reported, although one patient with a presurgical BMI of 80 kg/m<sup>2</sup> died 9 months after surgery because of several complications. Complications of this surgery include shock, pulmonary embolism, severe malnutrition, postoperative bleeding, and gastrointestinal obstruction. Because the RYGB weight-loss surgery often results in nutritional deficiencies, it is recommended to postpone this surgery in children and adolescents until after they have attained at least 95% of adult stature. Two assessments should be completed before surgery, Tanner staging and evaluation of bone age (Reference 50). Because most linear growth spurts occur before puberty, it is advised to defer weight-loss surgery until after Tanner stage IV is reached in both boys and girls. In addition, bone age can be determined with radiography of the hands and feet. If this criterion is followed, the child will typically be older than 12 years. The RYGB can still be considered in individuals not meeting this criterion if they present with severe obesity and comorbidities.

The LAGB involves the placement of a silicone adjustable band on the upper portion of the stomach that results in a small pouch for food (Reference 51). The band is adjusted after surgery and throughout the weight-loss period. This form of weight-loss surgery is not restrictive and does not result in the same nutritional deficiencies as the RYGB. The LAGB has shown weight loss in adolescents ranging from 11 to 14 BMI units with weight loss efficacy rates reported from 15% to 87% (Reference 48). To date, no deaths have been reported with LAGB surgery. Complications of surgery in this population include band slippage, gastric dilation, intragastric band migration, psychological intolerance of band, hiatal hernia, cholecystitis, and cracking of the band. Currently, the LAGB is not indicated in pediatric patients and is considered investigational.

Both forms of surgery still require further research to determine long-term efficacy and safety. These forms of surgery should not be considered until all other treatment options have been attempted and failed.

It is crucial for any child or adolescent being considered for weight-loss surgery to have the emotional maturity to understand the risks associated with surgery, the motivation to adhere to lifestyle modifications after the surgery, and familial support. In addition, any psychiatric condition should be actively treated and in remission for at least 1 year before the surgery is performed. Typically, the surgery is performed at a center with a multidisciplinary team specializing in obesity.

## THErapy MONITORING

All children and adolescents should have a yearly height and weight assessment. In those older than 2 years, a BMI should be calculated and plotted on the CDC growth charts to determine the percentile. Any child classified as overweight or obese may require additional laboratory analysis and a physical examination for existing complications of obesity. Weight, height, and BMI are adequate assessments for follow-up; anthropometric measurements (such as skinfold and waist circumference) are unnecessary. Follow-up laboratory parameters will vary according to the individual child and his or her presenting symptoms. Dietary intake and physical activity should be reviewed at each visit.

For children and adolescents on pharmacotherapy for obesity, additional monitoring is necessary. During treatment with orlistat, a baseline vitamin D level should be obtained. Regardless of whether a multivitamin is also prescribed to the patient, a follow-up vitamin D level should be considered every 3–6 months during orlistat therapy. Patients should be monitored for adverse reactions, which typically subside within 4 weeks of therapy (Reference 36). During treatment with metformin, a baseline serum creatinine level is recommended. Metformin is contraindicated if serum creatinine levels are greater than 1.4 mg/dL and 1.5 mg/dL in females and males, respectively (Reference 43). It is also not recommended for use in those with hepatic disease (Reference 43).

## CONCLUSIONS

Many challenges exist in the prevention and treatment of pediatric obesity. However, assessing BMI at each encounter with a pediatric patient will assist in identifying those who are overweight and obese for the implementation of lifestyle modifications. Early intervention may halt the progression of complications in this population.

# CHAPTER 22

## NEPHROTIC SYNDROME

Michael Chicella, Pharm.D.

### LEARNING OBJECTIVES

1. Recognize the signs and symptoms of nephrotic syndrome.
2. List the three common pathologic types of nephrotic syndrome.
3. Explain the treatments that can be used to control edema associated with nephrotic syndrome.
4. Discuss the drug treatments used to induce remission and prevent relapse of nephrotic syndrome.
5. Discuss the adverse drug effects associated with drug treatments used in nephrotic syndrome.
6. Discuss the prognosis associated with nephrotic syndrome.

### ABBREVIATIONS IN THIS CHAPTER

ACE	Angiotensin-converting enzyme
ARB	Angiotensin type II receptor blocker
HMG-CoA	Hydroxymethylglutaryl coenzyme A

### INTRODUCTION

Nephrotic syndrome is one of the more common childhood kidney diseases. It is characterized by edema, proteinuria, and hypoalbuminemia that cycle through periods of exacerbation and remission. Proper diagnosis and treatment of nephrotic syndrome are essential because it is associated with a spectrum of clinically important sequelae that can progress to end-stage renal disease if not properly managed.

### EPIDEMIOLOGY

Nephrotic syndrome affects 16 in 100,000 children, making it one of the more common childhood kidney diseases (Reference 1). Most patients present between 1 and 7 years of age. There is a male predominance in nephrotic syndrome, as there is in chronic kidney disease in general (Reference 2). In addition, African-American and Hispanic children have a greater incidence of disease, a poorer prognosis, and a more rapid progression to renal failure (Reference 3).

### ETIOLOGY

Nephrotic syndrome can result from any glomerular injury associated with proteinuria. Most cases are idiopathic; however, nephrotic syndrome can be congenitally acquired, or it can develop in patients with other diseases such as Berger's disease, Henoch-Schonlein purpura, systemic lupus erythematosus, and poststreptococcal glomerulonephritis. Nephrotic syndrome has also been associated with infections such as syphilis, hepatitis B, and human immunodeficiency virus. In addition, certain medications, including nonsteroidal anti-inflammatory medications and anticonvulsants, may cause nephrotic syndrome.

There are three common pathologic types of nephrotic syndrome: membranoproliferative glomerulonephritis, focal segmental glomerulosclerosis, and, most commonly, minimal lesion or minimal change disease. Minimal change disease accounts for more than 70% of nephrotic syndrome cases (Reference 1). Patients with minimal change disease generally respond well to corticosteroids and have the most favorable prognosis. Patients with either membranoproliferative glomerulonephritis or focal segmental glomerulosclerosis are generally less responsive to corticosteroids and are at a greater risk of progressing to renal failure (Reference 4).

### CLINICAL PRESENTATION AND DIAGNOSIS

The primary clinical features of nephrotic syndrome are proteinuria, hypoalbuminemia, and edema. Hyperlipidemia and hypertension are also often associated with nephrotic syndrome. Some patients may lack one or more of these features; however, both proteinuria and hypoalbuminemia must be present to establish this diagnosis. With respect to edema, most patients present with periorbital, lower extremity, or genital edema. The edema can range from mild localized edema to generalized anasarca. It is generally worse in the morning because of gravitational shifts and sleep position; however, the edema can persist throughout the day. Patients may also report changes in urine appearance (e.g., "foamy urine"). Although urine normally forms bubbles in the toilet, protein acts like a stabilizer and can give urine a beer-like "head" (Reference 5). Once suspected, a urinalysis should be performed looking specifically for proteinuria. Most patients with nephrotic syndrome will have a urine

protein concentration greater than 300 mg/dL; however, a detectable level of protein in the urine lower than 300 mg/dL does not necessarily rule out nephrotic syndrome. Other laboratory analyses including blood urea nitrogen, serum creatinine, serum albumin, cholesterol, antinuclear antibody, and serum complement 3 levels should be measured to rule out other causes of proteinuria. Serum albumin is usually less than 2.5 mg/dL in patients with nephrotic syndrome (Reference 1). Most patients will have a serum cholesterol concentration above 200 mg/dL, and it is not uncommon for patients to have a serum cholesterol concentration of 600 or 700 mg/dL (Reference 5). Some experts recommend a 24-hour urine collection; however, this is difficult to accomplish, especially in children who are not toilet trained. Therefore, collection of the first morning urine to determine a urine protein-to-creatinine ratio is adequate (Reference 1). A urine protein-to-creatinine ratio greater than 2 is indicative of nephrotic syndrome (Reference 6). A renal biopsy can be performed; however, it is usually reserved for patients older than age 12 years at presentation and for patients with steroid-resistant nephrotic syndrome (Reference 1).

## TREATMENT

Treatment response, which can be variable, depends on the pathologic type of nephrotic syndrome. Corticosteroids are the mainstay of treatment for children with nephrotic syndrome, and patients are quickly determined to have either steroid-dependent or steroid-resistant nephrotic syndrome. Steroid-dependent nephrotic syndrome is associated with a good long-term prognosis (Reference 3). Many of these patients can maintain disease remission with low-dose corticosteroids given daily or every other day. Some of these patients may need other medications combined with corticosteroids to maintain remission. Prednisone, or prednisolone, is the corticosteroid commonly used. Depending on the guidelines being used, it may be dosed as milligrams per kilogram or milligrams per square meter. Prednisone is initially dosed at 2 mg/kg/day (60 mg/m<sup>2</sup>/day) up to 60 mg/day. It can be given as a single daily dose in the morning or divided into several doses. Although no difference in efficacy exists, there is at least a theoretical advantage to once-daily morning administration. This regimen would mimic the normal diurnal secretion of endogenous adrenal corticosteroids. The initial dose is usually continued for 6 weeks (Reference 1). After symptom resolution, the dose is reduced to 1.5 mg/kg/day (40 mg/m<sup>2</sup>/day) and given every other day for 6 weeks. Historically, corticosteroids were tapered off during the next 6 months, provided no recurrence of symptoms occurred; however, newer guidelines indicate that no taper is required after the initial 12 weeks of therapy (Reference 1).

Because of the extensive toxicity profile associated with exogenous corticosteroids, the sooner they can be discontinued, the better. Short-term adverse effects include hyperglycemia, hypertension, and leukocytosis. Long-term adverse effects include the previously mentioned effects plus growth retardation, osteoporosis, peptic ulcer disease, vision changes, behavioral changes, and Cushing syndrome. In addition, children receiving a prolonged course of corticosteroids can develop adrenal gland suppression. Therefore, patients may need to be given “stress” doses of corticosteroids if they are traumatized or infected or if they require surgery. If steroids cannot be discontinued, the goal should be to achieve the lowest possible dose that controls a relapse of symptoms while minimizing toxicity. Therapy response is determined by monitoring the urine protein concentration. Often, the urine protein concentration becomes undetectable within the first few weeks of corticosteroid administration. As the corticosteroid dose is reduced, urine protein should be monitored. Recurrence of proteinuria for 3 or more consecutive days indicates relapse. In patients who experience infrequent relapses, the prednisone dose is increased to 2 mg/kg/day (60 mg/m<sup>2</sup>/day) until the urine protein concentration is undetectable for 3 consecutive days. Then, the dose is reduced to 1.5 mg/kg/day (40 mg/m<sup>2</sup>/day), given every other day for 4 weeks. In patients who experience relapses more frequently, the same regimen is followed. However, after the 4 weeks of therapy is completed, the prednisone dose is tapered off over 2 months (Reference 1).

Other medications may be added to further reduce the dose of corticosteroids used or to treat patients who relapse frequently. Calcineurin inhibitors such as cyclosporine are often the first of these agents used. Cyclosporine inhibits helper T cell interleukin-2 production and causes renal arteriolar vasoconstriction. It reduces proteinuria by many mechanisms of action. In addition, cyclosporine has antiproteinuric effects by changing glomerular permeability. The usual initial dose of cyclosporine is between 3 and 5 mg/kg/day divided twice daily. Cyclosporine has several adverse drug effects associated with its use; therefore, it should be used at the lowest effective dose possible. Adverse drug effects from cyclosporine include hypertension, hirsutism, electrolyte abnormalities, and nephrotoxicity. In addition, variability exists in bioavailability between various cyclosporine products; therefore, it is usually recommended to avoid switching or substituting one product for another.

Tacrolimus is another calcineurin inhibitor used in nephrotic syndrome. Tacrolimus has inhibitory effects on CD4 helper cells. However, the mechanism behind the efficacy of tacrolimus in nephrotic syndrome is not completely understood. Investigators have shown increased inhibition of vascular permeability with tacrolimus in patients with minimal change disease (Reference 7). The

efficacy of tacrolimus may also be due to its better cytokine inhibition compared with cyclosporine (Reference 8). Regardless of the mechanism, up to 94% of patients with nephrotic syndrome improve while taking tacrolimus. Eighty-one percent of patients experience complete remission of disease (Reference 8). Tacrolimus is initially dosed between 0.05 and 0.1 mg/kg/day divided twice daily. Adverse drug effects associated with tacrolimus include hypertension, altered mental status, electrolyte abnormalities, and nephrotoxicity. Similar to cyclosporine, tacrolimus is nephrotoxic and should be used cautiously in patients with progressive renal dysfunction.

Mycophenolate mofetil is another immunomodulatory agent that is effective in the management of nephrotic syndrome. Mycophenolate is a purine synthetase inhibitor, not a calcineurin inhibitor. It has an active metabolite, mycophenolic acid, which inhibits the synthesis of T- and B-cell lymphocytes. In addition, mycophenolate inhibits vascular smooth muscle and mesangial cell proliferation, inhibits nitric oxide synthase, and induces apoptosis in activated T cells. One or more of these actions account for the effects seen in patients with nephrotic syndrome (Reference 9). Mycophenolate is initially dosed between 24 and 36 mg/kg/day divided twice daily. Adverse drug effects associated with its use include dyspepsia, diarrhea, leukopenia, and rarely lymphoma. Because nephrotoxicity is less likely with mycophenolate than with cyclosporine or tacrolimus, it may be a good alternative in patients with progressive renal insufficiency.

Cytotoxic agents such as cyclophosphamide and chlorambucil may also be used to reduce the risk of relapses without corticosteroids. Furthermore, studies have shown that the use of cytotoxic agents can extend remission by 1 year or longer (References 10, 11). These agents act by interfering with DNA by inserting alkyl chains onto purine bases, thereby causing separation during cell division. They also destroy cells by interfering with nucleic acid synthesis. Cyclophosphamide is initially dosed 2–3 mg/kg/day orally given once a day. The effectiveness of cyclophosphamide at inducing remission and reducing relapse appears to be related to the length of treatment. The optimal length of treatment appears to be 8–12 weeks (Reference 12). Chlorambucil is less commonly used than cyclophosphamide; however, when used, it is usually dosed at 0.1–0.2 mg/kg/day given once daily for 6–8 weeks (Reference 13). Alkylating agents also have significant adverse drug effects that must be weighed against their potential benefits. These include nausea and vomiting, alopecia, growth retardation, bone marrow suppression, cystitis (cyclophosphamide), and seizures (chlorambucil). Children receiving alkylating agents are also at greater risk of both viral and bacterial infections.

Some patients with nephrotic syndrome have steroid-resistant disease. The pharmaceutical management of these patients is much more difficult. Steroid resistance puts the patient at greater risk of developing complications associated with nephrotic syndrome and progression to end-stage kidney disease. The optimal therapy for steroid-resistant nephrotic syndrome remains poorly defined. Commonly used medications include calcineurin inhibitors, mycophenolate mofetil, and the cytotoxic agents. Non-immunosuppressive agents are also considered in these patients. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin type II receptor blockers (ARBs) have been shown to have an antiproteinuric effect in adults with glomerular diseases (Reference 14). Case series and small studies are available that suggest a reduction in proteinuria in children with nephrotic syndrome (References 15, 16). The mechanism responsible for the antiproteinuric effects of the ACE inhibitors is not clearly defined. Reduction of systemic and intraglomerular pressures and improved size selectivity of the glomerular basement membrane may contribute to this effect (Reference 17). In addition, because many children with nephrotic syndrome also present with hypertension, an ACE inhibitor or an ARB helps control blood pressure until disease remission is achieved. Enalapril, an ACE inhibitor, has been shown to reduce proteinuria in children with steroid-resistant nephrotic syndrome (Reference 17). Enalapril should be initiated at a dose of 0.2 mg/kg/day. Its effectiveness appears to be dose related, so its dose should be increased to a goal dose of 0.5–0.6 mg/kg/day (Reference 17). Fosinopril is another ACE inhibitor that has been shown to reduce proteinuria and renal tubular damage in children with nephrotic syndrome (Reference 18). When initiating an ACE inhibitor, or an ARB, serum electrolytes including serum creatinine should be monitored periodically.

The use of B cell-depleting therapy, rituximab, is increasing in patients with nephrotic syndrome. Rituximab is a chimeric monoclonal antibody with activity against the CD20 surface antigen of B cells. A single dose of rituximab of 375 mg/m<sup>2</sup> has been shown to be effective in children with steroid-dependent and steroid-resistant nephrotic syndrome. Treatment may have to be repeated, if necessary (Reference 19). Adverse drug effects from rituximab can include infusion-related reactions, such as fever, hypotension, rash, and bronchospasm. The adverse effect of most concern, however, is rituximab-associated lung injury, or RALI (Reference 20). Although the pulmonary injury associated with rituximab is often transient and reversible, it can be associated with potentially fatal pulmonary injuries like interstitial pneumonitis, pulmonary fibrosis, and bronchiolitis obliterans (Refer-

ence 21). A chest radiograph should be checked before starting rituximab treatment and periodically during and after treatment because the time to onset of symptoms ranges from 1 to 3 months (Reference 21).

### Supportive Therapy

The goal of supportive therapy is to control edema until remission can be achieved. Edema should be reversed slowly. To begin, dietary sodium intake should be restricted. Although restricted sodium intake is recommended, most patients have difficulty adhering to a low-sodium diet because they are less palatable than regular diets. In general, a 1-g sodium diet is recommended for younger children, and a 2-g diet is recommended for older children and adolescents. It may be possible to manage mild edema in this way. For patients with severe edema, or anasarca, diuretic therapy is often used. A loop diuretic such as intravenous furosemide is usually chosen. Furosemide is initially dosed as 1 mg/kg/dose; however, higher doses of furosemide are often required to achieve effective intratubular concentrations (Reference 22). This is because furosemide is bound to albumin in the tubular lumen of patients with proteinuria. In addition, many clinicians will give intravenous albumin before diuretic administration, although data showing improved diuresis with sequential dosing of albumin and furosemide versus furosemide alone are lacking (References 23, 24). Albumin is administered as 25% albumin, initially dosed as 0.5–1 g/kg per dose. It is given to increase the oncotic pressure and draw fluid into the intravascular space from the interstitium. Albumin is followed by furosemide. Sequential dosing of furosemide and albumin may be repeated as often as every 6 hours, depending on the patient's clinical status and response.

Patients with nephrotic syndrome are at greater risk of developing thromboembolic complications such as pulmonary embolism and deep venous thrombosis. Renal venous thrombosis is also seen in 20% to 30% of adults with membranoproliferative glomerulonephritis (Reference 25). The factors that may contribute to the risk of thromboembolic complications in nephrotic syndrome include low factor IX and factor XI levels, increased factor V and factor VIII, decreased antithrombin III, and increased platelet reactivity (Reference 22). Most of this information is from adult data, and it is difficult to extrapolate this information to children. As children get older, or if the patient has other risk factors for thromboembolic complication, they may benefit from prophylactic anticoagulant therapy. Refer to the Anticoagulation chapter for further information on appropriate anticoagulation management.

Children with nephrotic syndrome are also at increased risk of bacterial infections, particularly pneumococcal peritonitis. This is because patients with nephrotic syndrome have low levels of endogenous immune globulin. Children with nephrotic syndrome should be kept up to date on their vaccines, especially pneumococcal vaccines (Reference 26). The administration of intravenous immune globulin to maintain serum immunoglobulin G levels greater than 600 mg/dL may also help reduce the rate of bacterial infections in these children (Reference 27).

Hyperlipidemia associated with nephrotic syndrome may increase the risk of atherosclerosis and cardiovascular complications. A diet limiting fat to less than 30% of calories, saturated fat to less than 10% of calories, and cholesterol to less than 300 mg/day is recommended (Reference 1). Hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors can be used to manage hyperlipidemia in patients whose condition cannot be controlled by diet alone. There is also evidence that HMG-CoA reductase inhibitors decrease proteinuria and thus decrease renal injury (Reference 28). To date, two prospective studies have been performed to assess the efficacy of HMG-CoA reductase inhibitor therapy in children with steroid-resistant nephrotic syndrome (References 29, 30). Because some HMG-CoA reductase inhibitors may interact with other medications often used in nephrotic syndrome, such as the calcineurin inhibitors, this is an important consideration before beginning a new medication.

### Prognosis

The prognosis depends on the pathologic type of nephrotic syndrome and on whether the patient has steroid-dependent or steroid-resistant disease. Children with minimal change disease generally respond well to treatment, with the best prognosis and the fewest disease-related complications. Conversely, patients with focal segmental glomerulosclerosis can develop considerable glomerular scarring, leading to end-stage renal disease and ultimately resulting in transplantation (Reference 31). Similarly, patients with steroid-resistant disease are at greater risk of developing progressive kidney injury than patients with steroid-dependent disease (Reference 1). Regardless of the type of nephrotic syndrome, exacerbations can occur in most patients throughout life, and many of these patients will eventually become steroid-dependent (Reference 32).

### CONCLUSIONS

Nephrotic syndrome is a chronic disease that begins in childhood and continues throughout life. It is characterized by periods of remission and exacerbation. For many patients, it can be controlled with the use of corticosteroids; however, in some patients, other

medications with significant adverse drug reaction profiles need to be used. Hence, the pharmacist should play an integral role in the pharmaceutical management of children with nephrotic syndrome.

# CHAPTER 23

## OSTEOGENESIS IMPERFECTA

Michael Chicella, Pharm.D.

### LEARNING OBJECTIVES

1. Compare and contrast the seven pathologic types of osteogenesis imperfecta (OI).
2. Describe the prognosis of OI.
3. List the signs and symptoms of OI.
4. Describe the use of calcitonin in the management of OI.
5. Describe the use of bisphosphonates in the management of OI.

### ABBREVIATION IN THIS CHAPTER

OI                      Osteogenesis imperfecta

### INTRODUCTION

Osteogenesis imperfecta (OI), historically referred to as brittle bone disease, is a rare genetic bone disorder. It is a heterogeneous group of conditions characterized by bone fragility and decreased bone mass. The classic and most common manifestations of OI are categorized as four types: I–IV. Patients with these four types of OI have mutations in the type I or type II collagen (*COL1A1*, *COL1A2*) genes. These mutations are caused by autosomal dominant genetic derangements of collagen type I, which is the main protein found in bone. Collagen type I contributes to cortical thickness and bone strength. Recently, other types of OI that have no collagen mutation were identified. Type V is also caused by an autosomal dominant genetic derangement. The mode of inheritance of type VI is unknown; type VII is caused by an autosomal recessive disorder. Type VII has only been reported in First Nations people in Quebec (Reference 1).

Individuals with OI suffer from recurrent fractures. Patients who live into adulthood experience chronic bone pain, deformities, and disabilities. Caring for these patients can be challenging for families and caregivers. In the most extreme cases, even minor activities, such as changing diapers or cuddling, can result in fractures if not done with the utmost care. As children with OI grow older, traditional childhood activities like playing football, jumping on a trampoline, or playing on playground equipment can result in significant injury. Parents and caregivers can find it difficult to allow their children to be “normal” while protecting them from injury.

### EPIDEMIOLOGY

Osteogenesis imperfecta occurs in about 1 of every 20,000 births, and according to the Osteogenesis Imperfecta Foundation, between 20,000 and 50,000 people in the United States have OI (Reference 2). There is no ethnic or sex-based predisposition to OI. Because most types of OI are caused by a dominant genetic mutation, most patients will have a parent with a diagnosis of OI. However, around 25% of children with OI are born into a family with no history of OI (Reference 2). The diagnosis of OI is usually made in infancy; however, some mild forms of the disease may not be diagnosed until later in childhood.

### PATHOPHYSIOLOGY

The pathophysiology of OI with collagen type I molecule mutations (types I–IV) is best understood and is discussed in this section. Very little is known about the pathogenesis of OI types V–VII (Reference 3). Collagen type I molecules consist of three polypeptide chains — two alpha 1 and one alpha 2 chains. These chains twist to form a triple-helical structure. For the chains to intertwine correctly, they must have a glycine residue at every third position. Substitution at the glycine residues can result in abnormalities and produce a mixture of normal and abnormal collagen strands. Abnormal collagen has lower tensile strength, resulting in brittleness of the bones (Reference 4).

### CLINICAL PRESENTATION

The presentation of OI varies according to the age of the patient at diagnosis and the type of disease the patient has. The clinical features of each type are outlined in Table 1. Patients may present asymptotically or with classic signs of OI such as blue sclera and a history of fractures and wormian bones (extra bone pieces in the suture lines of the skull). The severity of illness also depends on the type of OI. Severity increases in the following order: type I < IV, V, VI, VII < type III < type II (Reference 3).

Type I is the most common form of the disease and is considered the mildest. Patients with OI type I have minimal bone deformities. Fractures usually involve

**Table 1.** Types of Osteogenesis Imperfecta

Type	Severity	Clinical Features
I	Mildly deforming	Normal height, blue sclera
II	Life threatening	Rib and long bone fractures at birth, severe deformities, dark or blue sclera
III	Severely deforming	Very short stature, triangular face, scoliosis, blue to gray sclera, dentinogenesis imperfecta
IV	Moderately deforming	Short stature; scoliosis; gray, blue, or white sclera; dentinogenesis imperfecta
V	Moderately to severely deforming	Short stature, dislocated radial head, calcification of interosseous membrane, hyperplastic callus
VI	Moderately to severely deforming	Short stature, scoliosis, accumulation of osteoid in bone tissue, fish-scale pattern of bone lamellation imperfect
VII	Moderately to severely deforming	Short stature

Adapted from Reference 3.

the long bones; however, vertebral compression fractures can also occur, especially during periods of rapid growth such as puberty.

Patients with OI type II are at high risk of dying during the perinatal period. These patients develop several fractures, both in utero and during the birth process. Many patients die of respiratory distress or failure secondary to rib fractures. Theoretically, fractures could potentially be minimized by delivering the baby by cesarian section if OI is diagnosed before delivery; however, literature showing that cesarian sections reduce fractures or improve mortality is lacking (Reference 5). Patients with OI type II also have bone deformities. Their bones have low mineral density and are usually short and broad.

Children with OI type III usually do not survive past the newborn period. These patients typically suffer from fractures even after mild trauma and develop bone deformities involving the long bones and vertebrae. Because of this, children with OI type III are unable to walk and will require mobility assistance with a wheelchair. They may also have mandibular deformities, giving the child a triangular face. Similar to patients with OI type II, patients with OI type III die of respiratory failure associated with rib fractures. Other manifestations of OI common to types I–III include dentinogenesis imperfecta (tooth abnormalities), hyperlaxity of ligaments, and wormian bones. Most of these patients will also have bluish sclera because of abnormal collagen formation.

The presentation of patients with OI type IV varies greatly. Patients may experience very few fractures, or they may experience multiple fractures even after the most minor trauma. These patients may be ambulatory,

or they may require a wheelchair for mobility. Patients with type IV also have dentinogenesis imperfecta and bluish sclera. The more severe the variant of OI type IV, the poorer the patient's prognosis.

Patients presenting with OI types V–VII share similar physical presentations. These patients are short in stature. Unlike patients with other types of OI, these patients do not have dentinogenesis imperfecta. In addition, patients with types V–VII do not have sclera discoloration because normal collagen makes normal sclera white.

## COMPLICATIONS/PROGNOSIS

During infancy, patients with OI present with several unexplained fractures and are often suspected of being victims of non-accidental trauma or child abuse. Although this should be in the differential diagnosis, health care professionals are cautioned not to wrongly accuse parents or caregivers of wrongdoing.

In childhood, as patients with OI learn to stand and walk, fractures become more common. Children with more severe forms of OI can have severe bowing of their long bones; therefore, they may have difficulty walking or be unable to walk at all. Similar to patients who present during infancy, patients who present with OI during childhood are potentially misdiagnosed and thought to be victims of non-accidental trauma or child abuse.

During adolescence and the teenage years, patients experience periods of rapid bone growth and are at high risk of developing fractures. Both long bone fractures and vertebral fractures can occur. Vertebral fractures are often initially misdiagnosed as “growing pains,” back pain, and even scoliosis.

For patients with OI who survive into adulthood, the incidence of fractures tends to decrease. This occurs for many reasons. First, the bones have matured and are not undergoing instability associated with growth (Reference 6). Second, by adulthood, most patients with OI limit their exposure to situations in which bodily injury is likely. Adults with OI, however, are not without complications of their disease. They can suffer from chronic bone pain. In addition, patients with OI can develop hearing loss caused by the involvement of the bones in the inner ear. Although hearing loss is an uncommon complication in infants and children, it can occur in up to 50% of adults with OI (Reference 7).

The prognosis of the patient depends on the type of OI and the patient's clinical course. In general, the prognosis is poor, and most patients suffer from recurrent fractures, bone deformities, chronic bone pain, and disabilities. Surgical and medical treatments are often required continuously or intermittently for the duration of life. Unfortunately, for patients with OI, no cure is available for this life-threatening disease.

## DIAGNOSIS

There are no standard diagnostic criteria for OI (Reference 1). Osteogenesis imperfecta can be diagnosed antenatally because bone demineralization is detectable by ultrasonography as early as 13–14 weeks' gestation (Reference 6).

Postnatally, the diagnosis is based on clinical presentation. Analysis of serum laboratory values does not help, although some laboratory values, such as serum alkaline phosphatase, can help differentiate OI from other, similar diagnoses such as idiopathic hyperphosphatasia, hypophosphatasia, or rickets. In patients with OI, the serum alkaline phosphatase is usually normal or on the upper end of the normal range for age, whereas in other bone diseases, alkaline phosphatase concentrations can be markedly elevated (Reference 8).

Gene analysis can be used to identify mutations in the gene responsible for encoding collagen type I, *COL1A1* or *COL1A2*. Either blood or saliva can be analyzed for *COL1A1* or *COL1A2* gene mutations (Reference 9). Alternatively, a skin biopsy to determine the amount and type of type I procollagen present in the skin fibroblasts can be used to diagnose OI (Reference 10). These tests can detect around 90% of collagen type I mutations (Reference 11). Although a positive study leads to the diagnosis of OI, a negative study cannot rule out types V–VII because they are not associated with a collagen type I mutation.

## THERAPY GOALS

Currently, there is no cure for OI, and the variety of mutations responsible for this disease make a cure in the near future unlikely. Therefore, the goals of treatment, whether nonpharmacologic or pharmacologic, are to support bone structure, avoid bone fractures, and promote bone strength.

## NONPHARMACOLOGIC TREATMENT

Historically, supportive treatments such as orthopedic procedures and physical therapy were the cornerstones of treatment. Orthopedic procedures of inserting rods and braces have been used to strengthen bones and minimize or correct deformities. Physical therapy and assistive devices are used to increase muscle strength and expand range of motion. However, physical therapy can be a painful experience for many of these patients. In addition, patients with severe forms of OI may be too fragile to perform range-of-motion exercises.

## PHARMACOLOGIC THERAPY

No standard first-line medication is recognized for OI management. Various treatments have been attempted, including hormones, anabolic steroids, vitamins, and minerals. Even highly toxic agents such as arsenic and hydrochloric acid have been tried. Unfortunately, none of these treatments has consistently shown efficacy (Reference 12).

Calcitonin has been shown to decrease the number of fractures experienced annually by patients with OI types I–III (References 13–15). In addition, in one study, patients showed an increase in the ability to stand and move and reported a subjective feeling of strength in their lower extremities during calcitonin therapy (Reference 15). Calcitonin works by inhibiting osteoclast activity, thereby inhibiting bone resorption. It is available as an injection that can be given either intramuscularly or subcutaneously, and there is an intranasal solution. Both have been used in patients with OI. Dosing for the intramuscular or subcutaneous injection is 2 international units/kg three times/week (Reference 15). Intranasal calcitonin is dosed as follows. Patients weighing less than 20 kg receive 50 units intranasally, and patients weighing more than 20 kg receive 100 units intranasally. It is administered twice weekly for 2 weeks, followed by 2 weeks of no therapy (Reference 13). Calcitonin therapy has been continued safely for 76 months (Reference 13). Case reports have associated calcitonin therapy with electrolyte derangements such as hypophosphatemia, hypokalemia, hyponatremia, and

hypomagnesemia (Reference 16). Therefore, electrolytes should be monitored periodically while the patient is receiving calcitonin.

The bisphosphonates are clinically useful in the setting of OI, despite the lack of large randomized controlled trials supporting their safety and efficacy. The bisphosphonates inhibit osteoclast bone resorption, thereby increasing bone formation. Bisphosphonates bind to calcium in bone because their structure is similar to pyrophosphate. Osteoclasts absorb the calcium and bisphosphonate. The bisphosphonates inhibit farnesyl-pyrophosphate synthase, an enzyme involved in the synthesis of intracellular proteins. By inhibiting protein synthesis, the bisphosphonates decrease the ability of lipids to attach to and form cell membranes of osteoclasts, thereby ultimately causing osteoclast cell death (Reference 17).

Studies that have evaluated bisphosphonate use in children with OI have shown that bisphosphonates significantly improve bone density (References 18–23). One study showed a mean bone density increase of 41% per year while patients were on bisphosphonate therapy (Reference 23). During treatment, studies have shown that vertebral bone mass increases faster in the bisphosphonate group than in the controlled group (Reference 24). Bisphosphonates also reduce the risk of fractures (References 18, 19, 22) and increase strength (Reference 25). One study showed that the incidence of fractures decreased from  $2.3 \pm 2.2$  per year before bisphosphonate treatment to  $0.6 \pm 0.5$  per year during treatment (Reference 23). Bisphosphonates, however, neither completely eliminate the risk of fractures nor cure OI (Reference 26).

Pamidronate has been studied in children with severe OI (References 23, 27, 28). It is administered as a 4-hour infusion, on a cyclic schedule, the frequency of which varies according to the patient's age (Reference 3). Children younger than 2 years receive 0.5 mg/kg/day intravenously for 3 days repeated every 2 months. Children older than 2 years but younger than 3 years receive 0.75 mg/kg/day intravenously for 3 days repeated every 3 months. Patients 3 years and older should receive 1 mg/kg/day intravenously, up to a maximum of 60 mg/day, for 3 days and then repeated every 4 months.

Risedronate and zoledronate have also been studied. Similar to pamidronate, zoledronate is administered intravenously. In one study of patients with OI type III, children younger than 6 months were given 2 mg intravenously over 15 minutes every 3–4 months, and patients older than 6 months were given 4 mg intravenously over 15 minutes every 3–4 months (Reference 29).

Risedronate has been used in children with mild to severe OI. A potential advantage of risedronate compared with the other bisphosphonates is that it can be administered enterally (References 17, 30). Children

weighing less than 40 kg receive 15 mg orally once weekly, and children weighing more than 40 kg receive 30 mg orally once weekly (Reference 30). Other investigators indicate that the efficacy of risedronate may be dose-dependent and that a higher dose (2 mg/kg once weekly) increases bone mass and reduces bone deformities more significantly than lower doses (0.2 mg/kg or 1 mg/kg) (Reference 17).

Several potential adverse drug effects are associated with bisphosphonate use. Acute-phase reactions such as fever, muscle aches, and vomiting can occur in up to 85% of patients (Reference 28). These reactions usually occur with the initial dose; however, they can occur with subsequent doses and with dose changes. Acute-phase reactions primarily occur with intravenous infusions; however, acute reactions associated with the oral administration of bisphosphonates have also been reported (Reference 28). If acute-phase reactions occur, a lower dose may be administered to determine whether this will alleviate reactions. There are also case reports of mandibular osteonecrosis associated with bisphosphonate therapy (Reference 31), which commonly presents as jaw pain. Although many patients with OI will be followed by a dentist, patients receiving bisphosphonate therapy should have semiannual dental examinations. In addition, there have been reports of severe symptomatic hypocalcemia associated with intravenous bisphosphonate therapy; however, none of the reports involved patients with OI (References 32, 33). Respiratory distress has also been associated with bisphosphonate therapy in children with OI (Reference 34). One study reported that 7% of infants with type III OI developed respiratory distress during their first pamidronate infusion. Two infants in this study required intensive care, and all the infants had a history of respiratory distress. The etiology of this is unknown, but it is hypothesized that respiratory distress is caused by tumor necrosis factor release or acute bronchospasm or that it is associated with the volume of fluid administered during pamidronate infusion. Therefore, pamidronate should be used with caution in infants with OI and a history of acute respiratory distress.

Zoledronate has been associated with renal dysfunction, including renal failure. Renal failure can occur after a single infusion of zoledronate, or it can occur after several infusions. Additional risk factors for renal dysfunction include underlying renal impairment, concomitant nephrotoxin use, concurrent use of diuretics, and dehydration. Patients receiving zoledronate should have their renal function monitored periodically while receiving treatment.

Oral bisphosphonates like risedronate have been associated with the development of esophagitis and esophageal cancer. Patients taking risedronate should take it first thing in the morning and remain upright

for at least 30–60 minutes after the dose. Any swallowing difficulties, chest pain, or heartburn may indicate signs of esophageal problems; these should be reported to their health care provider.

Questions remain to be answered before bisphosphonate treatment can be recommended for all children with OI. In children with recurrent, low-trauma fractures, the benefits of bisphosphonate therapy may outweigh the risks associated with therapy. However, the role of bisphosphonates in children with mild OI and infrequent fractures is unclear (Reference 28). In addition, the appropriate length of bisphosphonate therapy and the time to terminate treatment need to be elucidated (Reference 28). A few children with OI have been treated for up to 9 years with monthly doses of pamidronate without experiencing long-term adverse effects (Reference 24).

## CONCLUSIONS

Osteogenesis imperfecta is a rare genetic disorder of the bone. Individuals with OI suffer from recurrent fractures throughout their lives. Patients who live into adulthood experience life with chronic bone pain, deformities, and disabilities. At present, there is no pharmacologic cure for OI. Calcitonin has been associated with a reduced risk of fractures, and the bisphosphonates, specifically pamidronate, have been associated with improved bone density and reduced risk of fractures.

# CHAPTER 24

## DIABETES MELLITUS

Sandra Benavides, Pharm.D.

### LEARNING OBJECTIVES

1. Differentiate the pathophysiology between type 1 and 2 diabetes mellitus (DM) in pediatric patients.
2. List the criteria for the diagnosis of DM in pediatric patients.
3. Describe acute and chronic complications of DM in pediatric patients.
4. Develop an insulin regimen for a pediatric patient.
5. Discuss the available pharmacologic agents for the treatment of type 2 DM in pediatric patients.

### ABBREVIATIONS IN THIS CHAPTER

BG	Blood glucose
CSII	Continuous subcutaneous insulin infusion
DDP-IV	Dipeptidyl peptidase IV enzyme
DKA	Diabetic ketoacidosis
DM	Diabetes mellitus
ESRD	End-stage renal disease
GLP-1	Glucagon-like peptide-1
HHS	Hyperosmolar hyperglycemic syndrome
PG	Plasma glucose
SMBG	Self-monitoring of blood glucose

### INTRODUCTION

Diabetes mellitus (DM) is one of the most common chronic diseases in pediatrics. Either a lack of insulin release from the pancreas or a resistance to insulin in peripheral tissues, resulting in hyperglycemia, causes DM. Persistent hyperglycemia leads to several acute, microvascular, and macrovascular complications necessitating metabolic control with pharmacologic treatment. Children and adolescents present unique challenges in achieving metabolic control. This chapter will focus on such challenges and appropriate pharmacotherapy strategies in pediatric patients.

### EPIDEMIOLOGY

Ongoing prevalence estimates 1.82 cases of some form of DM per 1,000 youths in the United States. The overall prevalence of DM increases with increasing age, with rates reaching 3.35 cases per 1,000 youths aged 15–19

years in 2001 (Reference 1). Although type 1 DM accounts for most diabetes in pediatrics, the number of children and adolescents with type 2 DM is increasing (Reference 1).

### CLASSIFICATION

It is necessary to classify diabetes upon diagnosis to initiate appropriate pharmacologic treatment. Before the 1990s, most DM cases diagnosed in youth were type 1. However, because of increases in obesity rates, pediatric patients are now presenting with type 2 DM (Reference 2). Youths can also be affected with other forms of diabetes, including maturity-onset diabetes of youth; neonatal diabetes; mitochondrial diabetes; diabetes associated with lipodystrophy; diabetes secondary to other pancreatic, endocrine, or genetic syndromes; or drug-induced diabetes (e.g., corticosteroids, immunosuppressants) (Reference 3). This chapter will focus on the two most common forms of DM in pediatrics, types 1 and 2. Table 1 highlights differences between type 1 and 2 DM.

### PATHOPHYSIOLOGY

Type 1 DM is the result of a T-cell-mediated autoimmune attack on the beta cells of the pancreas, resulting in complete insulin deficiency. Individuals with type 1 DM typically have a genetic predisposition, indicated by the presence of human leukocyte antigens. The *DR3-DQ2* and *DR4-DQ8* alleles are associated with increased risk, whereas the *DR2-DQ6* allele is protective against type 1 DM (Reference 5). The T-cell-mediated attack on the beta cells results in an inflammatory process in the islets of Langerhans and the production of antibodies. Antibodies to insulin, glutamic acid decarboxylase, and the protein tyrosine phosphatase are detectable even before the clinical presentation of disease. The autoimmune process can take months to years to occur. Signs of insulin deficiency do not become evident until about 80% of the beta cells are destroyed. Typically, the earlier the onset of destruction, the more rapidly insulin deficiency is evident. Although controversial, it is believed that in addition to a genetic predisposition, an environmental toxin contributes to the development of type 1 DM. Environmental factors thought to trigger

**Table 1.** Characteristics of Type 1 and Type 2 Diabetes Mellitus in Children and Adolescents (Reference 4)

	Type 1	Type 2
Age of presentation	Throughout childhood	Typically at puberty
Onset	Acute	Insidious to severe
Ketosis at onset	Common	Variable
Affected relative	5%	75% to 90%
Female/male	1:1	2:1
HLA <sup>a</sup> DR3, DR4	Increased association	No association
Ethnicity	All, whites	All
Insulin secretion	Decreased/absent	Variable
Insulin sensitivity	Normal when controlled	Decreased
Insulin dependence	Permanent	Episodic
Obesity	< 24%	> 90%
Acanthosis nigricans	No	Common
Pancreatic autoantibodies	Yes	No

<sup>a</sup>Human leukocyte antigen-DR.

type 1 DM include certain foods (e.g., cow's milk, nitrosamines) or viral infections (e.g., enterovirus, rotavirus). To date, only exposure to congenital rubella has been associated with the onset of type 1 DM.

Type 2 DM results from both impaired insulin secretion from the pancreas and insulin resistance. Various factors increase the susceptibility to decreased insulin sensitivity, including family history, obesity, physical inactivity, diet, and intrauterine factors (Reference 4). Most pediatric patients with a diagnosis of type 2 DM have at least one first- or second-degree relative with type 2 DM. Infants who are born to mothers with gestational diabetes or who are small for gestational age have an increased risk of insulin resistance. The decrease in insulin sensitivity initially leads to an increase in insulin secretion, compensatory hyperinsulinemia, and ultimately beta-cell destruction. Before clinical presentation of type 2 DM, children and adolescents present with hyperinsulinemia or signs of insulin resistance such as acanthosis nigricans. Acanthosis nigricans is a dermatologic disorder characterized by brown to blackish, raised, velvety lesions usually found in skinfolds or creases in the back of the neck, axilla, and genital area (Reference 6). Acanthosis nigricans is thought to be the result of increased insulin levels binding insulin-like growth factor receptors, fibroblasts, and keratinocytes,

resulting in the proliferation of epidermal cells (References 6, 7). During puberty, insulin resistance worsens, precipitating glucose intolerance and, subsequently, clinical manifestations of type 2 DM.

## SCREENING

Typically, the time from abnormal glucose control to clinical symptoms of disease occurs fairly rapidly in type 1 DM; therefore, routine screening is not recommended. However, the American Diabetes Association recommends screening for type 2 DM (Reference 8). Children and adolescents who are overweight (defined as a body mass index percentile greater than 85 for age and sex) with two additional risk factors are recommended for screening. Additional risk factors include having a family history of type 2 DM in a first- or second-degree relative, being of a racial/ethnic group with high rates of type 2 DM (i.e., American Indian, African American, Hispanic, Asian, Pacific Islander), or showing evidence of existing insulin resistance. Conditions associated with insulin resistance include acanthosis nigricans, hypertension, dyslipidemia, polycystic ovarian syndrome, and maternal history of gestational diabetes during the child's gestation (References 8). Screening consists of a fasting plasma glucose (PG) or an oral glucose tolerance test every 2 years starting at age 10 or at onset of puberty in any child or adolescent meeting these criteria.

## CLINICAL PRESENTATION AND DIAGNOSIS

The classic signs and symptoms of diabetes are polydipsia, polyuria, polyphagia, and weight loss. Those presenting with type 1 DM may have symptoms for 1 month to several months before diagnosis. Female patients with type 2 DM might present with candidal vulvovaginitis in addition to classic symptoms. Although it is more common for a patient with type 1 DM to present with diabetic ketoacidosis (DKA), patients with type 2 DM are still at risk of developing DKA. Other potential findings on presentation include glycosuria and ketonuria. Of note, however, DM can also present asymptotically in both types 1 and 2, and its presence can be discovered coincidentally with routine laboratory analysis.

Diagnostic criteria for DM include at least one of the following (References 8, 9):

1. Fasting PG of 126 mg/dL or greater;
2. Two-hour PG of 200 mg/dL or greater during an oral glucose tolerance test; or
3. Random PG of 200 mg/dL or greater and symptoms of hyperglycemia.

A fasting PG of 126 mg/dL or greater or a 2-hour PG of 200 mg/dL or greater is repeated for confirming the diagnosis. To differentiate between type 1 and 2 DM, it is recommended to measure islet autoantibodies, insulin, and C-peptide. The presence of islet autoantibodies is indicative of type 1 DM. Interpretation of insulin and C-peptide can be less conclusive because both may still be present in a person with an early diagnosis of type 1 as well as in those with type 2 DM (Reference 9).

## COMPLICATIONS

Diabetes mellitus in children and adolescents is associated with short- and long-term complications. Short-term complications include hypoglycemia, DKA, and hyperosmolar hyperglycemic syndrome (HHS). Long-term microvascular complications include retinopathy, nephropathy, and neuropathy. Macrovascular disease, including peripheral, cerebrovascular, and cardiovascular disease, are also long-term complications of DM. Common comorbidities with type 1 DM include thyroid and celiac disease.

### Hypoglycemia

Hypoglycemia is experienced in patients treated with insulin for DM. Severe hypoglycemia has been estimated to occur 8–30 times per 100 patient-years of diabetic exposure (Reference 10). Children and adolescents are at higher risk of severe hypoglycemia than are adults

because of the lack of symptom recognition, inability to communicate symptoms to the caregiver, and variable eating and exercise habits (Reference 9). Young children tend to be most at risk for severe complications from frequent or severe episodes of hypoglycemia (Reference 9). Hypoglycemia in children can be associated with seizures, acute and chronic impaired cognitive function, coma, and death. Signs, symptoms, and treatment strategies for hypoglycemia will be discussed later in the chapter.

### Diabetic Ketoacidosis

Diabetic ketoacidosis results from lack of insulin and increases in counterregulatory hormones (e.g., glucagon, catecholamines, cortisol, growth hormone), resulting in a catabolic state (Reference 11). Diabetic ketoacidosis is characterized by hyperglycemia, acidosis, ketonemia, and ketonuria (Reference 12). Around 29% and 10% of patients with type 1 and 2 DM, respectively, will present with DKA at initial diagnosis (Reference 13). Other factors that precipitate DKA after diagnosis are insufficient exogenous insulin administration, sepsis, trauma, or excessive diarrhea and vomiting (Reference 12). Complications of DKA can include death, usually caused by cerebral edema. Additional causes of death in DKA include other neurologic complications, hypokalemia, hyperkalemia, thrombosis, sepsis, aspiration pneumonia, and pulmonary edema. Long-term complications may include neurologic deficits. Diabetic ketoacidosis will be discussed more thoroughly later in the chapter.

### Hyperosmolar Hyperglycemic Syndrome

Hyperosmolar hyperglycemic syndrome is a rare but life-threatening complication of uncontrolled type 2 DM. The incidence of HHS in pediatric patients is unknown, but it is estimated that 4% will present with HHS at time of diagnosis with type 2 DM (Reference 14). Similar to DKA, HHS is characterized by hyperglycemia and hyperosmolarity but not acidosis, ketonemia, and ketonuria (Reference 15). Complications of HHS include thrombosis, rhabdomyolysis, malignant hyperthermia-like syndrome, and death. Death results from severe dehydration, electrolyte imbalance, and hypertonicity (Reference 15).

### Retinopathy

Retinopathy results from damage to the blood vessels of the retina. It is the most common cause of adult blindness in the United States. Nonproliferative retinopathy (background retinopathy) is transient and consists of microaneurysms and pre- and intraretinal hemorrhages (Reference 16). Nonproliferative retinopathy is not associated with vision loss and does not always progress to proliferative retinopathy. Proliferative retinopathy is

a severer form of retinopathy and is characterized by the development of new blood vessels, which may rupture or bleed into the vitreoretinal space. Visual loss may occur with proliferative retinopathy (Reference 16).

Retinopathy can be present in children and adolescents within 1–2 years after diagnosis of DM, although it is not usually seen for 5–10 years. It occurs in pediatric patients of all ages, but it tends to present post-pubertally. Proliferative retinopathy does not typically present in those younger than 20 years. Risk factors for retinopathy include poor glycemic control, longer duration of diabetes, elevated blood pressure, smoking, hyperlipidemia, albuminuria, and pregnancy (Reference 9). Annual ophthalmologic examinations are recommended when the child is at least 10 years old and has had diabetes for 3–5 years (Reference 9).

### Nephropathy

End-stage renal disease (ESRD) requiring dialysis or transplantation is a microvascular complication of DM. The first clinical signs of diabetic nephropathy are microalbuminuria followed by proteinuria. Proteinuria, when coupled with increased blood pressure, can result in ESRD. About 30% to 40% of those receiving a diagnosis of type 1 DM will develop ESRD (Reference 17). The incidence of developing ESRD in children and adolescents having a diagnosis of type 2 DM remains unknown. However, studies have shown that children and adolescents with diagnoses of type 2 DM have higher rates of microalbuminuria and earlier onset of diabetic nephropathy than those with diagnoses of type 1 DM (Reference 18). Risk factors for the progression of renal disease include poor metabolic control, smoking, and hypertension. Additional risk factors reported in those with type 1 DM include a family history of hypertension or cardiovascular disease. For patients with type 1 DM, annual screening for microalbuminuria is recommended beginning at age 10 years or in patients with a history of diabetes for 5 years. More frequent testing is required if microalbumin levels are elevated (Reference 9). For type 2 DM, it is recommended to screen for microalbuminuria from the time of diagnosis and then yearly thereafter (Reference 8). In patients with microalbuminuria, treatment with an angiotensin-converting enzyme inhibitor is suggested. In addition, any concomitant hypertension or hyperlipidemia should be treated.

### Neuropathy

Peripheral and autonomic neuropathies, a complication of DM in adults, are not commonly seen in pediatric patients. Peripheral neuropathies are associated with pain, burning, and diminished sensation to filament testing (Reference 16). With time, peripheral neuropathies result in a loss of motor function (Reference 19). Children and adolescents suffering from peripheral neuropathies

have persistent ongoing pain. Autonomic neuropathies include the cardiovascular, gastrointestinal, and genitourinary systems (Reference 20). Clinical presentation can include postural hypotension, gastroparesis, neurogenic bladder, impotence, and hypoglycemic unawareness. In rare instances, sudden death has been associated with abnormal heart rate responses and prolonged QT intervals (References 19, 20). Increased disease duration, particularly with poor metabolic control, is associated with earlier onset of neuropathies. Currently, the American Diabetes Association recommends foot examinations for all children with type 1 DM beginning at puberty and then yearly thereafter (Reference 9). It is also important to provide patient education on proper footwear and regular monitoring of feet. Although no recommendations exist for children and adolescents with type 2 DM, annual testing from the time of diagnosis and patient education should be considered.

### Macrovascular Complications

Macrovascular complications of diabetes include cardiovascular, cerebrovascular, and peripheral vascular disease caused by atherosclerosis. Although these complications are rare in pediatric patients with DM, identifying and modifying the risk factors are important. Risk factors for atherosclerosis include hyperlipidemia, smoking, hypertension, obesity, and a family history of cardiovascular disease (Reference 9). A fasting lipid panel in children with type 1 DM older than 2 years up to puberty after 2 years of diagnosis is recommended. The test is to be repeated every 5 years if the low-density lipoprotein cholesterol is less than 100 mg/dL. For pubertal children and adolescents with type 1 DM, a lipid panel should be obtained at diagnosis and subsequently every 3–5 years if the low-density lipoprotein is less than 100 mg/dL (References 9, 21). For children and adolescents with type 2 DM, annual lipid profiles are recommended (Reference 22). Pharmacologic treatment is recommended for children older than 10 years if the low-density lipoprotein cholesterol is greater than 130 mg/dL (Reference 21).

### THERAPY GOALS

The Diabetes Control and Complications Trial showed a decrease in microvascular complications in patients with type 1 DM when treated with intensive insulin therapy to maintain blood glucose (BG) as close to normal physiologic values as possible (Reference 23). In the trial, adolescents randomized to intensive treatment achieved lower glycosylated hemoglobin percentages, although unable to achieve glycosylated hemoglobin levels as low as the adults enrolled in the study (Reference 23). Despite being unable to achieve glycosylated hemoglobin levels less than 7%, adolescents in the

intensive treatment group had decreases in the onset of retinopathy or improvements in existing retinopathies, improved conduction velocities, and modest improvements in low-density lipoprotein cholesterol levels compared with those in conventional treatment (Reference 23). Long-term outcomes for those enrolled in the trial found that the continuation of intensive therapy (despite not achieving normal glycosylated hemoglobin levels) provided benefits, such as non-progression to proliferative retinopathy (Reference 24). However, an intensive insulin regimen predisposes an individual to increased weight gain and an increased number of hypoglycemic episodes. As mentioned previously, younger children are more vulnerable to hypoglycemia. Therefore, the American Diabetes Association has developed age-specific glycemic goals to balance the benefits and risks of tight glycemic control. Age-specific goals are listed in Table 2. Glycemic goals are higher for younger children because of the greater risk of hypoglycemia and low risk of long-term complications (Reference 9).

Glycemic goals for patients with type 2 DM more closely resemble goals for adult patients with DM. Goals for fasting BG are less than 126 mg/dL. In addition, the target for glycosylated hemoglobin is less than 7% (Reference 8).

In all pediatric patients with DM, attainment of normal growth and weight, prevention of acute and chronic complications, and minimization of adverse effects secondary to medications are desired.

## NONPHARMACOLOGIC THERAPY

Limited data exist on specific nutrition recommendations for children and adolescents with DM. Nutrition recommendations should be aimed at normal growth and development, attainment of glycemic goals, and management or prevention of comorbid conditions such as hypertension or hyperlipidemia (References 8, 9).

Children and adolescents with diagnoses of type 1 DM are typically underweight, whereas those presenting with type 2 DM tend to be overweight. However, in both groups, attaining a normal body weight is important. At this time, specific nutritional requirements for pediatric patients with either type 1 or 2 DM are

unavailable; therefore, dietitians specializing in DM provide medical nutrition therapy by helping patients develop healthy eating habits as recommended by the U.S. Department of Agriculture. Height, weight, body mass index, and nutrition assessment should be conducted at least yearly (References 8, 9).

Medical nutrition therapy must consider specific insulin regimens prescribed to the patient. Initially, a consistent carbohydrate content for all meals and snacks is recommended, particularly for those on a fixed insulin regimen. However, this provides a challenge because of the erratic eating habits in this population. Some toddlers and young children may refuse to eat some or all of a meal, leaving them prone to hypoglycemia if insulin has been administered. In children with unreliable eating habits, the caregiver can administer rapid-acting insulin with the first bite of a meal. Adolescents also provide a challenge in eating appropriate (i.e., healthy) foods at regular intervals. In these instances, it is crucial for the patient and caregiver to count carbohydrate content in meals. Once a patient and caregiver are able to count carbohydrate content to adjust insulin doses, meals and snacks can be more flexible with respect to carbohydrate content. Other considerations in developing meal plans include increasing the consumption of carbohydrates (in the form of fruits, vegetables, and grains) and fiber and establishing a regular meal pattern because these factors have been shown to improve glycemic control in children and adolescents with type 1 DM (Reference 25).

Children and adolescents with DM benefit from regular exercise. In type 1 DM, adolescents who exercised regularly had an improved sense of well-being, quality of life, body composition, blood pressure, and lipid profiles (References 26, 27). Moderate physical activity for 30–60 minutes/day is recommended for children and adolescents with type 1 DM (Reference 9). However, exercise can increase the risk of hypoglycemia, necessitating a decrease in the insulin dose. For children and adolescents with type 2 DM, increasing physical activity as tolerated and minimizing sedentary behaviors are recommended. Exercise in this population can improve insulin resistance (Reference 8).

**Table 2.** Age-Specific Glycemic Goals for Type 1 Diabetes Mellitus (Reference 9)

Age (years)	Plasma Blood Glucose Goal Range (mg/dL)		Glycosylated Hemoglobin
	Before Meals	Bedtime/Overnight	
< 6	100–180	110–200	Between 7.5% and 8.5%
6–12	90–180	100–180	< 8%
13–19	90–130	90–150	< 7.5%

## PHARMACOLOGIC THERAPY

Because type 1 DM is a result of insulin deficiency, exogenous administration of insulin is required for the patient's survival. Although oral agents are typically used in type 2 DM, insulin is often necessary to achieve glycemic control.

### Insulin

Insulin is a protein composed of 51 amino acids naturally produced by the pancreas. It is made up of two chains, alpha and beta, which are connected with disulfide bonds. Although porcine and bovine insulin were initially used, insulin products on the market today are manufactured from recombinant DNA technology (using human insulin) and then modified to various insulin analogs. Modifications in the structure allow alterations in the onset, peak, and duration of action of insulin as illustrated in Table 3. Because of pharmacokinetic differences, combinations of different types of insulin are used to mimic the normal physiologic release of insulin. For example, rapid- or short-acting insulin is used with meals to mimic pancreatic release in response to food, whereas long-acting insulin is used to provide basal insulin coverage throughout the day.

### Efficacy of Insulin in Pediatric Patients

To date, no studies have reported increased efficacy of one form of insulin over another. Many forms of insulin have been studied in pediatric patients and have been shown efficacious. Table 4 lists advantages and disadvantages of specific insulin types in pediatric patients.

### Dosing

The total daily dose of insulin depends on several factors including age, weight, pubertal status, diabetes duration, diet, exercise, BG, and concomitant illnesses

(Reference 29). Dosing guidelines for various populations are listed in Table 5. Insulin dosing decreases during the "honeymoon phase." The honeymoon phase occurs after the initial onset of type 1 DM in which the pancreas increases insulin production before complete cessation of insulin secretion. The honeymoon phase begins several weeks after the diagnosis of type 1 DM and can last from several months to a year (Reference 28). During puberty, insulin requirements increase because of insulin resistance secondary to elevated growth and sex hormone secretion (Reference 9).

The total daily dose of insulin can be divided by various methods depending on the ability and needs of the patient and caregiver. Factors dictating which insulin regimen to use include the age of the child or adolescent, dietary patterns, exercise patterns, and school attendance (Reference 29). Types of regimens include split/mixed, basal/bolus, and administration by an insulin pump.

### Split/Mixed Regimen

The split/mixed regimen consists of two or three daily injections of a standard insulin dose given as a combination of intermediate- or long-acting insulin and rapid- or short-acting insulin. Below is one common method of calculating the exact insulin doses for a patient using two daily injections:

1. Calculate the total daily dose for a patient. For example, a postpubescent adolescent weighing 60 kg would require 1 unit of insulin per kilogram (as indicated in Table 5) or 60 units of insulin per day.
2. Of the total daily dose, two-thirds of the insulin is administered in the morning and one-third in the afternoon/evening. In the example, the 60 units of insulin per day would be divided into 40 units in the morning and 20 units in the afternoon/evening.

**Table 3.** Insulin Types and Pharmacokinetic Parameters (References 28–30)

Insulin Type	Brand (Generic) Names	Pharmacokinetics		
		Onset of Action	Peak of Action	Duration of Action (hours)
Rapid-acting	NovoLog (aspart insulin) Humalog (lispro insulin) Apidra (glulisine insulin)	10–15 minutes	30–90 minutes	3–4
Short-acting	Novolin-R (regular insulin) Humulin-R (regular insulin)	30–60 minutes	2–4 hours	4–6
Intermediate-acting	Novolin-N (NPH insulin) Humulin-N (NPH insulin)	1–2 hours	3–10 hours	8–15
Long-acting	Lantus (insulin glargine)	2–4 hours	No peak	20–24
Long-acting	Levemir (insulin detemir)	1–2 hours	6–12 hours	6–24

**Table 4.** Advantages and Disadvantages of Insulin Types in Pediatric Patients

Insulin Type	Advantages	Disadvantages
Rapid-acting	Can be given with meals or immediately after meals (useful for toddlers with variable eating patterns) Treats hyperglycemia faster than regular insulin Can be used in CSII	Expensive
Short-acting	Abundant studies available Inexpensive	Must be given 30 minutes before meal Child may experience hypoglycemia with incomplete meals
Intermediate-acting	Can be mixed with other insulin without modification of pharmacokinetic parameters	Compared with long-acting insulin, may require more daily injections
Long-acting	Less intra-patient variability compared with intermediate-acting insulin Fewer hypoglycemia episodes compared with intermediate-acting insulin Greater satisfaction in adolescents compared with intermediate-acting insulin Less weight gain with insulin detemir compared with intermediate-acting insulin	Expensive Glargine may cause a burning sensation upon administration because of acidic pH

CSII = continuous subcutaneous insulin infusion.

**Table 5.** Recommended Insulin Dosage for Pediatric Patients (References 9, 29)

Stage/Type of Diabetes Mellitus Diagnosis	Recommended Total Daily Dose
Initial diagnosis	0.5–1 unit/kg/day
Honeymoon phase	< 0.5 unit/kg/day
Prepubertal children (out of honeymoon phase)	0.5–1unit/kg/day
Pubertal adolescents	May require up to 1.5 units/kg/day
Type 2 diabetes mellitus initial dosing (basal)	0.15–0.2 units/kg/day
Type 2 diabetes mellitus	May require up to 2 units/kg/day

- When intermediate-acting insulin is used, the total amount of insulin is divided into two-thirds intermediate- and one-third rapid- or short-acting insulin. In the morning, 26 and 13 units of intermediate- and short-acting insulin, respectively, will be given. The afternoon/evening dose would be 13 and 7 units of intermediate- and short-acting insulin, respectively.
- If long-acting insulin is administered, the dose is given as one-half long-acting and one-half short-acting insulin divided into AM and PM doses. The morning dose would be 30 units of long-acting insulin and 15 units of short-acting insulin. The evening dose would be 15 units of short-acting insulin. (Of note, if the patient is stabilized on an intermediate-acting insulin and is being converted to glargine, the dose of glargine must be decreased by 20% to prevent hypoglycemia. The dose need not be decreased if switching to detemir.)

The split/mixed regimen provides basal insulin coverage with the intermediate- or long-acting insulin and coverage of meals with the rapid- or short-acting insulin. This insulin therapy requires the patient to eat at regularly scheduled times and eat a consistent amount of carbohydrates per meal. Additional snacks may also be required to avoid hypoglycemic events, particularly if short-acting insulin is used. The use of intermediate-acting insulin may increase the frequency of nocturnal hypoglycemia. In some cases, replacing the intermediate-acting insulin with long-acting insulin decreases episodes of nocturnal hypoglycemia. The split/mixed regimen is typically not adequate in most patients to achieve desired glycosylated hemoglobin (Reference 9). Although administering insulin in this manner is ideal upon diagnosis of DM, after the honeymoon phase, it is recommended to move pediatric patients to a basal/bolus regimen (Reference 9).

### *Basal/Bolus Regimen*

The basal/bolus regimen more closely resembles normal physiologic release of insulin than the split/mixed regimen. Long-acting insulin is administered to emulate normal physiologic basal insulin secretion, whereas pre-prandial insulin mimics pancreatic secretion in response to meals. Pre-prandial doses of insulin depend on the BG level before the meal, the anticipated amount of carbohydrates in the meal, and the expected amount of physical activity in subsequent hours (Reference 9).

In the basal/bolus regimen, one-half of the total daily insulin dose is administered as the basal insulin. The most commonly used basal insulin is glargine. Administration at bedtime is common; however, if nocturnal hypoglycemia is experienced, administration of glargine at dinner or breakfast is preferred. The other one-half of the total daily dose of insulin is divided between meals and snacks. The amount of insulin administered before each meal is calculated by estimating the insulin required to cover the carbohydrates eaten (determined by the carbohydrate factor and the insulin-to-carbohydrate ratio) and to correct a BG outside the goal range (determined by the correction factor). Although the basal/bolus regimen increases the daily number of injections, it has been associated with lower glucose concentrations and a lower incidence of nocturnal hypoglycemia.

The number of grams of carbohydrates consumed in a meal is calculated with the carbohydrate factor. Carbohydrate factors are available online at the U.S. Department of Agriculture Web site, or they can be calculated for prepackaged foods using the nutrition facts label. Once the carbohydrate factor is known, it is multiplied by the weight of the food (in grams) to determine the total amount of carbohydrates. Below is an example of how to calculate the number of grams in a particular food.

A banana has a carbohydrate factor of 0.23  
(meaning 23% of the banana is carbohydrate).

If the banana weighs 120 g, it has 27.6 g of carbohydrates.

The insulin-to-carbohydrate ratio is the amount of insulin required per gram of carbohydrate in a meal. Typically, the ratio is 10–15 g of carbohydrates per unit of insulin, but it varies per patient and throughout the day. The insulin-to-carbohydrate ratio is calculated by dividing the total number of carbohydrate grams per day by the total daily dose of insulin. Typically, prepubescent children require less insulin per gram of carbohydrate, whereas pubertal adolescents require more (Reference 30). For example, if the total daily dose of insulin is 30 units and the child

consumes 450 g of carbohydrates per day, the insulin-to-carbohydrate ratio is 15. This means that 1 unit of insulin is required for every 15 g of carbohydrates consumed. If this child ate the banana mentioned above, 1.8 units of insulin would be necessary to cover the carbohydrates in the banana.

The correction factor is the amount an individual's BG will decrease with 1 unit of insulin. The correction factor is calculated using the 1800 rule (for those using rapid-acting insulin as the bolus insulin). To estimate how much the BG will decrease per unit of insulin, 1800 is divided by the total daily dose (e.g., if the total daily dose is 20 units, the correction factor will be 90). A correction factor of 90 requires 1 unit of insulin for every 90 BG points above goal. For patients using short-acting insulin as the bolus insulin, 1500 should be used in place of 1800. With the basal/bolus regimen, the patient and caregiver must keep daily food logs, understand how to read nutrition facts labels, and monitor BG frequently.

### *Continuous Subcutaneous Insulin Infusion*

The continuous subcutaneous insulin infusion (CSII) offers patients the benefit of a basal/bolus regimen without the need for several daily injections. The CSII provides a continuous infusion of insulin, and boluses are programmed with meals. In addition, the continuous infusion can be stopped during exercise to prevent hypoglycemic episodes. A recent study comparing different insulin regimens found that children and adolescents using an insulin pump had the lowest glycosylated hemoglobin compared with those using other regimens (Reference 31). In addition, there were fewer emergency department visits and hospitalizations. The CSII also decreases the incidence of hypoglycemic episodes (Reference 32). Other advantages and disadvantages of the CSII are listed in Table 6. Before a child or adolescent begins CSII therapy, the patient and caregiver must be motivated and understand the benefits and limitations of the CSII. At the very least, the patient and caregiver ought to be testing BG at least four times/day and be able to count carbohydrates. They should also be able to administer insulin by injections in case of pump malfunction (Reference 32).

### *Administration*

Insulin is administered subcutaneously into the abdomen, front or lateral thigh, buttocks, or lateral aspect of the arm. In younger children with a small amount of fat, the upper outer quadrant of the buttocks is the preferred site of injection. Typically, insulin injected into the abdomen will absorb faster than insulin injected into the thigh (Reference 29). Injection in the

**Table 6.** Advantages and Disadvantages of Continuous Subcutaneous Insulin Infusion (References 29, 32)

Advantages	Disadvantages
Allows flexible dosing regimens	Larger needles inserted for pump
Decreases the amount of daily injections	Placement of pump may be difficult because of size
Small doses of insulin can be administered.	Dislodgment and risk of infection
Allows several boluses throughout meals	Costly
Families can download information regarding insulin doses.	
Increased patient and family satisfaction	
“Smart pumps” can automatically calculate meal or correction boluses.	

arm is not recommended in children because of the small amount of subcutaneous fat. This increases the chance of injecting the insulin intramuscularly instead of subcutaneously. Disinfecting the area is not necessary.

When mixing insulin to administer, it is important to instruct the patient or caregiver to draw up the regular insulin (clear) in the syringe before the intermediate-acting insulin (cloudy) to prevent contamination of the short-acting insulin. Although the manufacturer recommends not mixing glargine with any insulin, one study evaluated BG and glycosylated hemoglobin after the administration of glargine mixed with either lispro or aspart (Reference 33). Although the stability of the mixture remains unknown, if it is administered immediately after mixing, there are no differences between BG or glycosylated hemoglobin compared with being administered separately. Mixing insulin minimizes the number of injections administered to the child or adolescent.

### Adverse Drug Reactions

Adverse drug reactions associated with insulin include injection-related reactions, hypoglycemia, hypokalemia, and weight gain. Injection-related reactions include local hypersensitivity reactions, lipohypertrophy, lipoatrophy, pain, insulin leakage, and bruising or bleeding (Reference 29).

Hypoglycemia is the most common and serious adverse reaction of insulin in children and adolescents. Hypoglycemia occurs more frequently in younger children and adolescents, those with low glycosylated hemoglobin (i.e., less than 8%), those with a history of severe hypoglycemia, and those who use higher insulin doses (References 9, 10). Common signs and symptoms of hypoglycemia include tremor, tachycardia, diaphoresis, pallor, impaired vision, dizziness, difficulty concentrating, slurred speech, irritability, inconsolable crying, headache, nausea, and seizures. Nocturnal hypoglycemia can lack symptoms or

present with nightmares, restless sleep, or confusion upon awakening. Patients who have repeated episodes of hypoglycemia or a long duration of diabetes may develop hypoglycemic unawareness. Hypoglycemic unawareness results from the lack of counterregulatory hormones responding to low BG, specifically the lack of an adrenergic response. In these instances, the patient and caregiver must monitor BG more frequently. In addition, it may be necessary to decrease insulin doses to prevent hypoglycemia.

Hypoglycemia is categorized into mild, moderate, and severe hypoglycemia, although specific BG levels have not been defined for each category. Descriptions of each category of hypoglycemia and recommendations for management are listed in Table 7.

Caregivers (and teachers if the child is in school) should be counseled on how to recognize and treat hypoglycemia. In addition, it is necessary to explain when hypoglycemia is more likely to occur, such as during changes in insulin therapy, alterations in diet, increased physical activity, lower glycosylated hemoglobin levels, and after alcohol ingestion (Reference 10).

**Table 7.** Categories and Treatment of Hypoglycemia in Children and Adolescents (Reference 9)

Category	Symptoms	Management
Mild	Sweating Pallor Palpitations Tremors	10–15 g easily absorbable carbohydrate, such as juice
Moderate	Aggressiveness Drowsiness Confusion	20–30 g of glucose administered by another person
Severe	Altered state of consciousness Coma Seizure	30 mcg/kg (maximum 1 mg) subcutaneous glucagon

### Drug Interactions

Several drugs increase or decrease the hypoglycemic effects of insulin as listed in Table 8. In addition, the signs of hypoglycemia can be masked with the concomitant use of a nonselective  $\beta$ -blocker. If a  $\beta$ -blocker is required, a cardioselective  $\beta$ -blocker (e.g., atenolol) should be considered.

### Oral Antihyperglycemic Agents

Oral antihyperglycemic agents are indicated for the management of type 2 DM. Currently, only one medication, metformin, is approved for use in pediatrics. However, other oral agents have been studied. Table 9 summarizes the medications, available pediatric dosages, adverse drug reactions, and drug interactions of these medications.

### Biguanides

Metformin (Glucophage) was studied in 10- to 16-year-old children and adolescents with new-onset type 2 DM in a double-blind, placebo-controlled trial for 16 weeks. Compared with placebo, those in the metformin

treatment group had improved fasting BG and glycosylated hemoglobin, and they were more likely to meet at least one of the American Diabetes Association glycemic target levels (Reference 35). Subjects taking metformin had improvements in serum cholesterol concentrations compared with those on placebo. Metformin also resulted in weight loss, which is usually indicated in children and adolescents with type 2 DM.

Advantages of treatment with metformin are its proven efficacy (decreases glycosylated hemoglobin by 1% to 2%), generic availability, positive impact on weight and serum lipid concentrations, and relative safety (References 41, 42). Initially, metformin may cause gastrointestinal disturbances, including diarrhea. To minimize this adverse drug reaction, the medication is titrated to the maximal dose slowly, preferably over 3–4 weeks, and administered with food. Although the risk of lactic acidosis is low, metformin is contraindicated in children and adolescents with renal dysfunction or any condition that might predispose them to poor tissue perfusion such as alcohol abuse, radiographic studies with contrast, or surgery with general anesthesia (Reference 36). Metformin is considered first line in the treatment of type 2 DM in children and adolescents.

### Thiazolidinediones

Rosiglitazone (Avandia) was compared with metformin in an 8-week, double-blind, controlled, parallel-group trial (Reference 37). The investigators found no difference between rosiglitazone and metformin with respect to lowering glycosylated hemoglobin. In June 2012, the results of a large, randomized, placebo-controlled trial evaluating the role of monotherapy (metformin) versus combination therapy (metformin and rosiglitazone) were published. The study enrolled patients 10–17 years of age having a diagnosis of type 2 DM for less than 2 years. The participants were initially treated with metformin until glycemic control was obtained. Then, the participants were randomized to metformin (1000 mg twice daily) monotherapy, metformin with lifestyle intervention (i.e., family-focused weight-loss behavioral changes including diet and exercise), or metformin with rosiglitazone (4 mg twice daily). Those who continued on metformin monotherapy experienced treatment failure 50% of the time, whereas participants treated with metformin and rosiglitazone had significantly lower treatment failures (39%). Those randomized to metformin monotherapy with lifestyle intervention had higher treatment failures (47%) than those on combination therapy. Common adverse effects reported in this study included gastrointestinal disturbances, infection, myalgia, elevation of liver enzymes (metformin), and mild hypoglycemia (metformin and rosiglitazone). One case of nonfatal lactic acidosis was

**Table 8.** Drug Interactions with Insulin (Reference 34)

Increases the Effect of Hypoglycemia	Decreases the Effect of Hypoglycemia
ACE inhibitors	Acetazolamide
Alcohol (acute use)	Alcohol (chronic use)
$\alpha$ -Blockers	Antiretrovirals
Anabolic steroids	Asparaginases
$\beta$ -Blockers	Calcitonin
Calcium	Corticosteroids
Fluoxetine	Cyclophosphamide
Lithium	Diltiazem
MAO inhibitors	Dobutamine
Mebendazole	Epinephrine
Metformin	Isoniazid
Octreotide	Lithium
Pentamidine	Morphine
Pramlintide	Niacin
Pyridoxine	Nicotine
Sulfonamides	Oral contraceptives
Sulfonylureas	Phenytoin
Tetracyclines	Somatropin
Thiazolidinedione	Thiazide diuretics
	Thyroid hormone

ACE = angiotensin-converting enzyme; MAO = monoamine oxidase.

**Table 9.** Oral Antihyperglycemic Medications (References 35–40)

Medication	Drug Class/ Mechanism of Action	Dose	Contraindications	Adverse Drug Reactions	Drug Interactions
Metformin (Glucophage)	Biguanide: decreases hepatic production of glucose, decreases absorption of glucose in the gastrointestinal tract, and improves insulin sensitivity by increasing peripheral uptake of glucose.	10–16 years of age: 500 mg BID with meals, may titrate by 500 mg weekly to a maximal dose of 2,000 mg/day in divided doses	Renal disease or dysfunction (SCr $\geq$ 1.5 in males and $\geq$ 1.4 in females) Hypersensitivity to metformin Acute or chronic metabolic acidosis (including DKA)	Diarrhea Nausea/vomiting Flatulence Asthenia Indigestion Abdominal discomfort Headache Lactic acidosis	Alcohol Iodinated IV contrast
Rosiglitazone (Avandia)	Thiazolidinedione: agonist for the PPAR- $\gamma$ ; binding to the PPAR- $\gamma$ improves insulin sensitivity in the peripheral tissues.	10–17 years of age: 2 mg twice daily titrated to a maximal dose of 8 mg/day after 8–12 weeks	Heart failure	Weight gain Edema Hepatotoxicity	Drugs that inhibit CYP2C8 may increase rosiglitazone concentrations, whereas inducers may decrease rosiglitazone concentrations.
Pioglitazone (Actos)	Thiazolidinedione: agonist for the PPAR- $\gamma$ ; binding to the PPAR- $\gamma$ improves insulin sensitivity in the peripheral tissues.	Adult dose: 15 mg daily titrated to a maximal dose of 45 mg after 8–12 weeks as monotherapy and 30 mg if used with combination therapy	Heart failure Hypersensitivity to pioglitazone	Weight gain Edema Hepatotoxicity	Drugs that inhibit CYP2C8 may increase concentrations of pioglitazone, whereas inducers may decrease concentrations of pioglitazone; if coadministered with a strong inhibitor, the maximal dose of pioglitazone should be 15 mg/day.
Glimepiride (Micronase)	Sulfonylurea: enhances insulin secretion from the pancreas	8–17 years of age: 1 mg/day, titrated every 2 weeks by doubling the dose to a maximum of 8 mg/day taken 15 minutes before a meal	Hypersensitivity to glimepiride or sulfonamides	Hypoglycemia Weight gain Nausea/vomiting Photosensitivity	Highly protein bound drugs may increase the hypoglycemic effects of sulfonylureas.

BID = twice daily; CYP = cytochrome P450; DKA = diabetic ketoacidosis; IV = intravenous; PPAR- $\gamma$  = peroxisome proliferator-activated receptor gamma; SCr = serum creatinine.

reported in the metformin monotherapy group. Those in the metformin and rosiglitazone arm had a slight increase in body mass index throughout the study. No long-term adverse effects on bone density were reported. Given the results of the study, rosiglitazone may be a viable adjunctive therapy in those who fail to respond to metformin monotherapy.

The short-term safety of pioglitazone (Actos) in adolescents was evaluated in a single- and multidose pharmacokinetic study (Reference 39). Adverse drug reactions reported in the study included nausea, diarrhea, headache, hypoglycemia, increased glutamyl-transferase, and peripheral edema. Efficacy and long-term safety were not established.

A potential advantage of thiazolidinediones is preserving pancreatic beta-cell function (Reference 43). One major disadvantage for this population is the weight gain associated with the thiazolidinediones. The thiazolidinediones have a class black box warning on the relationship between the onset and worsening of congestive heart failure in adults. In addition, in adults, the thiazolidinediones have been associated with hepatotoxicity and bone fractures. Because of the lack of efficacy data in pediatric patients and the associated adverse effects with the thiazolidinediones, rosiglitazone and pioglitazone are not recommended as first-line therapy in type 2 DM at this time.

### ***Sulfonylureas***

Glimepiride (Amaryl) has been studied in children and adolescents between 8 and 17 years of age in a 24-week, randomized, single-blind, parallel-group trial with metformin as the control (Reference 40). Both groups had significant decreases in glycosylated hemoglobin from baseline. Participants taking glimepiride had slight increases in serum cholesterol, low-density lipoprotein, triglycerides, and weight. No differences were reported in adverse drug reactions between the two treatment groups. Adverse reactions included hypoglycemia, abdominal pain, diarrhea, nausea, and headache. Glimepiride may be useful as adjunctive therapy to metformin in children and adolescents not wanting to use insulin. Disadvantages include the risk of hypoglycemia and weight gain. No other sulfonylureas have been studied in children. Glipizide and glyburide do not have any pediatric dosing, efficacy, or safety information.

### ***Meglitinides***

Meglitinides are considered short-acting insulin secretagogues. Compared with sulfonylureas, they have a more rapid onset and shorter duration of action. Because of their shorter duration of action, these medications must be taken with meals. This could be advantageous for children and adolescents who do not eat at regularly scheduled times. Nateglinide (Starlix) and repaglinide (Prandin) are two medications in this drug class. These medications have not been evaluated for use in the pediatric population.

### ***Glucosidase Inhibitors***

Glucosidase inhibitors inhibit the  $\alpha$ -glucosidase enzyme located in the small intestine, resulting in the inhibition of breakdown and absorption of glucose and other monosaccharides. A common adverse reaction with this class of medications is flatulence, which may be unacceptable to adolescents. Drugs in this class include acarbose (Precose) and miglitol (Glyset). These medications have not been evaluated for use in the pediatric population.

### **Approach to Pharmacotherapy in the Pediatric Patient with Type 1 DM**

Children and adolescents with diagnoses of type 1 DM require immediate treatment with insulin. If the patient presents with DKA, intravenous administration is the preferred route. Once the patient is stabilized, they may be transitioned to a split/mixed regimen to allow the patient and caregiver to become familiar with injecting insulin. During the honeymoon phase,

the split/mixed regimen or the use of intermediate- or long-acting insulin alone is typically adequate for glycemic control (Reference 29). After the honeymoon period, a split/mixed regimen can be reinstated, or the patient can begin to move toward a basal/bolus regimen.

### ***Special Considerations in Pediatric Patients with Type 1 DM***

#### ***Sick Day Management***

Children and adolescents are prone to hypoglycemia, hyperglycemia, ketosis, and DKA during times of illness. Consulting with the medical team and careful monitoring of hydration status, BG, and urine ketones is necessary.

Illness can cause an increase or decrease in insulin requirements; however, it is imperative to continue insulin administration during an illness. Discontinuing insulin during an illness predisposes a child or adolescent to DKA (Reference 44). At a minimum, basal insulin should be continued even if dose requirements are less (Reference 28). Lack of appetite, diarrhea, or nausea and vomiting contribute to hypoglycemia with continued insulin therapy. If the child or adolescent is unable to tolerate or eat solid foods, sugar-containing foods and drinks (e.g., soda, juice, ice pops) can be given to avoid hypoglycemia. If the child or adolescent is unable to tolerate such foods and drinks, glucagon administration is warranted (Reference 9). Because glucagon is associated with nausea and vomiting, a smaller dose of 10 mcg per year of age is typically administered (Reference 45).

Increased levels of stress hormones during an illness precipitate hyperglycemia and insulin resistance, thus increasing insulin requirements. Ketones can develop, despite euglycemia, in response to low glucose availability for intracellular metabolism. For this reason, monitoring of BG and urine ketones is necessary to determine whether the administration of more insulin is needed. Often, smaller doses of insulin are administered more frequently such as 5% to 10% or 10% to 20% (if ketones are present) of the total daily insulin dose every 3–4 hours (Reference 28). Hydration is especially important to aid in the diuresis of glucose and ketoacids.

#### ***School Administration***

Because children and adolescents spend a large part of their day in school or day care, it is important to educate school nurses and teachers about diabetes, monitoring BG, administering insulin, and recognizing the signs, symptoms, and treatment of hypoglycemia. A child or adolescent with diabetes can participate fully in school activities.

### *Adolescents and Adherence*

Adolescence becomes a difficult time for glycemic control for several reasons. The onset of puberty increases growth and sex hormones, resulting in increased insulin resistance. In addition, some adolescents seek more independence, may become rebellious, or may experiment with alcohol or illicit substances, which can result in nonadherence to diabetes management.

Adolescents with type 1 DM are at increased risk of psychiatric and behavioral disorders compared with adolescents without type 1 DM. Eating disorders, such as bulimia nervosa and binge eating disorder, occur in up to 30% of adolescents with type 1 DM, with females being affected more than males (References 46, 47). Teenagers may also resort to excessive exercise, laxative use, or omission of insulin in an attempt to lose weight (Reference 47). Other disorders seen commonly in this population include depression, anxiety, impulsivity, hyperactivity, and aggression (References 48, 49). Ongoing screening for such psychiatric disorders is recommended.

### **Approach to Pharmacotherapy in the Pediatric Patient with Type 2 DM**

Initial treatment of type 2 DM in a child or adolescent depends on the clinical presentation at diagnosis. Insulin therapy may be necessary to achieve glycemic control initially, particularly if the child or adolescent presents with a glycosylated hemoglobin greater than 9%, symptomatic hyperglycemia, HHS, or DKA. Once stabilized, an oral antihyperglycemic agent, such as metformin, can be initiated and insulin discontinued. Lifestyle intervention (i.e., diet, exercise) should also be incorporated into treatment.

Lifestyle intervention for a 3- to 6-month period before initiating pharmacologic therapy is an option for a patient who is asymptomatic or has a glycosylated hemoglobin between 7% and 9% at diagnosis. Adding an oral antihyperglycemic agent is considered either at the end of the 3- to 6-month trial of lifestyle modification or at diagnosis. Failure to reach a therapeutic glycosylated hemoglobin goal after 3–6 months of therapy typically necessitates the addition of a second oral antihyperglycemic agent or insulin. Initially, a basal insulin can be administered once daily. If therapeutic goals are still not achieved, the addition of rapid- or short-acting insulin with meals may be warranted. A small retrospective study evaluating various treatment regimens in type 2 DM reported few patients were able to attain therapeutic goals with monotherapy (Reference 50). However, further studies are necessary to determine optimal combination therapy.

## **MONITORING PHARMACOTHERAPY**

### **Monitoring Therapeutic Outcomes**

Glycemic control in DM is monitored with glycosylated hemoglobin and BG. Glycosylated hemoglobin represents glycemic control during a 3-month period. Therefore, it is monitored every 3 months in both type 1 and 2 DM. Self-monitoring of blood glucose (SMBG) by the patient or the caregiver is performed daily to monitor trends in BG and to adjust insulin doses or food intake. Self-monitoring of blood glucose is ideally performed pre- and post-prandially, nocturnally, during dose adjustments of medications, during illness, or when symptoms of hyper- or hypoglycemia are present (References 9, 22). In type 1 DM, at least four tests per day are necessary including before breakfast and dinner, before bedtime, and nocturnally (e.g., between 3:00 AM and 4:00 AM). The frequency in type 2 DM may be less often. In those with hypoglycemic unawareness, during periods of increased activity or illness, more frequent testing is warranted. In type 1 DM, monitoring of urine glucose and ketones is indicated when BG is greater than 250 mg/dL or during an acute illness to detect early ketosis and subsequent DKA (Reference 28).

Nocturnal monitoring is necessary to differentiate the dawn phenomenon and Somogyi effect when fasting hyperglycemia occurs in the morning. The dawn phenomenon is a result of normal BG increases in the early morning because of increases in growth hormone, increased hepatic glucose production, and increased insulin resistance (Reference 29). The Somogyi effect is a rebound hyperglycemia caused by a hypoglycemic event during the night. Management of the dawn phenomenon and Somogyi effect is provided in Table 10.

Self-monitoring of blood glucose allows adjustments in insulin doses and self-management of diabetes by the patient and caregiver. For a patient on a basal/bolus regimen, preprandial SMBG (and carbohydrate content of the meal) dictates the amount of insulin to be administered before a meal. Table 10 provides insulin adjustment recommendations for some situations of hyper- or hypoglycemia.

### **Monitoring Toxicities Associated with Pharmacotherapy**

While on insulin therapy, patients and caregivers must be counseled on recognizing the signs, and treatment, of hypoglycemia. Hypoglycemia is also detected with SMBG. In addition, patients and caregivers should monitor injection sites for local adverse effects including allergic reactions, lipoatrophy, and lipohypertrophy.

**Table 10.** Insulin Adjustments for Hypo- and Hyperglycemia in Children and Adolescents

Deviation	Adjustment	Precautions
Elevated fasting BG before breakfast (dawn phenomenon) <sup>a</sup>	(1) Increase the PM dose of intermediate- or long-acting insulin.  OR  (2) Administer the PM dose of intermediate-acting insulin later.	Obtain BG at 3–4 AM to ensure nocturnal hypoglycemia does not occur.
Elevated fasting BG before breakfast (Somogyi effect) <sup>a</sup>	(1) Decrease the PM dose of intermediate- or long-acting insulin.	
Elevated BG after meal	(1) Increase the rapid- or short-acting insulin administered before meals.	Evaluate the carbohydrate content of the meal to ensure it is appropriate.
Elevated BG before lunch/dinner	(1) Increase the AM basal insulin dose (if using intermediate-acting insulin).  OR  (2) Increase the prebreakfast rapid- or short-acting insulin dose.	

<sup>a</sup>Must differentiate between dawn phenomenon and Somogyi effect. AM = morning; BG = blood glucose; PM = nightly.

Renal and hepatic function and a complete blood cell count are usually obtained before initiating metformin and then yearly. Metformin alone does not cause hypoglycemia; however, BG monitoring is necessary to assess efficacy. Although lactic acidosis is rare, it is important to monitor for conditions that may predispose the patient to a hypoxic state.

Hepatic function should be evaluated before initiating a thiazolidinedione. If liver enzymes are elevated, the underlying liver disease is treated, or the thiazolidinedione is not used (Reference 51). Monitoring of hepatic function is recommended periodically throughout treatment with a thiazolidinedione. Because of an increased risk of fractures, it is necessary to monitor bone health in pediatric patients and supplement with calcium or vitamin D when indicated. When used as monotherapy, thiazolidinediones do not cause hypoglycemia. However, in combination with insulin or an insulin secretagogue, the risk of hypoglycemia increases. It is not recommended to use rosiglitazone in combination with insulin (Reference 51).

Sulfonylureas can cause hypoglycemia; therefore, patients must be educated about the signs and treatment of hypoglycemia. Patients with G6PD (glucose-6-phosphate dehydrogenase) deficiency are at increased risk of hemolytic anemia if treated with a sulfonylurea (Reference 52). An alternative treatment (e.g., metformin, insulin) is indicated in this population. Other

hematologic reactions, such as agranulocytosis, thrombocytopenia, and pancytopenia, are rare. No specific laboratory monitoring is indicated unless an adverse reaction is suspected.

#### FUTURE PHARMACOTHERAPY/ ADJUNCTIVE PHARMACOTHERAPY

Three classes of medications are currently approved for adults as adjunctive treatment of DM, amylin analogs, glucagon-like peptide-1 (GLP-1) receptor agonists, and dipeptidyl peptidase IV (DPP-IV) inhibitors. None is currently approved in pediatrics.

#### Amylin Analogs

Pramlintide (Symlin), an amylin analog, is approved as adjunctive therapy in adults with either type 1 or 2 DM on mealtime insulin not achieving glycemic control (Reference 53). Amylin is naturally secreted by the beta cells of the pancreas with insulin in response to food. It is reported to enhance the action of insulin by decreasing glucagon production, slowing gastric emptying, decreasing hepatic glucose production, and increasing satiety (Reference 54). Pramlintide, which is administered subcutaneously before meals, mainly decreases postprandial hyperglycemia. The most common adverse drug reactions include nausea, vomiting, and anorexia. Pramlintide alone does not cause hypoglycemia; however, hypoglycemia can occur (and is

listed as a black box warning) when used in combination with insulin, and concomitant use may require dose adjustments of the insulin. Weight loss has been associated with pramlintide use.

Short-term pilot studies have been conducted in children and adolescents with type 1 DM (References 55–57). Pramlintide may be beneficial in decreasing postprandial hyperglycemia, glycosylated hemoglobin, weight, and insulin doses. Pramlintide appears to be well tolerated, with nausea being the most common adverse drug reaction. There were no reports of hypoglycemia.

### Incretin Mimetics

Exenatide (Byetta), a GLP-1 receptor agonist, is approved for use in adults with type 2 DM. Glucagon-like peptide-1 is an incretin secreted by intestinal L-cells in response to food ingestion (Reference 54). Incretins enhance insulin release from the pancreas in response to elevated BG, inhibit glucagon release after meals, decrease gastric emptying, and increase satiety (Reference 58). Exenatide is administered subcutaneously before meals. The most common adverse effects are nausea, hypoglycemia (particularly when used in combination with a sulfonylurea), vomiting, diarrhea, dizziness, headache, and dyspepsia (Reference 59). Exenatide has been associated with fatal pancreatitis in adults. Exenatide improves postprandial BG, glycosylated hemoglobin, and weight in adults (Reference 59).

Exenatide pharmacokinetics have been evaluated in adolescents with type 1 and 2 DM and are comparable to those in adults (References 58, 60). In both studies, postprandial BG decreased with the administration of exenatide. Exenatide was well tolerated with no reports of hypoglycemia.

### DPP-IV Enzyme Inhibitors

Dipeptidyl peptidase IV enzyme inhibitors, which include sitagliptin, vildagliptin, alogliptin, and saxagliptin, are oral agents approved for use in adults with type 2 DM. The DPP-IV inhibitors block the enzyme responsible for GLP-1 degradation, resulting in increased activity of GLP-1. These agents decrease glycosylated hemoglobin as well as fasting and postprandial BG. The agents, however, are not associated with weight loss. The DPP-IV inhibitors are well tolerated (Reference 61). No data in pediatrics are currently available.

## DIABETIC KETOACIDOSIS

Diabetic ketoacidosis is a life-threatening acute complication of DM. It is characterized by hyperglycemia, severe dehydration, electrolyte losses from the intra- and extracellular fluid compartments, and acidosis. It results from

absolute insulin deficiency, whether from undiagnosed DM, nonadherence to insulin therapy, insulin pump malfunction, illness, infection (particularly gastrointestinal illness with nausea and vomiting), stress, or trauma.

### Pathophysiology of DKA

The lack of circulating insulin results in hyperglycemia caused by the inability to uptake glucose into peripheral tissue or into glycogen storage. It also stimulates the release of counterregulatory hormones including glucagon, catecholamines, cortisol, and growth hormone. These hormones further increase serum glucose levels because of increased glycogenolysis and gluconeogenesis. The hyperglycemia results in serum hyperosmolarity and an osmotic diuresis. The osmotic diuresis results in dehydration, electrolyte loss, and decreased glomerular filtration rates. The lack of insulin also results in increased lipolysis, leading to the release of free fatty acids and subsequent production of ketones, particularly  $\beta$ -hydroxybutyric and acetoacetic acids. The ketones, together with lactic acidosis from poor tissue perfusion, result in a metabolic acidosis. Until exogenous insulin is administered, the counterregulatory hormones continue to be released, resulting in further hyperglycemia and ketone production (Reference 62).

### Presenting Signs and Symptoms

Common presenting signs and symptoms of DKA include dehydration, polyuria, polydipsia, recent weight loss, rapid, deep sighing (Kussmaul respiration), and fruity-smelling breath. Changes in mental status, such as decreased alertness or loss of consciousness, can also be present. Other nonspecific symptoms, such as nausea, vomiting, or fever, may indicate the presence of an infection that could have precipitated DKA (Reference 12). The physical examination typically includes an evaluation of hydration status, vital signs (cardiovascular and respiratory), and neurologic status. Laboratory tests include BG, blood or urine ketones, electrolytes (including sodium, potassium, calcium, phosphorus, bicarbonate, and blood urea nitrogen), blood gases, serum osmolarity, and a urinalysis for ketone detection (Reference 63). If available, blood levels of  $\beta$ -hydroxybutyrate are measured. Because of potassium abnormalities that occur, an electrocardiogram is obtained (Reference 12).

### Diagnosis of DKA

The diagnostic criteria for DKA are listed below (Reference 12):

1. BG greater than 200 mg/dL
2. Venous pH less than 7.3 or bicarbonate less than 15 mmol/L
3. Ketonemia or ketonuria

The severity of DKA is classified into mild, moderate, and severe depending on the serum pH. A pH between 7.2 and 7.3 is mild, between 7.1 and 7.2 is moderate, and less than 7.1 is severe DKA (Reference 62).

### Therapy Goals

The therapy goals in the management of DKA include the following (Reference 12):

1. Correction of dehydration
2. Correction of acidosis and reversal of ketosis
3. Decreased BG levels
4. Correction of electrolyte abnormalities
5. Prevention of DKA complications

### Treatment of DKA

#### *Treatment of Dehydration*

The initial goal of rehydration in DKA is reperfusion of organs, not complete restoration of fluid lost. For that reason, on initial presentation, a fluid bolus of 10–20 mL/kg over 1–2 hours with either 0.9% saline or lactated Ringer's is recommended. The bolus may be repeated if necessary, but not to exceed 40 mL/kg of total intravenous fluid within the first 4 hours of treatment (Reference 63). After the initial boluses, administration of the estimated fluid deficit is given over a 48-hour period to prevent cerebral edema. The total fluid deficit can be difficult to estimate; therefore, administering 1.5–2 times the daily maintenance fluid requirements is not exceeded (Reference 63). The tonicity of the replacement fluid should be at least 0.45% saline. If the serum sodium levels are low, 0.9% saline is recommended, whereas if the sodium levels are high, 0.45% saline is preferred (Reference 64).

#### *Correction of Acidosis and Ketosis Reversal*

The initiation of insulin not only decreases BG but also, more importantly, suppresses lipolysis and ketogenesis, which will reverse the ketoacidosis. Insulin therapy is started 1–2 hours after the initiation of the fluid boluses to minimize the risk of cerebral edema (Reference 62). Regular insulin administered intravenously is the preferred insulin and route of administration. The initial insulin dose is 0.1 unit/kg/hour until the serum pH is greater than 7.3, the bicarbonate is greater than 15 mmol/L, or the anion gap is no longer present. Because BG normalization can occur before the ketoacidosis resolution, dextrose 5% is added to the intravenous fluids once the BG level falls below 300 mg/dL to prevent hypoglycemia (Reference 12). If the BG falls rapidly, dextrose 10% or 12.5% is used in place of the 5%. In children and adolescents sensitive to insulin, the insulin dose is decreased to 0.05 unit/kg/hour. Despite BG correction, the insulin is continued until the ketoacidosis is

resolved. Once the ketoacidosis is resolved, the patient can be transitioned to a subcutaneous form of insulin. Bicarbonate is not generally recommended for the treatment of DKA (Reference 12).

#### *Correction of Electrolyte Abnormalities*

Although serum potassium levels can appear normal in a child or adolescent with DKA, total body potassium is typically low. Increased levels of serum potassium result from the extracellular shift of potassium secondary to acidosis and hypertonicity. Conversely, at presentation, low serum potassium levels are because of increased elimination caused by osmotic diuresis. In addition, on administration of insulin, serum potassium levels decrease because of the shift of potassium into the cells. Regardless, potassium replacement begins early in the treatment of DKA. If the potassium level is elevated at presentation, adequate renal output is established before initiating potassium replacement (Reference 65). The potassium is generally replaced as potassium chloride, acetate, or phosphate at 40 mEq/L. Potassium acetate or phosphate are preferred over potassium chloride to avoid hyperchloremic metabolic acidosis (Reference 64). However, if potassium phosphate is administered, it is limited to no more than one-half the total potassium replacement required (Reference 63).

Sodium and phosphate may be decreased in DKA. Sodium is typically replaced with the intravenous fluids administered for rehydration. Phosphate can be replaced when potassium phosphate is used to treat hypokalemia; however, unless the phosphate level is less than 1 mg/dL and the patient is experiencing muscle weakness, it is not recommended to replace phosphate (Reference 62).

#### Monitoring of Therapy

During the treatment of DKA, intensive monitoring is necessary. If possible, vital signs, neurologic status, fluid input and urine output, and capillary BG should be monitored hourly (Reference 12). Electrolytes and blood gases are monitored every 2–4 hours, whereas blood urea nitrogen, creatinine, and hematocrit can be obtained every 6–8 hours. Anion gap and serum osmolality should also be monitored with each laboratory draw.

Children and adolescents with DKA must be closely monitored for signs of cerebral edema. These signs include headache, vomiting, increasing blood pressure, decreasing heart rate, decreasing oxygen saturation, and changes in neurologic status such as confusion and lethargy. Computed tomography may assist in the diagnosis of cerebral edema; however, evidence of cerebral edema is not always present on imaging studies (Reference 12). The onset of cerebral edema is typically within 4–12 hours after the treatment initiation for DKA.

## CONCLUSIONS

It has been estimated that a child given a diagnosis of diabetes at age 10 in the year 2000 will live 20 years less than a child not receiving a diagnosis of DM at the same age (Reference 66). In addition, the quality of life for these children will be less than for those without DM. However, because of advances in pharmacologic therapy, such as insulin analogs, improvements in metabolic control in DM can prolong both the quantity and quality of life for pediatric patients afflicted with DM. Such care requires full participation of the caregiver and patient, when possible, with a multidisciplinary health care team to optimize pharmacotherapy (and minimize adverse reactions) to prevent complications.

# CHAPTER 25

## CEREBRAL PALSY

Mary A. Worthington, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. List underlying causes and risk factors for cerebral palsy (CP).
2. Discuss initial and ongoing assessment of the patient with CP.
3. Recognize and recommend treatment options for generalized and localized spasticity.
4. Discuss nonpharmacologic and pharmacologic treatment options for drooling.
5. Describe the role of pamidronate in the treatment of low bone mineral density associated with CP.

### ABBREVIATIONS IN THIS CHAPTER

AAN	American Academy of Neurology
BMD	Bone mineral density
CNS	Child Neurology Society
CP	Cerebral palsy
c-PVL	Cystic periventricular leukomalacia
CSF	Cerebrospinal fluid
EPNS	European Paediatric Neurology Society
GABA	$\gamma$ -Aminobutyric acid
GMFCS	Gross Motor Function Classification System
ODT	Orally disintegrating tablet
UCP	United Cerebral Palsy

### INTRODUCTION

In 2004, an International Workshop on Definition and Classification of Cerebral Palsy was convened in Bethesda, Maryland. Participants emphasized the importance of viewing cerebral palsy (CP) as a clinical descriptive term and defined CP as a group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to non-progressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of CP are often accompanied by disturbances of sensation, perception, cognition, communication, and behavior, by epilepsy, and by secondary musculoskeletal problems. (Reference 1)

Although CP results from a nonprogressive disturbance, the symptoms in patients change with time. This changing clinical course necessitates frequent assessment by health care providers to ensure that treatments are continually evaluated and adjusted to optimize overall function. As drug treatment options expand for motor disorders and other accompanying conditions, pharmacists play an increasing role in selecting optimal medication choices for patients with CP.

### EPIDEMIOLOGY AND CLASSIFICATION

Cerebral palsy is the most common childhood physical disability. United Cerebral Palsy (UCP) is a nonprofit organization dedicated to providing education about CP and advocacy and support for patients and their families. The UCP estimates that 764,000 children and adults in the United States manifest at least one CP symptom (Reference 2). The average prevalence in the United States is estimated at 3.3 per 1,000 for children 8 years of age (Reference 3).

Because CP covers a broad range of clinical presentations, the disorder is classified on the basis of motor abnormalities, accompanying impairments, anatomic and neuroimaging findings, causation, and timing (Reference 1). Patients may present with more than one movement abnormality, but it is recommended that they be classified by the dominant type: spasticity, dystonia, choreoathetosis, or ataxia (Reference 1). Around 81% of children have spastic CP (Reference 3). Functional motor abilities in individuals with CP are most often described using the Gross Motor Function Classification System (GMFCS) (Reference 4). The GMFCS has five levels of classification and is determined from self-initiated movement with an emphasis on sitting, transfer, and mobility. Table 1 defines the levels of classification for the GMFCS and estimates the percentage of children with CP who function at each level. The GMFCS may be used in the consideration of treatment options.

Accompanying impairments in patients with CP may interfere with the activities of daily living to an equal or greater extent than characteristic motor disabilities. Epilepsy is present in 35% of children with CP (Reference 3), and it can complicate treatment choices by increasing the risk of drug-drug interactions between

**Table 1.** GMFCS Levels and Estimates of Children Who Function at Each Level

Level	General Description <sup>a</sup>	8-Year-Old Children Who Function at Level (%) <sup>b</sup>
I	Walks without restrictions: limitations in more advanced gross motor skills	38.1
II	Walks without assistive devices: limitations walking outdoors and in the community	16.4
III	Walks with assistive mobility devices: limitations walking outdoors and in the community	13.2
IV	Self-mobility with limitations: children are transported or use power mobility outdoors and in the community	15.2
V	Self-mobility is severely limited even with the use of assistive technology.	17.1

GMFCS = Gross Motor Function Classification System.

therapies for the movement disorder and seizure control. Constipation and urinary incontinence are other frequently seen conditions that require concurrent drug therapies. Additional impairments include hearing and vision abnormalities, intellectual disabilities, emotional and behavioral disorders, and musculoskeletal problems.

Classification by anatomic and neuroimaging findings currently emphasizes the importance of assessing CP involvement in all body regions and using imaging technology as it develops. At present, it is difficult to categorize by causality; however, as mechanisms of injury in fetal and infant brain development become better understood, classification by cause may have greater utility. Categorization by timing of insult is only recommended when there is reasonably definitive evidence of the cause (Reference 1).

## ETIOLOGY AND RISK FACTORS

Because CP occurs because of an injury or disturbance in the developing fetal or infant brain, etiology and risk factors are often described as prenatal, perinatal, or postnatal (References 5, 6). It is estimated that 70% to 80%

of CP cases are acquired prenatally, often from unknown causes (References 6, 7). Birth complications, including intrapartum asphyxia, account for a small percentage, or 5% to 10%, of cases (Reference 7). Box 1 lists prenatal and perinatal risk factors associated with an increased risk of CP. The relationship between prematurity and CP is complicated by evolving neonatal intensive care practices. Cystic periventricular leukomalacia (c-PVL) and severe intraventricular hemorrhage are independent risk factors for CP in premature patients, and decreased incidence of CP has been attributed to decreasing c-PVL (Reference 8). Fewer patients acquire CP from postnatal causes occurring in infancy, including bacterial meningitis, viral encephalitis, or a brain injury from a motor vehicle collision, a fall, or child abuse (Reference 7). Prevention of postnatal causes is a promising strategy for decreasing the prevalence of CP (Reference 5).

## CLINICAL PRESENTATION AND DIAGNOSIS

### Initial Assessment and Diagnosis

Most children with CP present as infants and toddlers, and diagnosis often occurs by 2 years of age. In patients with milder symptoms, CP may not be confirmed before 4–5 years of age. Early, careful assessments of motor development, muscle tone, and risk factors are key aspects of diagnosis. A delay in reaching motor developmental milestones is usually viewed as a classic sign of CP in at-risk patients. However, some milestones, such as hand preference and even rolling over in select patients, may be achieved before typical ages. Box 2 lists early clinical features of CP. The differential diagnosis often focuses on eliminating disorders that are progressive, including metabolic or genetic disorders or central nervous system tumors. Targeted laboratory testing may help rule out these processes (Reference 7).

### Box 1. Prenatal and perinatal factors associated with an increased risk of cerebral palsy.<sup>a</sup>

- Preterm birth
- Lower gestational age
- Lower birth weight (particularly VLBW, ELBW)
- Neonatal encephalopathy
- Multiple pregnancy
- Assisted reproductive technology
- Intrauterine infection and inflammation
- Genetics

<sup>a</sup>Adapted from Reference 5.

ELBW = extremely low birth weight (less than 1,000 g).

VLBW = very low birth weight (1,000 g to less than 1,500 g).

Neuroimaging techniques may be helpful in distinguishing CP from other movement disorders and potentially identifying the location of injury in CP. Neuroimaging is often performed in the perinatal period if there is a history of prematurity or birth complications. In patients who present at a later age, neuroimaging is recommended if the etiology has not been identified (Reference 9). Magnetic resonance imaging is preferred to computed axial tomography because it results in a greater suggestion of the etiology and timing of insult that led to CP (Reference 9). In patients with unilateral (hemiplegic) CP, neuroimaging is helpful to evaluate for unexplained cerebral infarction, and in these patients, laboratory testing to evaluate for coagulopathies should be considered (Reference 9).

### Continuing Assessment of Muscle Tone, Movement, and Associated Conditions

Evaluation of muscle tone and movement is important for patients with CP to determine which motor abnormalities may be present. Symptoms related to motor dysfunction vary greatly from person to person and may be isolated or mixed. Box 2 lists symptom examples on the basis of motor abnormality type. Spasticity, the most common abnormality, describes a form of hypertonia,

which is characterized by a velocity-dependent resistance of a muscle to stretch (Reference 10). Dyskinesia describes a movement pattern that is involuntary, uncontrolled, recurring, and occasionally stereotypical (Reference 11). Dyskinetic CP is termed *dystonic* if movements are stiff with increased tone and *choreoathetotic* if movements are slow and writhing with decreased tone (Reference 11). Ataxia in CP describes a loss of orderly muscle contraction with movements that are performed with abnormal force, rhythm, and accuracy (Reference 11).

The motor abnormalities of CP may make it more difficult to recognize other, concurrent impairments. Although epilepsy, intellectual disabilities, and speech and language disorders are not always present, patients should be screened for them (Reference 9). For epilepsy assessment, electroencephalography should be obtained if the child exhibits any features that suggest a seizure disorder (Reference 9). Hearing and vision evaluations may require referral to specialists because some children are unable to cooperate and complete typical screenings.

In addition, nutrition, growth, and other problems with swallowing function should be monitored (Reference 9). An early sign of feeding difficulties is poor weight gain. In some infants, the difficulty may be caused by the delayed development of oral motor

#### Box 2. Clinical features of cerebral palsy.

##### Early clinical features<sup>a</sup>

- Slow to reach motor developmental milestones (examples: roll over, sit, crawl, smile, or walk)
- Hypotonia (floppy) or hypertonia (stiff, rigid)
- Unusual posture
- Persistence of the Moro reflex after 6 months
- Favoring of one side of the body or development of hand preference earlier than 12 months

##### Clinical symptoms related to motor abnormalities<sup>b</sup>

###### Spasticity

- Stiff or tight muscles
- Increased deep tendon reflexes
- Scissored gait with toe-walking
- May be unilateral (one body side) or bilateral (both body sides)
- Upper or lower extremities may be more affected.

###### Dyskinesia

- Slow, uncontrollable writhing movements
- Grimacing or drooling caused by hyperactive muscles of the face and tongue

###### Ataxia

- Unsteady wide-based gait
- Intention tremor
- Difficulty with precise motions, such as writing or buttoning a shirt

<sup>a</sup>Adapted from References 6 and 7.

<sup>b</sup>Adapted from Reference 7.

skills related to prematurity. The inability to control secretions can make feeding challenging and place the patient at risk of aspiration. Patients with feeding difficulties are often initially evaluated by assessing their swallowing function with a modified barium swallow study; then, diet modifications are made on the basis of the results obtained. Failure to thrive is common in children with moderate to severe CP. In these children, providing enteral nutrition through a gastrostomy tube is an option to improve nutritional status (Reference 7). When gastrostomy tubes are present, oral medications are often given through the tube. Liquid drug formulations should be used when available for this route of administration. If a tablet preparation is used by crushing and mixing with water, care should be taken to ensure this will not alter drug properties or cause a physical blockage of the gastrostomy tube (see the Parenteral and Enteral Nutrition chapter). Poor nutrition and altered growth also affect skeletal development and are contributing factors to the low bone mineral density (BMD) seen in patients with CP, especially in nonambulatory children with moderate to severe motor impairment (References 12, 13).

The use of outcome measures that help clinicians quantify and monitor function is a valuable aspect of CP assessment. The GMFCS (Reference 4) is fundamental in evaluating motor functional abilities in children 1–18 years of age with CP, and its use has increased as a clinical and research tool (Reference 14). The GMFCS and other instruments that measure outcomes in patients with CP are available on the CanChild Centre for Childhood Disability Research Web site (Reference 15). In patients with spasticity, determining the degree of spasticity is helpful in evaluating response to therapy. The Ashworth (Reference 16), the modified Ashworth (Reference 17), and the modified Tardieu scales (Reference 18) are three instruments used to grade levels of spasticity. The modified Tardieu scale may be more effective in quantifying a change in spasticity than the modified Ashworth scale (Reference 18).

## TREATMENT

The overall treatment goals for patients with CP are to improve function and aesthetics, capabilities, and quality of life. Early, intensive treatment optimizes clinical outcomes (Reference 7). Care plans are individualized and comprehensive. They incorporate several components including physical and behavioral therapy, drug therapy, surgery, and mechanical aids. Drug therapy is focused on managing spasticity and other issues related to the motor aspects of the disorder. Supportive care concerns (e.g., low BMD) also benefit from pharmacotherapy.

## Spasticity

Specific treatment objectives for spasticity are to maximize active function, ease caregiving, relieve pain, and decrease or prevent contractures (Reference 19). First, patients should be assessed for muscle weakness and strength. If weakness is present, it is important to determine whether spasticity is actually helping with function (e.g., with weight bearing or a caregiver's ability to transfer) (References 19, 20). In these patients, treatments should be carefully monitored for worsening weakness and counterproductive effects on function. Second, nonspastic causes of pain and poor positioning should be resolved before other treatments (Reference 20). Once these are addressed, nonpharmacologic management through physical therapy or orthotics is optimized. Regular stretching exercises of affected limbs are prescribed to maintain range of motion and prevent contractures (Reference 19). Typically, caregivers are taught and encouraged to perform these exercises. For patients with unilateral spasticity, constraint-induced movement therapy is a rehabilitation option. For example, in a patient with unilateral upper extremity spasticity, the arm with the greater function is constrained to force the use of the lesser functioning arm (Reference 21). Ankle-foot orthoses are commonly used to maintain proper foot position and decrease the propensity to toe-walk (Reference 19).

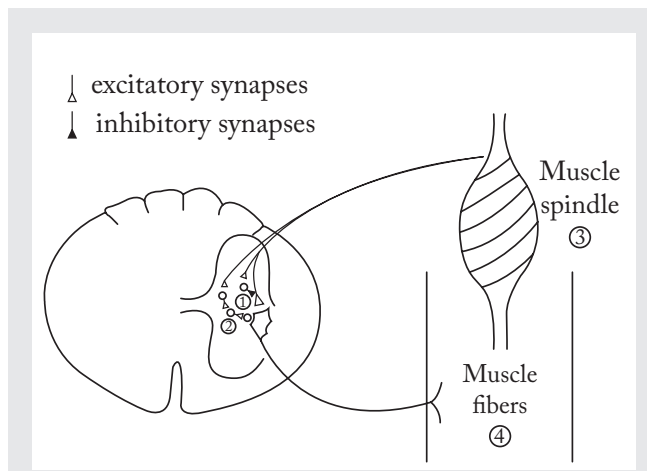

After physical management is maximized, pharmacologic therapy for spasticity is considered. Treatment options include drugs for generalized or localized spasticity. Although not fully elucidated, many symptoms of spasticity result from an upper motor neuron lesion causing disinhibition of spinal reflexes or the failure of reciprocal inhibition (Reference 22). The drug effect is aimed at altering these abnormalities. Figure 1 illustrates the proposed mechanisms of action for the drugs most commonly used to treat generalized spasticity: oral clonazepam, diazepam, baclofen, tizanidine, dantrolene, and intrathecal baclofen. Botulinum toxin products, phenol, and alcohol are used for localized spasticity as denervation agents (Reference 19).

The choice of an antispastic drug is often based on experience and trial and error as opposed to evidence-based medicine, particularly with oral medications. The research with these agents is older, did not use outcome measures for function or rigorous study design, or was conducted primarily in an adult population (Reference 19). The Quality Standards Subcommittee of the American Academy of Neurology (AAN) and the Practice Committee of the Child Neurology Society (CNS) addressed these limitations in a practice parameter published in 2010 that evaluated the

evidence basis for antispasticity treatments in children and adolescents with CP (Reference 24). Table 2 summarizes their conclusions and recommendations regarding drug therapy for spasticity. Oral baclofen is extensively used in clinical practice to treat children with CP and spasticity despite the recommendation that the evidence is insufficient to support its use (Reference 24).

### ***Diazepam and Clonazepam***

Diazepam, a benzodiazepine, is the oldest treatment option for spasticity still in use today (Reference 25) and is probably effective for short-term management (Reference 24). Clonazepam is another benzodiazepine used as an antispastic agent. Their effects on spasticity are mediated through  $\gamma$ -aminobutyric acid (GABA), specifically by increasing the affinity of GABA for GABA<sub>A</sub> receptors, resulting in presynaptic inhibition and reduced monosynaptic and polysynaptic reflexes (Reference 25). Both diazepam and clonazepam also have anticonvulsant activity, which may provide added benefit in patients with an accompanying seizure disorder. Clonazepam, in particular, has indications as a treatment for absence seizures and myoclonus.

**Figure 1.** Presumed sites of action for drugs used to treat generalized spasticity.

(1) Clonazepam and diazepam facilitate GABA-A-mediated presynaptic inhibition; (2) baclofen inhibits activity of polysynaptic reflexes by GABA-B receptor activation; (3) tizanidine acts on  $\alpha_2$ -adrenergic receptors; and (4) dantrolene reduces the sensitivity of peripheral intramuscular receptors and reduces release of calcium ions from the sarcoplasmic reticulum, which thus weakens muscle contraction. GABA =  $\gamma$ -aminobutyric acid.

Reproduced from Dietz and Young (Reference 23) with permission.

Sedation is the most common, often dose-limiting, adverse effect of the benzodiazepines when they are used for spasticity (Reference 25). However, for patients with insomnia, the benzodiazepines may aid with sleep difficulties if dosed at night. Other adverse effects that limit long-term use include weakness, sialorrhea, and ataxia (Reference 24).

Diazepam and clonazepam are given orally or enterally for spasticity, and both have rapid oral absorption (Reference 26). They are considered long-acting benzodiazepines with elimination half-lives of up to 50 hours in adults and faster rates in children (Reference 26). Long-acting benzodiazepines are considered to have a decreased risk of withdrawal, but this is a known concern with both agents. Because of this risk, abrupt discontinuation should be avoided after prolonged use, and if possible, substitution with intravenous or rectal diazepam should be made if oral or enteral cessation becomes necessary (References 24, 25).

Dosage should be initiated at a low dose and titrated up for the benzodiazepines. The lowest effective maintenance dose should be given to minimize sedation. Diazepam is available in tablets, a solution, and a liquid concentrate for oral use. Clonazepam is available in tablets and a newer orally disintegrating tablet (ODT) formulation. Although the clonazepam ODTs have increased dosing and administration options for pediatric patients, it is sometimes necessary to use a compounded oral liquid (Reference 27). Table 3 lists doses and available products for diazepam and clonazepam.

### ***Tizanidine***

Tizanidine is a newer oral agent whose effectiveness for spasticity has been primarily shown in adults with multiple sclerosis or a spinal cord injury (Reference 25). Little information exists on its effectiveness for spasticity reduction in children with CP (Reference 24). As an  $\alpha_2$ -adrenergic agonist, its ability to reduce muscle tone occurs through the hyperpolarization of motor neurons, with a subsequent decrease in excitability (References 25, 28, 29). It is also described as having antinociceptive effects mediated through substance P. This capability to reduce pain may be a contributory factor to its benefits on tone (Reference 25). Tizanidine is extensively metabolized in the liver. Cytochrome P450 (CYP) 1A2 is the primary enzyme for metabolism, and the potential for drug interactions should be assessed when it is given with other drugs metabolized through this pathway (Reference 30).

Sedation, hypotension, asthenia, dry mouth, dizziness, hallucinations, and hepatotoxicity have been reported as adverse effects in adults (Reference 24). Initiating tizanidine as a single daily dose at bedtime may minimize sedation effects on daily function. Dosage is then titrated upward by adding doses throughout the day. Titration may also help avoid nausea and vomiting in patients (Reference 25). A study found significant reduction in spasticity using the Ashworth scale in 10 children given tizanidine at a dosage of 0.05 mg/kg/day for 6 months versus 30 children who received placebo (Reference 31). Larger studies are needed to determine the optimal dosage in the pediatric population. Tizanidine is available as tablets and capsules. When tizanidine is given with food, the extent of absorption is increased for both tablets and capsules, but to a greater

degree with the tablet formulation. Peak plasma concentrations and time to peak are also altered and differ (Reference 29). Pediatric dosing is limited as well by the lack of a commercial or extemporaneous liquid formulation, but it is possible to open the capsules and sprinkle the contents on applesauce. This administration method increases the peak and extent of absorption and decreases the time to peak concentration (Reference 30). Table 3 summarizes oral dose and formulation information for tizanidine.

### **Dantrolene**

Dantrolene is unique among oral drugs used for spasticity, with a mechanism of action having direct effects on skeletal muscle. It acts by inhibiting the release of calcium at the sarcoplasmic reticulum, resulting in

**Table 2.** Evidence-Based Conclusions and Recommendations on Antispasticity Drug Therapy in Children and Adolescents with CP<sup>a</sup>

Drug	Conclusions	Recommendations
<b>For Generalized Spasticity</b>		
Baclofen (intrathecal)	Inadequate data on continuous intrathecal baclofen as antispasticity treatment; CSF leaks, seromas, catheter-related complications, and wound infections occur frequently and milder complications occur less often	Insufficient evidence to support or refute use for spasticity (U) <sup>b</sup>
Baclofen (oral)	Conflicting evidence regarding effectiveness to reduce spasticity and improve function; systemic toxicity is found in some patients	Insufficient evidence to support or refute use for spasticity or to improve motor function (U)
Dantrolene (oral)	Conflicting evidence regarding effectiveness to reduce spasticity; weakness, drowsiness, and irritability are frequent adverse effects.	Insufficient evidence to support or refute use for spasticity (U)
Diazepam (oral)	Probably effective short-term therapy for spasticity; improved motor function not addressed; ataxia and drowsiness were adverse effects in most studies.	Consider a short-term antispasticity treatment (B); insufficient evidence to support or refute use to improve motor function (U)
Tizanidine (oral)	Possibly effective spasticity treatment with no toxicity in one small study	May be considered for treatment of spasticity (C); insufficient evidence to support or refute use to improve motor function (U)
<b>For Localized Spasticity<sup>c</sup></b>		
AbobotulinumtoxinA, OnabotulinumtoxinA	Effective treatment to reduce spasticity in upper and lower extremities; conflicting evidence on functional improvement; generally safe, but severe generalized weakness may occur.	For localized/segmental spasticity in upper or lower extremities with CP that warrant therapy, should be offered as generally safe treatment (A); insufficient evidence to support or refute use to improve motor function (U)

<sup>a</sup>Adapted from Reference 24, which includes clinical context summaries.

<sup>b</sup>Classification of recommendations: A = established effective for the given condition in the specified population (requires two or more class I studies), B = probably effective for the given condition in the specified population (requires one class I study or two consistent class II studies), C = possibly effective for the given condition in the specified population (requires one class II study or two consistent class III studies), U = data inadequate or conflicting and treatment is unproved given current knowledge.

ODT = orally disintegrating tablet; tid = three times/day

muscle weakness (Reference 19). Because of its peripheral mechanism, it may be a helpful agent in patients whose spasticity results from a traumatic brain injury. However, conflicting results on the effectiveness of dantrolene led the AAN and CNS practice parameter to conclude that evidence was insufficient to support or refute its use for spasticity in children with CP (Reference 24).

The use of dantrolene is also limited by its adverse effect profile. Although the therapeutic effects occur outside the central nervous system, it is often associated with dose-dependent, diffuse weakness (Reference 29). Drowsiness and irritability are additional common adverse effects in children with CP (Reference 24). Dantrolene is associated with hepatotoxicity. In one series, the risk of fatal hepatic disease was increased in women older than 35 years, in patients receiving higher daily dosages, and in patients with a diagnosis of multiple sclerosis (Reference 32). Even though studies of dantrolene for spasticity in children with CP did not report hepatotoxicity (Reference 24), all children being initiated on therapy should undergo baseline and periodic liver function test monitoring. Dantrolene should be avoided if patients are receiving additional hepatotoxic therapies.

Dantrolene is extensively metabolized in the liver and has an active metabolite, 5-hydroxy dantrolene. It has potential for interactions with drugs metabolized through the CYP3A4 enzyme (Reference 26). Therapeutic benefit for spasticity may take several days for onset, and the dose is titrated to effect at 7-day intervals. When no advantage is seen with a dosage increase, the dose should be lowered to minimize toxicity (Reference 26). Dantrolene is commercially available in capsules that may be opened and mixed with juice or liquid. Extemporaneous oral liquids may be prepared, but these formulations are limited by their complexity in preparation or short time to expiration (Reference 33).

### **Baclofen**

Baclofen is a GABA agonist used to treat spasticity by oral and intrathecal administration. Baclofen crosses the blood-brain barrier and binds to GABA<sub>B</sub> receptors in laminae I–IV of the spinal cord (Reference 34). It appears to block both monosynaptic and polysynaptic afferents (Reference 28). The mechanism may be as a direct inhibitory neurotransmitter or through hyperpolarization of afferent nerve terminals (Reference

28). Baclofen is rapidly absorbed after oral administration. It is partly metabolized by the liver, but a significant amount is eliminated unchanged by the kidneys (Reference 29).

Oral baclofen is often considered the drug of choice for adults with spasticity caused by spinal cord injury (Reference 19), and it is widely used as a treatment for spasticity in children with CP (Reference 24). Oral baclofen is associated with sedation and confusion, which may lessen after several weeks of therapy (Reference 19). Initiating baclofen at the lowest possible dose may minimize these adverse effects (Reference 24). Various oral dosing regimens have been published for baclofen, largely based on small trials and expert opinion (References 28, 34, 35). A study assessed oral baclofen dosing in a retrospective review of 86 pediatric patients with spasticity (Reference 35). The study found that higher dosage requirements were associated with longer time since the onset of injury responsible for spasticity, increasing age of patient, and number of concurrent antispasticity medicines (Reference 35). If oral baclofen is discontinued, a gradual wean is recommended because abrupt discontinuation may cause withdrawal symptoms including increased spasms, hallucinations, confusion, fever, and seizures (References 24, 25, 29). Oral baclofen is commercially available as tablets. It can be compounded into a liquid form (References 36, 37), but it may be preferable to prescribe by ½- or ¼-tablet doses for consistency (Reference 25). Table 3 provides oral dosing and formulation information for baclofen.

Intrathecal baclofen is administered through an implantable pump that provides a continuous or variable-rate infusion. The AAN and CNS practice parameter concluded that the use of continuous intrathecal baclofen for spasticity in children with CP was not supported by adequate data (Reference 24). A consensus statement from the European Paediatric Neurology Society (EPNS) reviewed the efficacy of the treatment and stated that a reduction in spasticity is best established in patients with severe spasticity in the lower limbs consistent with GMFCS levels IV–V (Reference 38). Decreased spasticity has also been shown in upper limbs, but to a lesser extent (Reference 38). In a study of 37 patients with CP, the authors found significant improvement in motor function, as assessed by the Gross Motor Function Measure (Reference 39). The best improvements were seen in patients younger than 18 years (Reference 39). Box 3 summarizes the EPNS recommendations for selecting patients to receive intrathecal baclofen. Although there are no limitations on patient weight to be considered a candidate for therapy, children should have large enough body

mass to allow implantation of the pump, which is about the size of a hockey puck (Reference 19). Some experts recommend a minimum of 15 kg of body weight (Reference 29). Figure 2 illustrates a child with a baclofen intrathecal pump.

Because the drug is delivered directly to the subarachnoid space around the spinal cord, the required dosage of intrathecal baclofen is less than 1% of an oral dose, which decreases sedation risk (Reference 19). Children and adults (mean age 16 years) administered intrathecal baclofen at doses of 70–1,395 mcg/day had cerebrospinal fluid (CSF) concentrations equal to 0.2–20 mcg/mL from an intrathecal catheter aspirate (Reference 40). These levels did not statistically correlate with dose but did compare with CSF concentrations of 12–96 mcg/mL in adults receiving oral dosages of 30–90 mg/day (Reference 41). In contrast, plasma concentrations of baclofen were at or below the limit of detection (10 ng/mL) in children receiving intrathecal dosages of 77–400 mcg/day in a separate study (Reference 42). In summary, the CSF concentrations achieved by reported doses of intrathecal baclofen are comparable to levels seen with oral therapy while the plasma concentrations are minimized.

**Box 3.** Summary of selection criteria for patients receiving intrathecal baclofen.

- Confirmed spasticity
  - Aggravating factors managed
  - Spasticity not optimally managed by physical therapies, oral baclofen, and other drugs, botulinum toxin injection
  - Spasticity interferes with patients' abilities and quality of life
- Ability and motivation to attend regular follow-up and monitoring
- Age older than 4 years
  - NB. Baclofen for intrathecal use (Lioresal) is licensed for use in children older than 4 years; though children younger than this have been treated, regulations on patient age vary from country to country.
- No limitations on patient weight, though overweight patients may need to lose weight before surgery

Reproduced from Dan et al. (Reference 38) with permission.  
NB = nota bene; note well.

Once selected for therapy, the patient and his or her caregivers should receive education on the treatment, its possible effects, potential complications, what will be required of them, and protocols for emergency management (References 34, 38). A screening intrathecal dose is often given as a single injection to assess patient response. The aim of the test is to show spasticity reduction in several muscle groups (Reference 34). It may also help determine an initial dose. However, it does not reliably predict functional improvement (Reference 38). Dosage titration is recommended when a patient initiates continuous intrathecal infusion to minimize adverse effects (Reference 38). Dosage usually increases slowly during the first year and then stabilizes (Reference 34). With time, the pump can be programmed to vary the infusion rate to accommodate

**Figure 2.** Child with an intrathecal baclofen pump.

Reproduced with permission from United Cerebral Palsy Research Status Reports. The Treatment of Cerebral Palsy. Available at [affnet.ucp.org/ucp\\_printdoc.cfm/1/4/11654/11654-11654/4790](http://affnet.ucp.org/ucp_printdoc.cfm/1/4/11654/11654-11654/4790). Accessed June 11, 2012.

the patient's activities throughout the day (Reference 19). Patients with ventriculoperitoneal shunts may require lower doses (Reference 34). Box 4 provides dosing information for intrathecal baclofen.

Careful monitoring by health care professionals experienced with intrathecal baclofen and the infusion device is essential. Patients typically need to have the pump's reservoir transcutaneously refilled by their provider at 2- to 6-month intervals. Pump and battery function should be monitored, and the infusion device should be replaced before the battery expires (Reference 38).

Abrupt withdrawal after unexpected discontinuation and unintentional overdose are troublesome complications with intrathecal baclofen. Potential causes of discontinuation include an empty pump reservoir, a displaced or leaky catheter, or a programming or refill error (Reference 34). Withdrawal symptoms consist of elevated temperature, altered mental status, exaggerated rebound spasticity, and muscle rigidity (Reference 43). Severe itching, agitation, hallucinations, hypotension or labile blood pressure, and seizures have been reported (References 19, 34). Rarely, symptoms progress to rhabdomyolysis, multiple organ system failure, and death (Reference 43). Early recognition and reinstitution of therapy are essential to managing withdrawal. Benzodiazepines and life support may be needed (Reference 19).

#### Box 4. Intrathecal baclofen dosing.

##### Screening dose:

50 mcg (very small patients 25 mcg) intrathecally with observation for 4–8 hours

*If initial response is less than desired, a second dose of 75 mcg intrathecally may be given after 24 hours with observation for 4–8 hours. If response still inadequate, a final dose of 100 mcg intrathecally may be given 24 hours later. If the patient is unresponsive to the 100-mcg dose, he or she is not a candidate for an implanted pump for infusion.*

##### Initial total daily dose for infusion:

Double-screening dose that gave positive effect and administer over 24 hours

*If the efficacy of the screening dose lasted greater than 8 hours, then the initial dose should be the screening dose administered over 24 hours.*

##### Average daily dose:

12 years or younger: 100–300 mcg/day

Older than 12 years and adults: 300–800 mcg/day

Compiled from References 26 and 43.

Signs of intrathecal baclofen overdose include excessive hypotonia, drowsiness or decreased arousal, and respiratory depression (Reference 34). If toxicity is suspected, the patient should be taken to the hospital immediately for assessment and emptying of the pump reservoir. Overdose has generally been related to pump malfunction or dosing error (Reference 43). A careful appraisal of the device's programming is an important part of the evaluation. To lessen the risk of complications, patients should be educated on activities that may alter infusion flow. Examples are exposure to considerable changes in altitude or temperatures, excessive twitching or stretching, twiddling with the pump or catheter through the skin, and strong electromagnetic interference (Reference 44).

It is critical to monitor for infections associated with intrathecal baclofen therapy. Infections can occur in the pump area, or more rarely, meningitis can develop (Reference 24). In one survey, wound dehiscence with secondary infection, particularly in the first 2 months after implantation, was the most likely reason for pump removal (Reference 45). Children of small size, patients with a gastrostomy tube, or those unable to ambulate were at higher risk of wound complications (Reference 45).

#### *Botulinum Toxin A*

Botulinum toxin A is a commercially available denervation therapy given as an intramuscular injection to treat localized or segmental (unilateral or lower or upper extremity) spasticity (Reference 24). It is one of seven serotypes of exotoxin produced by *Clostridium botulinum*, the pathogen that causes botulism, an infectious disease characterized by a general paralysis (Reference 29). It acts as a denervation agent at the nerve terminal end plate by blocking acetylcholine release at the neuromuscular junction, a critical step in initiating a muscle response (References 34, 46). This results in a flaccid muscle paralysis and can provide a selective, reversible effect that can be used to balance forces across joints (Reference 46). Serotype B is available as a pharmaceutical product, but its clinical use is not as wide because of its shorter duration of muscle relaxation (Reference 34). In the United States, three preparations of botulinum toxin A and one preparation of botulinum toxin B are commercially available. In 2009, the U.S. Food and Drug Administration (FDA) issued a safety alert that included a recommendation to modify the established drug names of the botulinum toxin products to

emphasize their individual potencies and prevent medication errors (Reference 47). Table 4 lists the revised drug and trade names for botulinum toxins A and B and product availability.

Licensed use of botulinum toxin products for spasticity varies greatly between countries and is restricted to specific preparations, indications, and dose limits (Reference 48). In the United States, none of the products are currently labeled for treatment of spasticity in children, but onabotulinumtoxinA has an FDA-approved indication for treatment of upper limb spasticity in adults (Reference 49). The updated EPNS consensus statement on botulinum toxin for children with CP notes that, although unlicensed, individualized use on the basis of dose, dilution, indication, and muscle group(s) represents appropriate treatment when it is consistent with clinical experience (Reference 48). The AAN and CNS practice parameter recommends botulinum toxin A be offered as effective and generally safe therapy for localized or segmental spasticity in children with CP, but it notes conflicting evidence on functional improvement (Reference 24). It excludes botulinum toxin B from review because of insufficient published data (Reference 24). In a separate evidence-based review, the AAN recommends specific spasticity indications for botulinum neurotoxin injection for children with CP (Reference 50). The AAN recommends that injection of calf muscles be offered as treatment for equinus varus, a foot anomaly in which the heel turns

inward, and the foot is plantar flexed. It should be considered a therapeutic option for adductor spasticity, pain control in children undergoing adductor-lengthening surgery, and upper extremity spasticity (Reference 50). The studies supporting these recommendations used onabotulinumtoxinA and abobotulinumtoxinA.

All botulinum toxin products are unique with respect to molecular structure, method used to determine biologic activity, pharmacokinetics, pharmacodynamics, and manufacturing process (References 34, 48). The products are not interchangeable, and fixed-dose conversion ratios are not applicable in the treatment of spasticity in children with CP (Reference 48). Dosage is individualized per patient. The EPNS recommends calculations be made for “(1) total units per treatment session, (2) total units per kg body weight per session, (3) units per muscle, (4) units per injection site, (5) units per kg body weight per muscle” (Reference 48). Table 5 lists patient factors to consider when dosing botulinum toxin products. The clinical effects of onabotulinumtoxinA and abobotulinumtoxinA typically last 3–4 months, necessitating repeat injections (Reference 24). Maintaining an interval of at least 3 months is recommended to lessen the risk of antibody development (Reference 51).

The most common adverse effects reported with the use of botulinum toxin A products in children with CP are pain at injection site, excessive weakness, unsteadiness and increased falls, and fatigue (Reference 24). Strategies

**Table 4.** Botulinum Toxin Preparations

Drug Name	Trade Name [Manufacturer]	Product Availability
AbobotulinumtoxinA	Dysport [Ipsen Biopharm]	300- and 500-unit vials
IncobotulinumtoxinA	Xeomin [Merz Pharmaceuticals]	50- and 100-unit vials
OnabotulinumtoxinA	Botox [Allergan]	100- and 200-unit vials
	Botox Cosmetic [Allergan]	50- and 100-unit vials
RimabotulinumtoxinB	Myobloc [Solstice Neurosciences]	2500-, 5000-, and 10,000-unit vials

**Table 5.** Factors to Consider When Dosing Botulinum Toxin Products for Spasticity in Children with Cerebral Palsy

Patient Factors	Muscle Factors
Age	Mass
Severity of CP	Number of muscles to be injected
Predominance of movement disorder	Target muscle strength
Degree of joint deformity	Activity of muscle
General health	Dynamic vs. fibrotic type
Accompanying impairments	Motor end plate distribution in muscle
Experience from previous injections	

CP = cerebral palsy.

Compiled from References 46 and 48.

to manage local pain at injection include topical anesthetics before injection, anxiolytics, or light sedation during injection (Reference 51). Accurate localization of muscles for injection is aided by electromyography, electrical stimulation, and ultrasonography. If botulinum toxin A is administered at the hip level, transient urinary and bowel incontinence is an additional adverse effect (Reference 34). The risk of this complication generally peaks 1 month after injection (Reference 34). Patients receiving aminoglycosides, other drugs that interfere with neuromuscular transmission, or muscle relaxants should be monitored closely for potentiation of effect of botulinum toxin (References 49, 52).

Systemic toxicity from the spread of botulinum toxin effects from the injection site has been reported. The 2009 FDA safety alert addressed this concern for pediatric and adult patients. For pediatrics, the postmarketing case reports were primarily related to use for spasticity in children with CP (Reference 53). Specifically, the FDA stated:

The reported cases of spread of botulinum toxin effect from beyond the site injection were described as botulism, or involved symptoms including difficulty breathing, difficulty swallowing, muscular weakness, drooping eyelids, constipation, aspiration pneumonia, speech disorder, facial drooping, double vision, or respiratory depression. (Reference 53)

Cases involving ventilatory support and fatality were reported. On the basis of the postmarketing evaluation, the FDA recommended that health care professionals who use botulinum toxin products (1) recognize that dosage strength expressed in units is different between products and that doses expressed in units are not interchangeable between products; (2) be alert to and educate patients and caregivers about potential adverse effects because of the distant spread of botulinum toxin from the injection site; (3) understand that these adverse events have occurred as early as several hours and as late as several weeks after injection; and (4) advise patients to seek immediate medical attention if they develop any of these symptoms (Reference 53). The FDA safety alert has resulted in the revised names of products, labeling changes including a boxed warning, and the implementation of a Risk Evaluation and Mitigation Strategy with a Medication Guide for all products.

### ***Additional Treatments***

Phenol and alcohol are other injectable denervation agents used for localized spasticity. Their use is limited by complications of long-term pain or paresthesia and the need for expert technical skills for correct administration (Reference 51). The AAN and CNS practice

parameter excluded them from review because of insufficient published data (Reference 24). For surgical options, orthopedic and neurosurgical procedures are available that may improve gait, contractures, hip alignment, and neuromuscular scoliosis.

### **Drooling**

Drooling is involuntary loss of saliva from the mouth. Sialorrhea is often used as a synonym for drooling, referring to excessive flow of saliva. Sialorrhea may be caused by the overproduction of saliva. However, most patients with CP produce normal amounts of saliva but have difficulty managing it in the oral cavity (Reference 54). Drooling is described as anterior if the saliva spills from the mouth and as posterior if it pools in the pharynx, posing an aspiration risk. Drooling is considered normal in children up to 2 years; however, physiologic episodes occur later, particularly with teething (Reference 55).

In a study of children with CP attending special schools, 58% were found to drool, with 33% described as having severe drooling (Reference 56). Drooling can negatively affect social interactions, interfere with speech development and communication, and cause skin breakdown around the mouth and chin. In addition, drooling increases the difficulty of oral hygiene for patients and caregivers. In an assessment of participation issues in adolescents with CP, parents identified oral hygiene as their second-highest ranked problem when the adolescent was unable to communicate (Reference 57).

When a patient or parent presents with concerns about drooling, assessment should include a thorough history, a speech pathology examination of the oral region, a dental examination if the patient is older than 3 years, and a questionnaire to determine severity (Reference 54). The patient history should determine whether there is evidence of chronic aspiration, gastroesophageal reflux, feeding difficulties, or medications such as cholinergic drugs that could be contributing to the drooling. If present, these problems should be addressed (Reference 55).

In general, nonpharmacologic management is the first step to treatment of drooling. Patient and caregiver education on oral hygiene, attention to posture and positioning, and oral motor skills training may all provide benefit (Reference 55). After implementing these measures and addressing any dental issues, pharmacotherapy may be justified. Drug treatments include anticholinergic agents and botulinum toxin A products. Surgical management is another treatment possibility that is usually employed for more severe cases. Surgical procedures include redirection or excision of submandibular saliva ducts or parotid duct ligation (Reference 55).

Glycopyrrolate and scopolamine are the anticholinergic drugs most commonly used to treat sialorrhea. Their mechanism of action for drooling is to decrease the volume of saliva produced by blocking the cholinergic muscarinic receptors in the salivary glands. Unfortunately, they lack selectivity and are associated with other undesirable anticholinergic effects such as flushing, urinary retention, and constipation. Glycopyrrolate has the most available evidence on efficacy and a relative favorable adverse effect profile (Reference 58). A study reported a placebo-controlled, double-blind, dose-ranging, crossover study of glycopyrrolate in 39 pediatric outpatients with neurodevelopmental conditions and troublesome drooling (Reference 59). Most of the patients had CP and ranged in age from 4 to 19 years. They used a 4-week dose titration schedule, followed by 4 weeks of maintenance therapy with a 2-week washout and observation period before crossover. Twenty-seven children completed the study, and in those patients, drooling was significantly reduced on the basis of a 9-point scale. Adverse effects were common, occurring in 69% of the children during the glycopyrrolate arm; seven patients were receiving glycopyrrolate when they withdrew from the study because of an adverse effect. The most frequent adverse effects were behavioral changes, constipation, excessive oral dryness, and urinary retention. The authors recommended initiating therapy at 0.04 mg/kg/dose and increasing weekly up to 0.1 mg/kg/dose given two times/day in the morning and midafternoon (Reference 59). Glycopyrrolate was previously available only in a tablet formulation for oral administration. In July 2010, the FDA approved Cuvposa, an oral liquid formulation of glycopyrrolate, for chronic severe drooling in children aged 3–16 years with neurologic disorders (Reference 60). Dosing recommendations for the oral liquid formulation are to initiate therapy at 0.02 mg/kg/dose three times/day with increases of 0.02 mg/kg/dose at 5- to 7-day intervals if needed. The maximal recommended dose is 0.1 mg/kg/dose not to exceed 1.5–3 mg. Contraindications are medical conditions that preclude anticholinergic therapy and patients taking solid oral dosage forms of potassium chloride as glycopyrrolate may extend the time the potassium chloride is in the gastrointestinal tract increasing the risk of gastrointestinal irritation. Cuvposa is available as a 1 mg/5 mL concentration, and although expensive, a specialty pharmacy distribution system is available to help patients with insurance authorizations (Reference 60).

Scopolamine is administered transdermally to treat sialorrhea. Transderm Scop is commercially available as a 1.5-mg patch that delivers 1 mg of scopolamine over 3 days (Reference 61). It is licensed for adults to

prevent motion sickness and for nausea and vomiting associated with recovery from anesthesia and surgery. The patch is placed on a hairless area behind the ear with alternating ear sites within the 3-day interval. The patch should not be cut, and hands should be washed thoroughly after placing and discarding (Reference 61). A study evaluated scopolamine for drooling in a placebo-controlled, double-blind, crossover trial (Reference 62). The study's investigators enrolled 30 patients with neurodevelopmental disorders and persistent drooling. Each patient received 2 weeks of transdermal scopolamine and placebo with a 1-week washout interval before crossover. Scopolamine was administered as a 1.5-mg patch changed every 72 hours. They found a significant reduction in baseline drooling on a 3-point scale with scopolamine but not placebo. Four patients discontinued the study because of adverse effects: one case of irritability, one case of agitation, and two patients had skin reactions (Reference 62). Another study found similar results in a smaller trial of 10 patients 5–18 years of age with neurodevelopmental disorders and moderate to severe drooling (Reference 63). This trial was placebo-controlled but not blinded and used the 1.5-mg transdermal scopolamine patch applied twice a week for 2 weeks with crossover to placebo. Scopolamine significantly reduced scores on a 6-point drooling scale compared with placebo. Pupil dilation was noted in two-thirds of the patients receiving scopolamine (Reference 63). Although transdermal scopolamine may be a reasonable treatment option for drooling in older children and adolescents, questions remain whether it is acceptable to use the dosing form in younger patients and as long-term therapy.

The Cerebral Palsy Institute developed an international consensus statement on the use of botulinum toxin for adult and pediatric drooling (Reference 54). For this unlabeled indication, it is given by intraglandular injection into the submandibular and parotid salivary glands. It works by inhibiting the release of acetylcholine from cholinergic nerve endings in the gland, causing a reduction in the secretion of saliva. On the basis of a review of clinical trials, the consensus statement recommends the use of botulinum toxin A in patients with a significant problem with drooling. It recommends excluding patients (1) if they have been given botulinum toxin A for any reason in the previous 3 months; (2) if they have antibodies against botulinum toxin A; or (3) if they are unfit for sedation or anesthesia (Reference 54).

The largest study to date reported on the use of onabotulinumtoxinA for drooling in 131 children and young adults with a mean age of 10.9 years (range 3–27 years), as a prospective cohort study (Reference

64). Children were included in the study if they had CP or another nonprogressive neurologic disorder and moderate to severe drooling. They received onabotulinumtoxinA injected into submandibular glands at a dosage of 15 units per gland for body weight less than 15 kg; 20 units per gland for body weight 15–25 kg; and 25 units per gland for body weight greater than 25 kg. A clinically notable response was reported in 46.6% of children, as defined by a significant reduction in direct observational drooling quotients and caretaker visual analog scales. Children who initially responded to onabotulinumtoxinA relapsed after a mean of 22 weeks (Reference 64). The length of response is consistent with the consensus paper statement that there should probably be a 4- to 6-month interval between injections (Reference 54). Various doses of botulinum toxin A have been used in studies, and as with the use of botulinum toxin A for spasticity, it is critical to identify a particular product used and not to interchange doses between products.

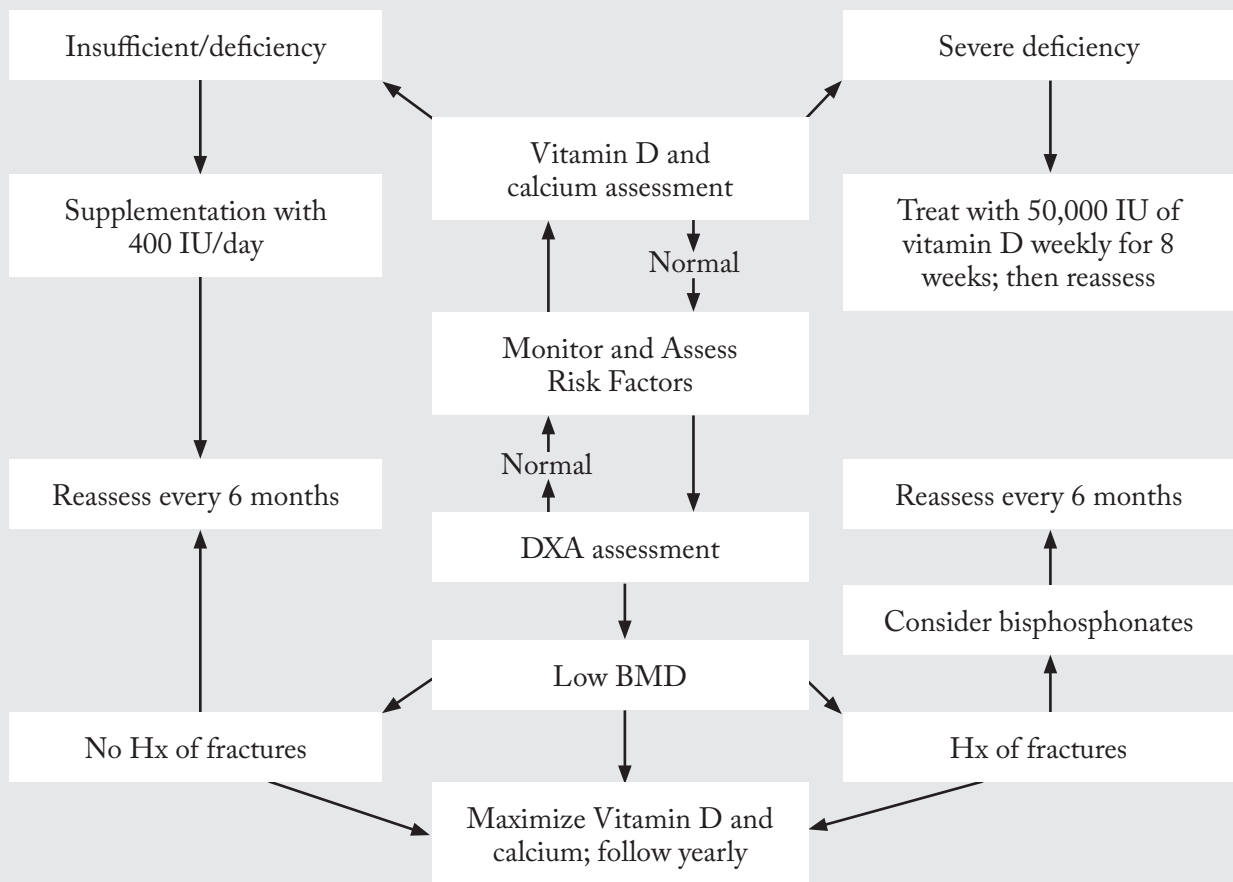

The consensus paper provided recommendations to prevent or minimize adverse events associated with botulinum toxin for drooling (Reference 54). Ultrasound guidance should be used for injection because it helps ensure intraglandular delivery as opposed to injection into surrounding tissue. Adverse effects related to trauma at the injection site include pain, hematoma, intraoral blood, swelling of the gland, and infection. Temporary swallowing difficulties may occur because of the swelling of the gland, and patients should be observed for at least 2 hours postinjection. If a swallowing problem persists, it may be caused by the diffusion of botulinum toxin into surrounding muscle tissue. Follow-up with the patient and his or her caregivers in the first week is recommended to assess for eating and drinking difficulties. Moist food or a pureed diet should be given for the first week after injection. It is important to be alert to thickening of the saliva, which can lead to swallowing or respiratory difficulties (Reference 54). As noted in the spasticity section, it is critical to monitor and counsel patients regarding adverse effects caused by the systemic spread of botulinum toxin.

### Low BMD

Children with CP are at risk of developing low BMD, particularly with moderate to severe functional classification of CP. In a study of 117 patients from this population aged 2–19 years, the authors found a 77% prevalence of osteopenia as defined by BMD *z* scores of less than -2.0 in femur measurements (Reference 13). Despite a mean age of 9.7 years, 15% of patients had a history of at least one fracture (Reference 13). Risk

factors for patients with CP to have low BMD include the inability to ambulate independently, feeding difficulties, use of antiepileptic drugs, and previous fracture (Reference 65). Low exposure to sunlight and lack of weight-bearing exercise are additional contributing factors to low BMD that have not yet been assessed in CP (Reference 65).

Figure 3 provides a treatment algorithm to identify and treat low BMD in patients with CP. The first steps in treatment are to reduce modifiable risk factors and ensure optimal nutritional intake, particularly of calcium and vitamin D (Reference 12). Measurement of 25-hydroxy vitamin D blood levels is helpful to determine whether a patient requires supplemental or treatment doses of vitamin D. Bisphosphonates are a pharmacologic treatment option in patients with a low BMD and history of fractures (Reference 12). Pamidronate has been studied in children with CP and osteopenia. In one retrospective review, the authors reported on longer-term rate of fracture in children with CP who had received about a 1-year course of intravenous pamidronate (Reference 66). They studied 25 children with severe CP (defined as GMFCS level IV or V) and at least one fracture before pamidronate for an observation period of 1–10.5 years after therapy. The patients received intravenous pamidronate on a protocol of 1 mg/kg/dose (maximum 35 mg) in normal saline, administered over 4 hours. This dose was given on 3 consecutive days every 3–4 months. The mean age of patients at the time of treatment was 11 years 2 months (range, from 3 years 10 months to 19 years 7 months). They found a significant decrease in the fracture rate during the observation period compared with pretreatment (13% vs. 30.6%). For most patients, the treatment effect lasted 4 years or longer (Reference 66). Patients who receive pamidronate should be monitored for infusion reactions, hypocalcemia, and other electrolyte abnormalities (decreased phosphate, potassium, and magnesium) (Reference 26). Serum creatinine should also be monitored because renal insufficiency has developed in patients taking pamidronate. In addition to pamidronate, alendronate has been investigated as treatment for osteopenia in children with cerebral palsy. In a small study, 26 children aged 3–17 years who had quadriplegic cerebral palsy and osteopenia were given alendronate 1 mg/kg/week with calcium and vitamin D supplementation for over a year. With treatment, lumbar vertebral bone mineral density increased over pretreatment values. None of the children had to interrupt treatment due to an adverse effect and there were no cases of esophageal irritation reported (Reference 67). However, patients should be counseled to stand or sit for administration of alendronate followed by an upright

posture for 30 minutes. These recommendations may limit the use of alendronate in young children and in patients with more severe CP. Osteonecrosis of the jaw is a relatively infrequent, but worrisome adverse effect associated with bisphosphonates. Although this adverse effect has occurred primarily in patients with cancer, patients with CP may have a theoretical increased risk if poor oral hygiene is present. A dental examination is warranted in a patient with CP before he or she undergoes treatment with a bisphosphonate.

## CONCLUSIONS

Cerebral palsy is a multifaceted disorder in childhood because of motor disabilities and challenging co-impairments. Children with CP are recommended to receive quality care through a primary care medical home model with multidisciplinary and community input (Reference 68). Comprehensive treatment plans are used to optimize function, capabilities, quality of life, and aesthetics.

Pharmacotherapy is an important component of treatment, and a pediatric pharmacist provides valuable support to the medical home, especially as the number and complexity of treatment options for spasticity and other conditions associated with CP increase.

# CHAPTER 26

## SEIZURE DISORDERS

Lea S. Eiland, Pharm.D., BCPS, FASHP

### LEARNING OBJECTIVES

1. Describe types of seizures common in children.
2. Identify pharmacologic treatment options for different seizure types in children.
3. Recognize common adverse effects from anticonvulsant therapy specific for children.
4. Describe treatment for status epilepticus in children.

### ABBREVIATIONS IN THIS CHAPTER

EEG	Electroencephalographic
GABA	$\gamma$ -aminobutyric acid
NMDA	<i>N</i> -methyl-D-aspartate

### INTRODUCTION

A seizure is a change in function or behavior caused by a paroxysmal electrical discharge of neurons in the brain (Reference 1). Seizure type varies depending on the area within the brain of the discharge, the direction and speed of the electrical impulse, and the age of the child. Epilepsy is defined as two or more seizures that occur without acute provoking factors (References 1, 2). Not all seizures lead to a diagnosis of epilepsy. There is a wide array of causes and classifications of epilepsies in children. An epileptic syndrome is a group of signs and symptoms that occur with a specific neurologic and electroencephalographic (EEG) finding. Idiopathic epilepsies refer to presumed genetic syndromes without structural brain abnormalities, whereas symptomatic epilepsies result from a structural brain lesion, which is identified (Reference 3). A seizure that lasts more than 30 minutes or two or more seizures that occur without a return to consciousness in between are termed *status epilepticus* (Reference 1). Seizures may be short without repercussions; however, prolonged seizures may be life threatening.

The treatment of seizures and epilepsies varies per condition. Some seizure types do not require any interventions, whereas others may require one or more anticonvulsant drugs to prevent a seizure from occurring. Potential nonpharmacologic therapies such as the ketogenic diet may be tried in certain patients with the goal

of obtaining seizure control. Each patient is individually treated for his or her specific seizure disorder. The anticonvulsant medications in general have shown efficacy for seizures; however, adverse reactions and dosing formulations of specific medications may limit their use in subgroups of the pediatric population. Thus, pharmacologic therapy for children should be monitored frequently and carefully. Controversy exists regarding switching patients from brand to generic drug formulations as more generic drugs become available and provide a decrease in cost for care. Many factors, such as those described, affect the selection of a pharmacologic treatment plan for each patient.

### Epidemiology

Seizures are the most common neurologic disorder of childhood (Reference 1). They occur in about 4% to 10% of children and account for 1% of all emergency department visits (References 4, 5). Annually, 150,000 children experience an unprovoked first seizure, with 30,000 of these children developing epilepsy (Reference 4). Children younger than 3 years have the highest incidence of seizures, with the incidence decreasing as the child ages (Reference 6). For children with epilepsy, 10% to 25% will develop status epilepticus (Reference 7). The highest risk is in those younger than 1 year.

### Etiology

#### *Pathophysiology*

A seizure is a result of the hypersynchrony of neuronal discharges of which the etiology varies (Reference 1). Mechanisms that promote seizure activity include the following: (1) ion channel problems (sodium and calcium, voltage regulated, inactivation gate), (2) decreased inhibition ( $\gamma$ -aminobutyric acid [GABA], adenosine), (3) excitatory neurotransmission (glutamate, *N*-methyl-D-aspartate [NMDA]), and (4) alteration in the extracellular concentration of potassium and calcium. Thus, pharmacotherapy is directed to one or more of these mechanisms.

Oxygen and glucose consumption, as well as lactate and carbon dioxide production, is increased during a seizure. Adequate ventilation usually compensates for these changes, but prolonged seizures or inadequate ventilation may lead to hypoxia, hypercarbia, and

respiratory acidosis, possibly resulting in permanent damage (Reference 1). Hypoglycemia, hyperthermia, hyperkalemia, lactic acidosis, or rhabdomyolysis can also occur from a prolonged seizure.

Several medical conditions can precipitate seizures. Children with developmental delay or cerebral palsy are at a higher risk of developing seizures. From 3% to 10% of children with head trauma will experience a seizure, usually in the first 24 hours post-accident (Reference 8). Most children have a good prognosis post-trauma without neurologic repercussions. Other secondary causes of seizures include cerebrovascular disease, neurodegenerative or developmental disorders, tumors, metabolic disorders, drug ingestion or withdrawal, and central nervous system (CNS) infections (Reference 1).

Neonatal seizures are usually a consequence of perinatal or intrauterine hypoxia (50% to 65%) (Reference 1). Intracranial hemorrhages are responsible for 15%, whereas 5% to 10% of cases are related to metabolic abnormalities, infections, and toxins. Pyridoxine, glucose, and calcium deficiencies are common metabolic etiologies.

### Genetic Basis

At least 20% of epilepsies have been linked to a genetic component (Reference 9). Epilepsies termed *idiopathic* are presumed to be genetic in origin (Reference 7). Benign rolandic epilepsy and benign familial neonatal

seizure have an autosomal dominant inheritance. Absence and tonic-clonic seizures show a genetic component (Reference 10). Febrile seizures also show a genetic component, with 25% to 40% of patients having a family history (Reference 1). The GABA<sub>A</sub> and acetylcholine receptors, as well as sodium, potassium, and chloride channels, have all been implicated in genetic abnormalities (Reference 10). Molecular genetic studies of different seizure types and syndromes are ongoing.

## CLINICAL PRESENTATION AND DIAGNOSIS

### Signs and Symptoms

During a seizure, extremities may physically convulse, go limp, or stiffen. One extremity or all may be involved in the seizure. Usually, a health care provider will not witness the seizure, therefore having to rely on someone else's description of the event. Specific signs and symptoms of a seizure depend on the type of seizure. An aura may precede a seizure. In children, the most common types of aura are a feeling of fear or epigastric pain and discomfort; however, children may have difficulty describing this (Reference 9). After a seizure, a period of fatigue, confusion, or irritability occurs (Reference 1). This is defined as the postictal period. The presence of cyanosis, vocalizations, loss of sphincter tone, and posture of the patient should be noted when describing the seizure (Reference 9).

### Box 1. Seizure type and characteristics (References 7, 9, 11, 12).

- **Partial** (begins locally, involves one cerebral hemisphere, unilateral motor manifestations)
  - Simple: No loss or impairment of consciousness
  - Complex: Loss or impairment of consciousness/altered mental status occurs
  - Secondary generalization: Presents initially as partial, but spreads to generalized tonic-clonic seizure
- **Generalized** (involves bilateral cerebral hemispheres without local onset, bilateral motor manifestations)
  - Absence: Sudden cessation of motor activity, brief loss of awareness, and blank stare
    - Simple: Not associated with postictal period
    - Complex: Associated myoclonic activity and altered consciousness
  - Myoclonic: Shocklike muscular contractions of the face, trunk, and extremities
  - Clonic: Rhythmic jerking and flexor spasms of the extremities
  - Tonic: Sustained contraction of muscles with progressive rigidity
  - Tonic-clonic: First tonic symptoms; then clonic
  - Atonic: Sudden loss of muscle tone and consciousness
  - Infantile spasms: Spasmodic clusters of jerking contractions of the extremities, head, and trunk
- **Unclassified** – All seizures unable to be classified because of incomplete or inadequate data
- **Status Epilepticus** – Seizure lasting more than 30 minutes or two or more seizures occurring in which the patient does not regain consciousness between episodes

The International League Against Epilepsy has classified seizures as four major types, as follows: partial, generalized, unclassified, and status epilepticus (Reference 11). Definitions and characteristics of these seizure types are provided in Box 1. The most common childhood seizure type is generalized tonic-clonic (Reference 12). Simple and complex partial seizures will progress to generalized tonic-clonic seizures in 30% of children. Status epilepticus will be the presenting seizure in 10% to 12% of children experiencing their first unprovoked seizure (Reference 13). Several pediatric epilepsy syndromes also exist. The International League Against Epilepsy has created a classification of epilepsies and epileptic syndromes (Reference 14). Some of the more commonly seen syndromes will be presented in this chapter.

Neonatal seizures occur in 1.8–3.5 of every 1000 newborns because of the immaturity of the neonatal brain (Reference 1). Signs and symptoms are usually atypical and include eye deviations, lip smacking, or apneic episodes. Seizures in this population generally cause little brain injury, but low-birth-weight infants tend to have a higher incidence and worse outcomes of seizures. A benign familial neonatal seizure is a syndrome that usually presents within the first 3 days of life and resolves spontaneously by age 6 months. “Fifth-day fits” are known as benign idiopathic neonatal convulsions that appear at day 5 of life and end by day 15 of life.

Infantile spasms usually occur during the first year of life (Reference 10). They are quick symmetrical contractions of the neck, trunk, and extremities that occur in clusters for less than 5 seconds (Reference 15). Abduction or adduction of the upper extremities can be seen with flexion or extension of the neck, and these clusters may be repeated several times a day (Reference 10). West syndrome is a disorder with three specific characteristics, as follows: infantile spasms (flexor, extensor, or mixed spasms); a particular EEG pattern (hypsarrhythmia); and developmental arrest or delay (Reference 15). In around 70% of children, developmental delay is seen before the onset of spasms (Reference 10). Diagnosis usually occurs between age 4 and 18 months, with a peak age of 4–7 months (Reference 12). Males are affected more than females, and most patients (95%) have developmental delay. Tuberous sclerosis is seen in 25% of children with infantile spasms (Reference 1).

Lennox-Gastaut syndrome accounts for 2.9% of all epilepsies (Reference 10). This syndrome is characterized by a mixture of intractable seizures such as tonic, myoclonic, atonic, and absence (References 1, 12). Tonic seizures generally occur during sleep, and absence seizures are usually atypical in characteristic (Reference 10). Children also tend to have developmental delay and severe behavioral issues. The onset is usually

between age 3 and 10 years, with a peak incidence at 3–5 years (Reference 10). Around 40% of patients have previously been given a diagnosis of infantile spasms. Seizure control is extremely difficult in patients with Lennox-Gastaut syndrome. Most of these patients will take several anticonvulsant medications, yet they will still experience seizures.

Another syndrome is benign rolandic epilepsy (benign childhood epilepsy with centrotemporal spikes), which manifests typically as seizures while sleeping. Clonic movements in the face usually wake the child from sleep. Twenty percent of patients have only one seizure, whereas 25% have repeated clusters (Reference 9). It typically occurs in children aged 3–13 years and is generally benign, as the name states. Most patients outgrow the seizures by young adulthood. The peak age of onset is age 9–10 years (Reference 9).

Juvenile myoclonic epilepsy (Janz syndrome) usually occurs in 12- to 18-year-old adolescents and presents as myoclonic jerks on waking (Reference 12). Most patients (80%) also have tonic-clonic seizures, and some have absence seizures (25%) as well. Hormonal changes, stress, alcohol, and sleep deprivation can provoke these seizures.

Febrile seizures are classified as a “special syndrome” (References 3, 15). Febrile seizures are defined as a seizure that is accompanied by a temperature of 100.4°F (38°C) or greater in children between age 6 months and 5 years (Reference 16). The child must not have a diagnosis of a CNS infection, and the temperature may be obtained by any method. Febrile seizures are not related specifically to the peak degree of temperature, but rather, to the rate of temperature rise. The specific mechanism for a febrile seizure is unknown, but it is hypothesized that fever lowers the seizure threshold (Reference 1). Febrile seizures are the most common type of convulsive event that occurs in children younger than 5 years, occurring in 2% to 5% of all children (Reference 15). The peak onset is age 14–18 months (Reference 9). Febrile seizures are characterized as simple or complex. Simple febrile seizures are primary generalized seizures that last less than 15 minutes and do not recur within 24 hours (Reference 16). Complex febrile seizures are focal, last 15 minutes or longer, and/or recur within 24 hours. Most febrile seizures are benign and self-limited, and 80% are classified as simple. No long-term effects from simple febrile seizures have been identified (References 12, 16). Children without risk factors are not at a higher risk of developing epilepsy by age 7 years than the general population (Reference 16). Those with risk factors such as multiple simple febrile seizures, first onset of febrile seizures that occurred at younger than 12 months, and family history of epilepsy are at a 2.4% risk of receiving a diagnosis of generalized afebrile epilepsy by age 25 years.

## Diagnostic Criteria

### Laboratory Data

No specific laboratory data diagnostic test for epilepsy exists, except when evaluating for metabolic or infectious causes of seizures (glucose, electrolytes, cerebral spinal fluid cultures, etc.). Prolactin may be transiently elevated after an acute episode for some seizure types, such as generalized tonic-clonic or complex partial seizures (Reference 17). Prolactin is thought to be released from the pituitary, which is controlled by the hypothalamus. It is theorized that a seizure can alter the hypothalamus relation. It is best to obtain the level 10–20 minutes postseizure. An elevated prolactin may help differentiate psychogenic nonepileptic seizures from epileptic seizures in adolescents. Serum prolactin use has not been determined for other circumstances (status epilepticus, repetitive seizures, neonatal seizures).

### Procedures

An EEG is helpful in the diagnosis of various epileptic seizure types or syndromes because most have a characteristic EEG wave. An EEG should be performed after the second seizure but may be performed after the first seizure in certain circumstances (Reference 3). It should not be used solely to confirm or exclude a diagnosis of seizures. Clinical history should always be considered when evaluating a diagnosis. Repeated EEGs are typically not indicated once a diagnosis is confirmed. However, a sleep-deprived, video, or continuous EEG may be tried if an interictal EEG is normal or for complicated cases (Reference 9). A continuous EEG with video recording (24–72 hours) is optimal but challenging to obtain because it usually involves admitting a patient to a hospital setting. An EEG is best obtained during a seizure; however, abnormal wave patterns may be present during the postictal state. Many times, the EEG between seizure episodes will be normal, limiting the test's utility. An EEG is not recommended in a patient with simple febrile seizures who is neurologically healthy (Reference 18).

Specific EEG wave patterns are characteristics for certain epileptic syndromes. Lennox-Gastaut syndrome shows as a slow, irregular, high-voltage spike pattern (Reference 6). Benign rolandic epilepsy has as perisylvian spiking pattern (Reference 12). Juvenile myoclonic epilepsy shows a pattern of fast spike and wave discharges. Hypsarrhythmia, seen in infantile spasms, shows random high-voltage slow waves with multifocal spikes. Absence seizures present as regular and symmetrical spike-and-slow-wave complexes (Reference 11). Clonic seizures show fast activity with slow waves, whereas tonic seizures show fast activity that decreases in frequency but increases in amplitude. Atonic seizures show as polyspikes and slow waves.

Neuroimaging is useful in identifying structural abnormalities (Reference 3). A magnetic resonance imaging (MRI) is the test of choice for epilepsy. A computed tomography scan should be used when urgent assessment is necessary or an MRI is contraindicated.

## Course and Prognosis of Disease

Most children who experience a first-time unprovoked seizure will likely not have another seizure (Reference 13). Risk factors for recurrence of seizures include an abnormal EEG, symptomatic cause, seizure while sleeping, history of febrile seizures, or postictal paresis (Reference 10). Of patients with a diagnosis of new-onset epilepsy, two-thirds will become seizure free with the first or second medication administered (Reference 19). In children with an unprovoked first seizure, the recurrence rate is 3% to 50% by 2 years (Reference 13). In a child presenting with status epilepticus as the first seizure, the recurrence rate is similar to those presenting with a brief first seizure. However, if they experienced a subsequent seizure, there is an increased risk of its being prolonged. One-third of children with simple febrile seizures will have a recurrence (Reference 16). The highest risk of recurrence is in children who experience their first febrile seizure before age 1 year (Reference 1). The second febrile seizure tends to occur within 6 months of the first one.

The prognosis of epilepsy is difficult to predict for each patient. Recurrence and relapse rates differ by type of seizure or syndrome. West and Lennox-Gastaut syndromes do not have a favorable prognosis. Benign rolandic epilepsy remits without relapse, whereas absence seizures have a 12% relapse rate, and juvenile myoclonic epilepsy has an 80% rate (Reference 10). Simple febrile seizures are usually outgrown by age 5 years.

Mortality from seizures or epilepsy also varies by type. In children, mortality rates of up to 16% have been associated with status epilepticus (Reference 7). As the duration of status epilepticus is prolonged, mortality rates increase (Reference 20). Neonates with status epilepticus tended to have the highest mortality and neurologic sequelae. Patients with infantile spasms have a 20% mortality rate (Reference 12). However, patients with simple febrile seizures are not at increased mortality risk (Reference 16).

## TREATMENT

### Therapy Goals

In an actively seizing patient, airway stabilization and termination of the seizure without recurrence are priorities. Once the seizure has stopped, diagnostic studies may be obtained to determine the etiology. Patients are placed on anticonvulsant medications to improve their

quality of life by decreasing the number of seizures they experience, with the ultimate goal of being seizure free. However, less than 50% of patients become seizure free; thus, most pharmacologic therapies are lifelong treatments, and chronic adverse effects must be considered (Reference 7).

The initiation of pharmacologic treatment is usually withheld until after the second seizure occurs because studies have not shown that treatment after the first seizure improves the long-term prognosis of remission (Reference 13). However, clinical decisions weighing the individual's risks and benefits of anti-convulsant therapy and the incidence of a subsequent seizure must be evaluated.

### Nonpharmacologic Therapy

Few nonpharmacologic therapies exist for seizures. The ketogenic diet is a popular therapy with patients who have refractory seizures and whose many medications for treatment have failed. The ketogenic diet is recommended for consideration in those with symptomatic generalized epilepsy (Reference 21). This diet consists of low protein and carbohydrate intake with high-fat meals, thus inducing ketosis in the patient. A ketogenic state has been shown to reduce seizure frequencies by 50% to 70% in some studies, but a specific mechanism of action is unknown (Reference 1). Patients are sometimes hospitalized during the initiation of the diet to monitor for hypoglycemia, dehydration, and vomiting. Long-term adverse effects include weight loss, hyperlipidemia, hypoproteinemia, nephrolithiasis, renal tubular acidosis, constipation, growth retardation, and increases in hepatic and pancreatic enzymes (Reference 1). Some patients may develop a prolonged QT interval; thus, this must be evaluated for cardiomyopathy (References 12, 21). All patients should be monitored routinely and will need vitamin supplementation. Patients on the ketogenic diet should not be initiated on valproic acid because of the risk of hepatotoxicity. Dextrose should also not be administered intravenously or by medications to a patient on the ketogenic diet because it may result in increased seizures (Reference 12). Many liquid forms of medications contain sugars or carbohydrates. The *Pediatric & Neonatal Dosage Handbook* traditionally provides a table of the carbohydrate amount in medications, which will assist pharmacists in providing information to the parent (Reference 22). The ketogenic diet requires strict control and adherence. Today, similar diets such as the modified Atkins and low Glycemic Index Treatment may be more tolerable and do not require inpatient initiation (Reference 12).

Vagal nerve stimulation used as adjunctive therapy for those with refractory epilepsy has resulted in a decrease of seizures. It is reserved for children 12 years

and older who have partial-onset seizures; however, off-label use extends to primary generalized epilepsy (Reference 7). The stimulator is placed under the skin with an electrode wrapped around the left vagus nerve. In studies, 23% to 50% of patients had a decrease in seizures by 50% or greater (Reference 7). Adverse effects such as hoarseness, cough, dyspepsia, nausea, and pain are generally tolerable. Serious adverse effects such as infections and nerve paralysis have been seen (Reference 7).

Surgical treatment is an option in patients with refractory focal epilepsy. The precise location of the epileptogenic area in the brain must be known. The average time from diagnosis to surgery ranges from 12 to 15 years (Reference 10). Temporal lobectomy is the most common surgery, with a 78% result of seizure freedom (Reference 18). A hemispherectomy or corpus callosotomy procedure may also be considered to control seizures in certain patients. Each surgery has risks; thus, each must be compared with possible benefits for the child.

### Pharmacologic Therapy

Pharmacologic treatment for seizures depends on the etiology and type of seizure or syndrome. Seizures caused early by head trauma seldom require medications (Reference 10). However, phenytoin, carbamazepine, or levetiracetam may be used prophylactically until acute neurologic signs have resolved to prevent early seizures. Seizures with metabolic causes such as hypoglycemia or hypocalcemia are treated by correcting the underlying etiology. Seizures secondary to infections such as meningitis should cease after the infection is identified and treated.

Pharmacologic treatment is typically indicated in patients with epilepsy. Monotherapy is preferred for patients, but combination therapy may be required for seizure control. Several trials of monotherapy with different anticonvulsants may be evaluated for efficacy before using combinations. After therapy is initiated, patients can be categorized into two groups: treatment-responsive or treatment-resistant (Reference 19). After the first or second medication is administered, two-thirds of patients will become seizure free. Unfortunately, 20% to 30% of patients will have uncontrolled or intractable seizures despite therapy, or they will experience significant adverse effects from the anticonvulsant medications (Reference 23).

Several anticonvulsants are available today for treatment. The "older" anticonvulsants are as follows: carbamazepine, phenobarbital, phenytoin, primidone, valproic acid, and ethosuximide. They share many characteristics such as complex pharmacokinetics, which require monitoring, and many drug interactions caused by hepatic induction or inhibition. The second-generation anticonvulsants are as follows: felbamate, gabapentin,

lamotrigine, topiramate, tiagabine, oxcarbazepine, levetiracetam, and zonisamide. These eight medications came on the market between 1993 and 2000 and have a more favorable drug profile because of fewer drug interactions and kinetics that do not require monitoring. The newest anticonvulsants to be approved are pregabalin (2004), rufinamide (2008), lacosamide (2008), vigabatrin (2009), ezogabine (2011), and clobazam (2011). Specific mechanisms of action have not been found for most anticonvulsants, but hypothesized or in vitro actions are usually provided in reference books. Most of the anticonvulsants are initially approved for use in adolescents and/or adults. After time, pediatric studies or reports from the literature will emerge, with potential pediatric indications following. As of today, not all the anticonvulsants listed are U.S. Food and Drug Administration (FDA) approved for use in children, but for most medications, pediatric dosing can be located. Table 1 lists recommended medications and corresponding seizure types. Table 2 provides the pediatric dosing of anticonvulsants, but it does not include all seizure types and ages.

Many factors must be considered before selecting an anticonvulsant for a patient. First, the medication choice will be based on the efficacy data available for the diagnosed seizure type. Not all anticonvulsants treat all seizure types. Next, characteristics of the patient such as age, comorbid disease states, concomitant medications, ability to take medications, lifestyle, and preference of the child/caregivers are considered. Medication characteristics are also evaluated such as drug interactions, adverse effects, cost, and dosage forms. Many anticonvulsants are unavailable in pediatric-friendly dosage forms, thus limiting their use. Adverse effects are an issue with all the anticonvulsants. Some of these effects are more prominent or occur only in the pediatric population. In general, medication selection should focus on an effective, tolerable drug with the least risk of harm for the patient. Many anticonvulsants are teratogenic; thus, patients of childbearing age must be educated on the possible fetal effects, or select medications may be avoided. Serum pregnancy tests may be obtained in these patients before initiating medication. All anticonvulsants must be initiated at low dosages and titrated slowly to a therapeutic dose. Fast titration or starting at higher dosages than recommended may cause increased adverse effects in the patient. Table 2 lists anticonvulsant medications with characteristics focused on pediatrics.

Controversy exists over the use of generic anticonvulsants in patients. Bioequivalence studies are conducted comparing a single dose of the generic with the brand formulation, not generic versus generic formulations (Reference 27). In addition, generic drugs are not required to complete bioequivalence studies in children unless the drug is targeted to this population. Most

anticonvulsants have several generic formulations available. However, the “older” anticonvulsants have more variable pharmacokinetics and are narrow therapeutic index drugs, unlike most of the “newer” anticonvulsants. Variability in pharmacokinetic parameters, especially between generic formulations, may cause an alteration of clinical efficacy in the patient. Breakthrough seizures in stable patients could result in harm to themselves or others, emotional distress, or loss of driving privileges or employment. Three case-controlled analyses using large national patient medical claims databases found that those who had a recent switch in formulation (brand-to-generic, generic-to-generic, or generic-to-brand) experienced an increase in epilepsy-related events requiring acute care (References 28–30). Cost and supply chain inconsistency also affects the decision to substitute medications. Because of concerns and lack of controlled, prospective data, patients should be initiated and remain on the same formulation consistently. Children who are stable on their current regimen should not have their regimen altered.

### *Status Epilepticus*

Status epilepticus is treated on the basis of etiology. A patient history can be very helpful as well. If hypoglycemia is present, intravenous infusions of dextrose are required. Some sources recommend glucose administration in all patients in status. Sodium and calcium levels should also be evaluated, and treatment should be initiated if abnormal values are confirmed. If a CNS infection is hypothesized, antibiotics are warranted. Status epilepticus is aggressively treated with medication if the seizure lasts more than 5 minutes. Benzodiazepines (lorazepam, diazepam, midazolam) can be administered once or twice; they will generally stop the seizure in 2–3 minutes (Reference 31). All benzodiazepines are equally effective for seizure cessation (References 20, 31). However, a Cochrane Database Review found lorazepam to be safer than diazepam in children (Reference 32). Diazepam has a longer half-life, but lorazepam has a smaller volume of distribution; thus, it stays in the CNS longer. Diazepam and lorazepam may be administered intravenously. If prehospital care is required and intravenous access is unavailable, both diazepam and lorazepam can be administered rectally, and midazolam may be administered intramuscularly, buccally, or intranasally. In fact, one study even found buccal midazolam more effective than rectal diazepam (Reference 32).

If benzodiazepines are not effective in terminating the seizure or if seizures recur after successful treatment with a benzodiazepine, phenytoin, fosphenytoin, or phenobarbital can be used as secondary agents. Phenytoin must be administered in a large vein to decrease the risk of extravasation. In addition, because of its vehicle (40%

**Table 1.** Medication Options by Type of Seizure (References 3, 10, 23–25)

Type of Seizure	Drugs of Choice	Alternatives	Drugs That May Worsen Seizure Type	FDA Approved (age of approval varies per medication)
Partial	<i>(newly diagnosed)</i>	Carbamazepine		Carbamazepine
	Carbamazepine	Gabapentin		Ezogabine
	Gabapentin	Lamotrigine		Felbamate
	Lamotrigine	Oxcarbazepine		Gabapentin
	Oxcarbazepine <sup>a</sup>	Phenobarbital <sup>a</sup>		Lacosamide
	Phenobarbital	Phenytoin <sup>a</sup>		Lamotrigine
	Phenytoin	Topiramate <sup>a</sup>		Levetiracetam
	Topiramate	Valproic acid <sup>a</sup>		Oxcarbazepine
	Valproic acid			Phenobarbital
				Phenytoin
	<i>(refractory monotherapy)</i>	Lamotrigine		Pregabalin
	Oxcarbazepine			Tiagabine
	Topiramate			Topiramate
				Valproic acid
				Zonisamide
		<i>(refractory adjunctive)</i>		
		Gabapentin <sup>a</sup>		
	Lamotrigine <sup>a</sup>			
	Levetiracetam			
	Oxcarbazepine <sup>a</sup>			
	Tiagabine			
	Topiramate <sup>a</sup>			
	Zonisamide			
Absence	Lamotrigine	Ethosuximide	Carbamazepine	Ethosuximide
		Valproic acid	Gabapentin	Valproic acid
			Oxcarbazepine	
			Phenobarbital	
			Phenytoin	
			Tiagabine	
			Vigabatrin	
Generalized tonic-clonic	Lamotrigine	Carbamazepine <sup>a</sup>	Tiagabine	Carbamazepine
	Topiramate	Lamotrigine	Vigabatrin	Lamotrigine
	Oxcarbazepine	Oxcarbazepine		Levetiracetam

		Phenytoin <sup>a</sup>		Phenytoin
		Topiramate <sup>a</sup>		Topiramate
		Valproic acid <sup>a</sup>		

<sup>a</sup>Specific recommendation for children.

propylene glycol), administration-related hypotension and cardiac arrhythmias may occur. Fosphenytoin is a water-soluble prodrug of phenytoin with a lower pH. Fosphenytoin is preferred to phenytoin because of its faster administration rate and ability to be administered intramuscularly. Although fosphenytoin may be an improved agent on the basis of its characteristics, cost may limit its use in some health care settings. Phenobarbital is another option for use to abate status and has been found to be as efficacious as phenytoin (Reference 31).

Several loading doses of phenobarbital may be administered, followed by maintenance dosing after the seizure has been stopped. Phenobarbital should not be administered intramuscularly for status epilepticus because of its slow absorption. Decreased respirations and consciousness are adverse effects of phenobarbital.

Status epilepticus that fails to cease after two adequate doses of benzodiazepines, phenytoin/fosphenytoin, or barbiturates is deemed refractory. Refractory status epilepticus is more difficult to treat the longer it

**Table 2.** Characteristics of Anticonvulsants (References 3, 10, 22, 24–26)

Anticonvulsant Generic (trade name)	Molecular Target	Pediatric Dosing/Therapeutic Levels	Dosage Formulations	Adverse Effects (Pediatrics Focused)	CYP Drug Interactions
Carbamazepine (Tegretol, Tegretol-XR, Carbamatrol, Epitol)	Sodium channel	< 6 yr: Initial: 10–20 mg/kg/day div BID or TID (suspension: QID); max: 35 mg/kg/day 6–12 yr: Initial: 100 mg BID (suspension); 50 mg QID; increase by 100 mg/day weekly; maintenance: 400–800 mg/day; max: 1000 mg/day > 12 yr: Initial: 200 mg BID (suspension: 100 mg QID); increase by 200 mg/day weekly; maintenance: 800–1200 mg/day; max: 12–15 yr: 1000 mg/day, > 15 yr: 1200 mg/day Adjust dose in renal impairment; use with caution in hepatic impairment. Therapeutic levels: 4–12 mcg/mL	ER capsule, suspension, tablet, chewable tablet, ER tablet, ext suspension	Boxed warnings: Aplastic anemia, agranulocytosis, dermatologic reactions (SJS, TEN), use in Asian patients with genotype: <i>HLA-B*1502</i> allele Accommodation disorders (blurred vision, diplopia, ataxia, and nausea), SIADH	Major 3A4 and minor 2C8 substrate; strong 1A2, 2B6, 2C8, 2C9, 2C19, 3A4 inducer, P-glycoprotein
Clobazam (Onfi)	GABA <sub>A</sub> receptor	< 2 yr: 0.5–1 mg/kg/day > 2 yr: ≤ 30 kg: Initial: 5 mg, increase to 10 mg at day 7, and increase to 20 mg at day 14; > 30 kg: Initial: 10 mg, increase to 20 mg at day 7, and increase to 40 mg at day 14 Doses > 30 mg should be divided. Adjust dose in renal impairment; contraindicated in severe hepatic impairment	Tablet	Somnolence, sedation, drooling, constipation, cough, urinary tract infection, aggression, insomnia, dysarthria, fatigue, suicidal behavior and ideation	Major 2C19 and 3A4 substrate
Ethosuximide (Zarontin)	Sodium and calcium channels	< 6 yr: Initial: 15 mg/kg/day div BID, increase every 4–7 days; maintenance: 15–40 mg/kg/day; max: 1.5 g/day ≥ 6 yr: 250 mg BID, increase by 250 mg/day every 4–7 days; maintenance: 20–40 mg/kg/day; max: 1.5 g/day Use with caution in renal and hepatic impairment. Therapeutic levels: 40–100 mcg/mL; toxic: > 150 mcg/mL	Capsule, solution, syrup	Nausea, headache, drowsiness	Major 3A4 substrate
Ezogabine (Potiga)	Potassium channel	≥ 18 yr: Initial: 100 mg TID, increase weekly by 150 mg/day; maintenance: 200–400 mg TID; max: 1200 mg/day Adjust dose in renal and hepatic impairment.	Tablet	Urinary retention, dizziness, somnolence, QT prolongation, neuropsychiatric symptoms (adult data)	Not cytochrome-dependent
Felbamate (Felbatol)	Sodium channel, GABA <sub>A</sub> and NMDA receptors	2–14 yr w/LGS: 15 mg/kg/day div TID or QID, increase by 15 mg/kg/day weekly; max: 45 mg/kg/day or 3600 mg/day ≥ 14 yr: Adjunct and conversion to monotherapy: 1200 mg/day div TID or QID, increase by 1200 mg/day weekly; max: 3600 mg/day; monotherapy: increase by 600 mg/day every 2 weeks Adjust dose in renal impairment.	Suspension, tablet	Boxed warnings: Aplastic anemia, acute hepatic failure Anorexia, somnolence, insomnia, vomiting, weight loss (usually first 3 months of treatment), nausea, gait abnormality	Minor 2E1 and major 3A4 substrate; weak 2C19 inhibitor; weak 3A4 inducer
Gabapentin (Neurontin)	Calcium channel	3–12 yr: Initial: 10–15 mg/kg/day div TID, maintenance: 3–4 yr: 40 mg/kg/day, 5–12 yr: 25–35 mg/kg/day > 12 yr: Initial: 300 mg TID; maintenance: 900–1800 mg/day; max: 3600 mg/day Adjust dose in renal impairment	Capsule, solution, tablet	Somnolence, fatigue, emotional lability, behavior changes, hostility, hyperkinesia, dizziness, fever	Not cytochrome-dependent

(continued)

**Table 2.** Characteristics of Anticonvulsants (References 3, 10, 22, 24–26) (continued)

Anticonvulsant Generic (trade name)	Molecular Target	Pediatric Dosing/Therapeutic Levels	Dosage Formulations	Adverse Effects (Pediatrics Focused)	CYP Drug Interactions
Lacosamide (Vimpat)	Sodium channel	<p>≥ 17 yr: Initial: 50 mg BID, increase by 100 mg/day weekly; maintenance: 200–400 mg/day</p> <p>Adjust dose in hepatic and renal impairment.</p>	Injection, solution, tablet	Prolonged PR interval, dizziness, headache, diplopia (adult data)	Carbamazepine, phenobarbital, and phenytoin may decrease lacosamide levels.
Lamotrigine (Lamictal, Lamictal ODT, Lamictal XR)	Sodium and calcium channels, inhibits glutamate release	<p>2–12 yr: Immediate release: Initial: 0.3 mg/kg/day div one or two doses for weeks 1 and 2; increase to 0.6 mg/kg/day div BID for weeks 3 and 4; increase as needed by 0.6 mg/kg/day every 1–2 weeks; maintenance: 4.5–7.5 mg/kg/day div BID; max: 300 mg/day div BID</p> <p>With valproic acid—containing regimens: 0.15 mg/kg/day div one or two doses for weeks 1 and 2; increase to 0.3 mg/kg/day div BID for weeks 3 and 4; increase as needed by 0.3 mg/kg/day every 1–2 weeks; maintenance: 1–5 mg/kg/day div BID; max: 200 mg/day div one or two doses; *for patients &gt; 6.7 kg and &lt; 14 kg, initial dosing is 2 mg QOD in weeks 1 and 2; then 2 mg/day for weeks 3 and 4</p> <p>With enzyme-inducing regimens, without valproic acid: Initial: 0.6 mg/kg/day div BID for weeks 1 and 2; increase to 1.2 mg/kg/day div BID for weeks 3 and 4; increase as needed by 1.2 mg/kg/day every 1–2 weeks; maintenance: 5–15 mg/kg/day div BID; max: 400 mg/day div BID</p> <p>&gt; 12 yr: Immediate release: Initial: 25 mg/day for weeks 1 and 2; increase to 50 mg/day for weeks 3 and 4; increase as needed by 50 mg/day every 1–2 weeks; maintenance: 225–375 mg/day div BID</p> <p>With valproic acid—containing regimens: 25 mg QOD for weeks 1 and 2; increase to 25 mg/day for weeks 3 and 4; increase as needed by 25–50 mg/day every 1–2 weeks; maintenance: 100–400 mg/day div in one or two doses; for patients with lamotrigine and valproic acid alone: maintenance dose: 100–200 mg/day</p> <p>With enzyme-inducing regimens, without valproic acid: Initial: 50 mg/day for weeks 1 and 2; increase to 100 mg/day div BID for weeks 3 and 4; increase as needed by 100 mg/day every 1–2 weeks; maintenance: 300–500 mg/day div BID; doses up to 700 mg/day have been used</p> <p>Converting to ER formulation: The daily dose of immediate release should total the initial daily dose of ER.</p> <p>Adjust dose in renal and hepatic impairment.</p>	Tablet, chewable/dispersible tablet, ER tablet, ODT, ext suspension	<p>Boxed warning: Rash (more common in pediatric population, 0.8%; usually occurs within 8 weeks of initiation and resolves after withdrawal; also more common with concomitant valproate)</p> <p>Drowsiness, diplopia, dizziness, headache, insomnia, tiredness, fever (associated with a rash as part of a hypersensitivity syndrome), agitation, confusion, hallucinations, myoclonus</p>	<p>Carbamazepine and phenytoin may increase lamotrigine metabolism, Phenobarbital may decrease lamotrigine levels; valproic acid may increase lamotrigine levels</p>

Levetiracetam (Keppra, Keppra XR)	Calcium channel	4–15 yr: Initial: 10 mg/kg/dose BID, inc by 10 mg/kg/dose every 2 weeks; max: 30 mg/kg/dose BID *Clinically, doses > 80 mg/kg/day are used. ≥ 16 yr (PO/IV): immediate release: 500 mg BID, increase by 500 mg/dose every 2 weeks; max: 1500 mg BID; ER: 1000 mg once daily, increase by 1000 mg/day every 2 weeks; max: 3000 mg/day IV daily dose = PO daily dose Adjust dose in renal impairment.	Injection, solution, tablet, ER tablet	Most common: Dizziness, somnolence, behavior/ personality changes, irritability, hostility, nervousness, accidental injury, asthenia; others: psychotic symptoms, insomnia, emotional lability, ataxia, tremor, headache, nausea	Not cytochrome-dependent
Oxcarbazepine (Trileptal)	Sodium and calcium channels	2–16 yr (adjunctive): < 20 kg: Initiate at 16–20 mg/kg/day div BID; > 20 kg: Initiate at 8–10 mg/kg/day div BID; max: < 20 kg: 600 mg/day, 20–29 kg: 900 mg/day, 29.1–39 kg: 1200 mg/day, > 39 kg: 1800 mg/day 4–16 yr (monotherapy): 8–10 mg/kg/day div BID; increase by 5 mg/kg/day every third day; maintenance: ranges from 600 to 2100 mg/day by weight > 16 yr (adjunctive): Initial: 300 mg BID, increase by 600 mg/day weekly; maintenance: 1200 mg/day div BID, may increase, most patients do not tolerate 2400 mg/day (CNS) > 16 yr (monotherapy): Initial: 300 mg BID; increase by 300 mg/day weekly; maintenance: 1200 mg/day div BID Adjust dose in renal impairment.	Suspension, tablet	More common: Somnolence, dizziness, diplopia, headache, nausea, vomiting; others: rash, ataxia, confusion, cognitive changes (difficulty concentrating, speech or language issues), SIADH	Strong 3A4 inducer, weak 2C19 inhibitor
Phenobarbital	Calcium channel, GABA <sub>A</sub> receptor	Maintenance: < 1 yr: 5–8 mg/kg/day div in one or two doses; 1–5 yr: 6–8 mg/kg/day div in one or two doses; 5–12 yr: 3–6 mg/kg/day div in one or two doses; > 12 yr: 1–3 mg/kg/day or 50–100 mg 2 or 3 times/day Adjust dose in renal and hepatic impairment. Therapeutic level: 15–30 mcg/mL Toxic: > 40 mcg/mL	Elixir, injection, tablet, ext suspension	Concentration-related effects: 35–80 mcg/mL: slowness, ataxia, nystagmus; 65–117 mcg/mL: coma with reflexes; > 100 mcg/mL: coma without reflexes Drowsiness, lethargy, mental depression, allergic skin reactions and hyperkinesia, paradoxical responses (hyperactivity, agitation)	Minor 2C9, 2E1, and major 2C19 substrate; strong 1A2, 2A6, 2B6, 2C8, 2C9, 3A4 inducer
Phenytoin (Dilantin, Dilantin-125, Phenytek)	Sodium channel	Loading dose (IV/PO): 15–20 mg/kg/dose Neonates: Initial: 5 mg/kg/day div BID; maintenance: 5–8 mg/kg/day div BID, some patients require TID dosing Infants/children: 5 mg/kg/day div in two or three doses; maintenance: 6 months to 3 yr: 8–10 mg/kg/day; 4–6 yr: 7.5–9 mg/kg/day; 7–9 yr: 7–8 mg/kg/day; 10–16 yr: 6–7 mg/kg/day, > 16 yr: 300 mg/day or 4–6 mg/kg/day in two or three doses	ER capsule, injection, suspension, chewable tablet	Boxed warning: Administer IV phenytoin slowly; not to exceed 1–3 mg/kg/minute in neonates, 50 mg/minute in adults; hypotension occurs with rapid administration Concentration-related effects: > 20 mcg/mL: far lateral nystagmus; > 30 mcg/mL: 45 degree lateral gaze nystagmus, ataxia; > 40 mcg/mL: decreased mental activity; > 100 mcg/mL: death	Major 2C9, 2C19 and minor 3A4 substrate; strong 2B6, 2C8, 2C9, 2C19, 3A4 inducer

(continued)

**Table 2.** Characteristics of Anticonvulsants (References 3, 10, 22, 24–26) (continued)

Anticonvulsant Generic (trade name)	Molecular Target	Pediatric Dosing/Therapeutic Levels	Dosage Formulations	Adverse Effects (Pediatrics Focused)	CYP Drug Interactions
Pregabalin (Lyrica)	Calcium channel	<p>* ~92-mg base phenytoin (suspension/chewable tablet) = 100 mg of phenytoin sodium</p> <p>*For obese patients, loading dose should be based on adjusted body weight, and maintenance dose should be based on ideal body weight.</p>	Capsule	Hypersensitivity reactions including rash. Common effects: Drowsiness, ataxia, slurred speech (dose related); coarsening of facial features, gingival hyperplasia, hirsutism (rare but with chronic use); anemias (these usually respond to folic acid); motor twitching, dyskinesias (rare), tremor (rare), mental confusion	Not cytochrome-dependent
Rufinamide (Banzel)	Sodium channel	<p>Adult: Initial: 150 mg/day in two or three doses, titrate as needed; max: 600 mg/day</p> <p>Adjust dose in renal impairment.</p> <p>≥ 4 yr: Initial: 10 mg/kg/day div BID; increase by 10 mg/kg/day QOD; maintenance: 45 mg/kg/day or 3200 mg/day div BID (whichever is lower)</p> <p>If taking valproic acid: initial dose: &lt; 10 mg/kg/day</p> <p>Adults: Initial: 400–800 mg/day div BID; increase by 400–800 mg/day every 2 days; max: 3200 mg/day div BID</p> <p>If taking valproic acid: initial dose: &lt; 400 mg/day</p> <p>Adjust dose in hepatic impairment.</p>	Tablet, suspension, ext suspension	QT-interval shortening (dose-dependent), headache, somnolence, fatigue, dizziness, vomiting	Weak 2E1 inhibitor; weak 3A4 inducer; valproic acid may increase rufinamide levels; carbamazepine, phenobarbital, phenytoin, and primidone may decrease rufinamide levels; rufinamide may increase phenobarbital and phenytoin levels
Tiagabine (Gabitril)	GABA transporter	<p>12–18 yr:</p> <p>With enzyme-inducing regimens: 4 mg/day for week 1; 4 mg BID for week 2; then increase by 4–8 mg/day; max: 32 mg/day in two to four doses</p> <p>Without enzyme-inducing regimen: Lower doses are required</p> <p>Adjust dose in hepatic impairment.</p>	Tablet, ext suspension	Dizziness, tiredness, nervousness (nonspecific), tremor, concentration difficulties, depressed mood	Major 3A4 substrate
Topiramate (Topamax)	Sodium channel, GABA <sub>A</sub> and glutamate receptors, weak carbonic anhydrase inhibitor	<p>2–16 yr (adjunctive): Initial: 25 mg/day or 1–3 mg/kg/day, increase by 1–3 mg/kg/day every 1–2 weeks; max: 5–9 mg/kg/day div BID</p> <p>≥ 17 yr: Initial: 25 mg/day or BID for 1 week; increase by 25–50 mg/week; maintenance: 100–200 mg/day. Doses &gt; 1600 mg not studied</p> <p>≥ 10 yr (monotherapy): Initial: 25 mg BID, increase by 50 mg/day weekly, up to 100 mg BID for week 4; may then increase by 100 mg/day weekly; max: 200 mg BID</p> <p>Adjust dose in renal and hepatic impairment.</p>	Sprinkle capsule, tablet, ext suspension	Headache, somnolence, dizziness, paresthesia, oligohidrosis, hyperthermia, weight loss (dose-dependent), behavior problems, difficulty with memory and concentration/attention, metabolic acidosis (chronic use may lead to decreased growth rates, nephrolithiasis, osteomalacia) <p>Secondary acute angle-closure glaucoma or acute myopia—may present as painful red eye (rare and usually occurs within 1 month of initiation)</p>	Weak 2C19 inhibitor; weak 3A4 inducer

Valproic acid (Depacon, Depakene)	GABA <sub>A</sub> and NMDA receptors	Children and adults: Initial: 15 mg/kg/day; increase by 5–10 mg/kg/day weekly to therapeutic levels, administered in two to four doses/day; max: 60 mg/kg/day Adjust dose in hemodialysis and hepatic impairment—see warnings Therapeutic levels; 50–100 mcg/mL, efficacy may improve with higher levels, but toxicity can also occur	Capsule, sprinkle capsule, injection, syrup, delayed-release tablet, ER tablet	Boxed warning: May cause teratogenic effects (neural tube defects), hepatic failure in children (< 2 years considerable risk), pancreatitis Occasional: Sedation and tremor; transient hair loss (may be dose related—regrowth normally begins within 6 months); weight gain; gastric disorders (initiation of treatment); hyperactivity, aggression and behavioral deterioration (occasional); transient increase in liver enzymes is common, especially at therapy initiation; hyperammonemia; amenorrhea and irregular periods	Minor 2A6, 2B6, 2C9, 2C19, 2E1 substrate; weak 2C9, 2C19, 2D6, 3A4 inhibitor; weak 2A6 inducer
Vigabatrin (Sabril)	GABA transaminase	Restricted access to medication per REMS program, available from SHARE program 1 month to 2 yr: Initial: 50 mg/kg/day div BID; increase by 25–50 mg/kg/day every 3 days; max: 150 mg/kg/day Adjust dose in renal impairment.	Powder for solution, tablet	Boxed warning: Permanent vision loss in infants, children, and adults (visual field defects) Very common: Somnolence, excitation, agitation; common: nausea, aggression, irritability, depression; fever, vomiting	May decrease phenytoin levels
Zonisamide (Zonegran)	Sodium and calcium channels, weak carbonic anhydrase inhibitor	Infants and children: Initial: 1–2 mg/kg/day div BID, increase by 0.5–1 mg/kg/day every 2 weeks; maintenance dose: 5–8 mg/kg/day; max for infantile spasms: 10–13 mg/kg/day in clinical studies ≥ 16 yr: Initial: 100 mg/day; increase to 200 mg/day after week 2; may increase by 100 mg/day every 2 weeks; if no evidence of increased response, > 400 mg/day in one or two doses Adjust dose in renal and hepatic impairment. Note: Zonisamide should not be used in patients with a sulfonamide allergy.	Capsule, ext suspension	Somnolence, dizziness, oligohidrosis, hyperthermia, metabolic acidosis (chronic may lead to decreased growth rates, rash, SJS, nephrolithiasis, osteomalacia), anorexia	Minor 2C19 and major 3A4 substrate

BID = twice daily; CNS = central nervous system; CYP = cytochrome P450; div = divided; ER = extended release; ext = extemporaneous; GABA =  $\gamma$ -aminobutyric acid; inc = increase; IV = intravenous; max = maximum; LGS = Lennox-Gastaut syndrome; NMDA = *N*-methyl-*D*-aspartate; ODT = oral disintegrating tablet; PO = by mouth; QID = four times/day; REMS = Risk Evaluation and Mitigation Strategies; SHARE = Support, Help, and Resources for Epilepsy; SIADH = syndrome of inappropriate secretion of antidiuretic hormone; SJS = Stevens-Johnson syndrome; TEN = toxic epidermal necrolysis; TID = three times/day; yr = years; XR = extended release.  
Reference 35.

lasts. Valproate, propofol, levetiracetam, and medically induced comas with pentobarbital or midazolam have all been used for refractory status epilepticus (References 20, 31). Intravenous valproate and levetiracetam are increasing in use because of safety profiles. Propofol should be used with caution, especially if long-term use is warranted, because of the irreversible propofol infusion syndrome seen in children (hemodynamic instability [hypotension, hyperkalemia, cardiac failure, renal failure], lipidemia, rhabdomyolysis, and severe metabolic acidosis) (References 20, 22). It is generally associated with high-dose, prolonged infusions (greater than 5 mg/kg/hour for more than 48 hours). Monitoring of electrolytes, organ function, and creatine phosphokinase is warranted with propofol infusions. Pentobarbital infusions were found effective in 74% to 100% of refractory status cases in one study (Reference 33). Pentobarbital can be rapidly titrated, but prolonged infusions result in slower elimination because of accumulation in fat stores. Adverse effects such as immunosuppression (high doses) and hypotension resulting in decreased cardiac contractility requiring inotropes may be seen. Pentobarbital contains propylene glycol as a vehicle, and toxicity can result in metabolic acidosis and renal toxicity. Midazolam is the preferred benzodiazepine for continuous infusion because of its short half-life, easy titration, and lack of propylene glycol, which is found in intravenous lorazepam. Some studies have shown midazolam to be less efficacious than other options, but the other options tend to have more adverse effects. All patients placed into a medically induced coma should be intubated, provided respiratory support, and monitored by EEG. Hypotension, which is common, should be observed in these patients. A lack of well-controlled studies with these medications limits the ability to state that one medication is superior to another.

### **Syndromes**

Many syndromes are treated with specific agents. Infantile spasms with or without a West syndrome diagnosis are primarily treated with adrenocorticotrophic hormone or vigabatrin as the first-line agent, with high-dose prednisone as an alternative (Reference 15). Valproic acid, lamotrigine, topiramate, and zonisamide also have been used. Lennox-Gastaut syndrome usually requires several concomitant anticonvulsants to reduce the number of seizure episodes. Typically, valproic acid, felbamate, topiramate, lamotrigine, and zonisamide are options in these patients (Reference 1). Carbamazepine is the anticonvulsant of choice for benign rolandic epilepsy. Juvenile myoclonic epilepsy is commonly treated with valproic acid, but lamotrigine, topiramate, levetiracetam, and zonisamide are alternatives.

### **Febrile Seizures**

Clinical trials have shown that antipyretics administered in a schedule or on an as-needed method are not effective in preventing a febrile seizure or the recurrence of febrile seizures (Reference 16). Simple febrile seizures are typically not treated with anticonvulsants. Many scheduled anticonvulsants have been tried for febrile seizures, but adverse effects or lack of efficacy limits their use; thus, they are not recommended (Reference 16). Carbamazepine and phenytoin have not shown efficacy (Reference 1). Adverse effects have limited phenobarbital (cognitive and behavioral adverse effects) and valproic acid (hepatotoxicity and pancreatitis) (Reference 1). Diazepam has been successfully used intermittently once a fever occurs, but sedation and irritability were reported (Reference 12). Thus, the American Academy of Pediatrics does not recommend continuous or intermittent anticonvulsant therapy for patients with one or more simple febrile seizures (Reference 16). However, anticonvulsants may be considered in patients with complex (atypical) febrile seizures or with neurologic abnormalities.

## **MONITORING OF THERAPY**

### **Therapeutic Outcomes**

Patients with epilepsy should be assessed and monitored by pediatric neurologists. The frequency of follow-up will depend on the patient, type of seizures, and control of episodes. In general, therapeutic outcomes for patients with seizures or epilepsy include a decrease in the frequency of seizures, with a goal to be seizure free. Patients should experience an improved quality of life and be free of the adverse effects of medication.

Withdrawal of pharmacologic therapy is a decision to be made by the health care providers, patient, and family. Withdrawal may be considered if the patient is seizure free for 2–5 years (mean: 3.5 years) while taking anticonvulsants, has a single type of partial or primary generalized tonic-clonic seizure, has the EEG normalized with treatment, and has a normal IQ and neurologic examination (Reference 34). Children who meet these criteria have a 69% chance of successfully remaining off pharmacotherapy (Reference 34). If patients meet the criteria to attempt to discontinue pharmacotherapy, the medications must be tapered down slowly for several months (Reference 3). Abrupt discontinuation of medications is not recommended unless the patient is experiencing a severe adverse effect. If patients are taking more than one anticonvulsant, one medication will be tapered down gradually first, and when off the first medication, the second medication will be tapered.

While tapering the regimen, if a patient experiences a seizure, the medication should be increased to the previous dose on which the patient did not have a seizure, and withdrawal of the medication should not occur.

### Toxicity

Toxicities and adverse effects vary by medication. A few key adverse effects that affect all anticonvulsants will be briefly discussed in this section. Table 2 lists the adverse effects of anticonvulsants that are usually seen in the pediatric population. This is not an inclusive list; thus, consult a drug information resource and literature for a complete list of adverse effects in children and adults. Adverse effects from medications used in status epilepticus are provided in the above treatment section.

Serum drug monitoring continues to be important with respect to the first-generation anticonvulsants because specific levels correspond to efficacy and toxicity in patients. Therapeutic drug serum concentrations are listed in Table 2. Of note, the targeted therapeutic range may be higher than the normal range if a patient is considered resistant to therapy or placed in a drug-induced coma (phenobarbital). However, the second-generation anticonvulsants, when studied, have not shown that serum levels correspond to efficacy or adverse effects. Serum levels are typically not recommended to be drawn for patients taking these medications, but they may be used to verify adherence.

Some anticonvulsants have a drug interaction with oral contraceptive medications (Reference 19). Topiramate, at doses of greater than 200 mg/day; oxcarbazepine; and rufinamide can decrease serum concentrations of ethinyl estradiol. Carbamazepine, phenobarbital, and phenytoin also decrease the estrogen concentrations because of cytochrome P450 drug interactions. Oral contraceptives can also result in a decrease in lamotrigine serum concentrations. Patients of childbearing potential should be notified of these interactions and educated on pregnancy risks.

Although several anticonvulsants are teratogenic, sometimes the benefit of using an anticonvulsant may outweigh the risk. Pregnancy registries are available for patients taking any anticonvulsant medication. Patients may enroll themselves, and all health care providers should educate their patients on using these registries. The FDA pregnancy ratings for anticonvulsants have been known to change as information on fetal effects have been determined. Childbearing women who take anticonvulsants should also supplement with folic acid to prevent birth defects.

In 2008, anticonvulsant labeling changed to include a warning for increased risk of suicidal thoughts or behavior in patients taking these medications (Reference 35). A pooled analysis of 199 trials (monotherapy and adjunctive) showed an incidence rate of 0.43% in treated

patients compared with 0.24% in those on placebo and an occurrence in 1 in every 530 patients treated. The risk was seen as early as 1 week after initiating the anticonvulsant and continued throughout the trials (most lasting 24 weeks or less). The FDA has required all manufacturers to develop a medication guide to be provided to patients who are prescribed any of these medications.

Vitamin D supplementation is warranted for patients taking chronic anticonvulsants that are hepatic inducers (Reference 19). Vitamin D levels should be evaluated every 2–5 years in these patients (Reference 3).

### FUTURE THERAPIES

Newer anticonvulsants are generally approved for use in adults first; then, studies may be formally completed or case reports may document the effects in children. Several anticonvulsant chemicals are in trials evaluating efficacy and safety; however, not all chemical entities will be successful enough to make it to the market for patient use.

### CONCLUSIONS

Seizures and epilepsy are a common pediatric disease state. Various types of seizures and etiologies exist and are the initial guidance for determining treatment options in patients. Not all seizures, epilepsy, or epileptic syndromes will require pharmacologic treatment. However, most patients will be prescribed an anticonvulsant. Anticonvulsants should be used for treatment while balancing the risks and benefits of efficacy and adverse effects. Most patients will be successfully treated with one anticonvulsant, but some patients will be classified as treatment-resistant. In general, therapy should be initiated slowly, and monitoring is required for every patient. The priority in treating seizures and epilepsy is to improve the patient's quality of life.

# CHAPTER 27

## MIGRAINES

Lea S. Eiland, Pharm.D., BCPS, FASHP

### LEARNING OBJECTIVES

1. Recognize signs and symptoms of migraines in children.
2. List nonpharmacologic treatment options for migraines.
3. Select appropriate pharmacologic treatment options for migraines.
4. Understand the use of prophylactic drugs for migraines in children.

### ABBREVIATIONS IN THIS CHAPTER

AAN	American Academy of Neurology
DHE	Dihydroergotamine
ED	Emergency department
IHS	International Headache Society
PedMIDAS	Pediatric Migraine Disability Assessment Score
PedsQL	Pediatric Quality of Life

### INTRODUCTION

Headaches are the third leading cause of emergency department (ED) referrals and rank in the top 5 health problems of children (References 1, 2). Headaches, diagnosable in children from young ages to adolescents, may disrupt school or social time. Migraine, a type of primary headache, commonly occurs in the pediatric population and is a chronic condition characterized by acute, recurrent, episodic attacks (Reference 3). Migraine characteristics and long-term prognosis vary among patients. Most adults who have migraines also experienced them during childhood (Reference 4). A child with migraine headaches should be assessed carefully to ensure a correct diagnosis. Optimal migraine management includes the use of both nonpharmacologic and pharmacologic therapies. Migraines appearing in childhood can be a chronic and debilitating disease; thus, appropriate diagnosis and management are warranted.

### Epidemiology

The prevalence of migraines in the pediatric population is 3% in children aged 2–7 years, 4% to 11% in children 7–11 years, and 8% to 23% in children 11 years and older (Reference 5). In children, migraine without aura

is more than twice as common as migraine with aura. Migraine without aura occurs in more than 60% of children with headaches, whereas migraine with aura occurs in 18% of children (Reference 6). Thirteen percent of children experience both migraines with and without aura. Boys younger than 7 years have a higher prevalence of migraines than girls. The rate of migraine headaches is equal between boys and girls age 7–11 years (Reference 7). Girls tend to have a higher prevalence of migraine headaches than boys do after adolescence. However, boys tend to show an earlier peak onset of migraines at age 7 years, whereas girls have a peak onset at 11 years.

### Etiology

#### *Pathophysiology*

Several theories exist regarding the pathophysiology of migraines; however, the exact pathophysiology is not clearly understood. Mechanisms include the following: intracerebral arterial vasoconstriction/vasodilation, neuronal dysfunction, activation of the trigeminovascular system, and unknown causes. The intracerebral arterial theory encompasses that during the aura, cerebral vasoconstriction occurs with a reactive extracranial vasodilation, resulting in a headache. Now, scientists believe that it is not simply a vascular mechanism but that other pathways are involved as well, such as neuronal dysfunction and trigeminal sensitization. Neuronal dysfunction is thought to be a depressed cortical spreading of electrical activity that corresponds to the symptoms associated with the presence of the aura (Reference 8). Voltage-gated P/Q-type calcium channels that release glutamate are also involved in the depressed cortical spreading.

Migraines are also thought to be caused by meningeal and blood vessel nociceptor stimulation with central pain modulation (Reference 8). When the trigeminal sensory neurons are activated, substance P, calcitonin gene-related peptide, and neurokinin A are released, resulting in dilation of the blood vessel wall, plasma protein extravasation, and platelet activation. The nerve fibers become more sensitive because of this neurogenic inflammation, resulting in the migraine pain. Conduction along the trigeminovascular fibers transmits signals to higher cortical pain centers. Repeated signaling produces a sensitization of central sensory neurons, resulting in hyperalgesia.

Biologic changes have also been reported because elevated interleukin 1 alpha and tumor necrosis factor have been identified in children with migraines (Reference 9). Decreased coenzyme Q<sub>10</sub> levels have also been seen in patients with migraines. Furthermore, theories regarding allodynia (pain caused by a stimulus that typically does not evoke pain) are undergoing assessment in children. Patients who experience allodynia during migraines have shown altered responses to treatment (Reference 9). A better understanding of the mechanisms can lead to improved treatment options for patients.

Several comorbid diseases exist with migraines: obesity, epilepsy, sleep disorders, asthma and allergic conditions, and psychological or emotional disease states (Reference 9). Specific mechanisms regarding how the disease state affects migraine development are unknown, but common neurologic pathways are hypothesized. It is also thought that the stress of dealing with multiple disease states can trigger migraines.

### ***Genetic Basis***

Genetics plays a large role in migraines. When both parents of a child are interviewed about a history of migraines, 90% will confirm that one or the other has a history of migraines (Reference 10). When only one parent is questioned, a history of migraines occurs in 80%, typically in the mother. Of adult patients with migraines, 50% will have at least one child with migraines. Specific genes are undergoing evaluation to understand the genetic role of migraines and better establish this relationship.

### ***Risk Factors for Disease***

Several known triggers and risk factors for migraine exist. Changes in sleep patterns, specific foods, stress, and the menstrual cycle can all exacerbate or be causative factors for a migraine. An attack may be triggered by changes in sleep patterns, such as when a child stays up late or all night to study for an examination. Only 20% of patients have a food trigger related to migraines (Reference 6). Caffeine consumption and hunger are associated with risk of migraines (Reference 6). During times of stress or during a relaxing period after stress, a migraine may occur. These associated attacks tend to occur during school or right after work (Reference 10). Stress from school can be a trigger for pediatric patients because the associated psychological factors and feelings (phobias or anxiety) affect headache frequency (Reference 9). In addition to stress, hormonal levels can be implicated in the onset of migraines. The decline in estrogen hormones during the menstrual cycle is proposed to be a triggering event for menstrual migraines (Reference 10). Oral contraceptives may increase the intensity and frequency of migraine attacks. More frequent attacks generally occur around mid-cycle. Head trauma caused

by competitive sports or accidental injury may also cause a migraine, but the specific mechanisms are unknown. Studies have also shown that female, obese children are about 4 times more likely to have headaches than are those with a normal weight (Reference 11).

## **CLINICAL PRESENTATION AND DIAGNOSIS**

The International Headache Society (IHS) classifies migraines in general for adults and children (Reference 12). Migraines are classified as one of six types, as follows: migraine without aura, migraine with aura, childhood periodic syndromes that are commonly precursors of migraine, retinal migraine, complications of migraine, and probable migraine. Some of these classifications have subcategories. The International Classification of Headache Disorders provides specific definitions and diagnosis criteria for each migraine type and subtype (Reference 12). This chapter will primarily focus on migraine without aura. In the diagnosis of migraines, it is important to rule out secondary causes of migraines as well as whether co-primary headaches (e.g., tension-type or cluster headaches) are also present (Reference 3). Examples of secondary causes of migraines include acute viral illness, sinus infection, posttraumatic headache, and intracranial infection (Reference 13).

### **Signs and Symptoms**

The IHS diagnostic criteria specifically describe migraine without aura in children. The IHS criteria include the following traits of children with this type of migraine. The criteria include that children should have at least five or more headaches that (1) last for a duration of 1–72 hours (untreated or unsuccessfully treated), (2) have two of the following characteristics (bilateral or unilateral location, pulsating quality, have moderate or severe pain intensity, or are aggravated by or causing avoidance of routine physical activities), (3) have nausea or vomiting or photophobia or phonophobia (may be inferred from a child's behavior or actions), and (4) not be attributed to another disorder (Reference 12). Migraine attacks can be divided into three phases: prodrome, headache, and postdrome (Reference 6). The prodrome phase can begin as early as 24 hours before the headache and be subtle, causing caregivers not to recognize these symptoms initially. Children may behave differently by experiencing increased thirst, craving particular foods, or refusing food altogether. Children may also have pallor, be inactive, or undergo mood changes. Head pain that follows the initial symptoms is the headache phase. “Throbbing” and “splitting” are commonly used to describe the pain intensity of children's migraines. If there is difficulty understanding children's descriptions, it can be beneficial to ask them to draw their headache. This scheme may help children explain what they are feeling (e.g., ax or

knife pointing to head). As children age, they are able to describe their pain better, and a diagnosis may become clearer. Young children may have difficulty verbally expressing their headache symptoms. Some symptoms may need to be inferred from young children. For example, photophobia may be interpreted when children place a blanket over their head and turn off the light in the room. Headache and vomiting are common symptoms among adults, but children may also have nausea, malaise, and personality changes. Physical activity such as climbing stairs or carrying backpacks can aggravate the pain as well (Reference 6). The duration of migraines in children tends to be shorter than in adults; an episode may last only 1 hour in children but must last at least 4 hours in adults to meet the diagnostic criteria (Reference 12). The duration and frequency of migraines will vary according to the individual child. After a migraine, children most likely are fatigued, but some children experience a paradoxical increase in energy and excitement (Reference 6).

One study of adolescent migraines (n=1,932) revealed that pulsating and unilateral were the most commonly described characteristics of pain presentation (Reference 14). Nausea, phonophobia, and photophobia were experienced by more than 50% of the patients. Younger adolescents had slightly more nausea and vomiting; however, older adolescents described more phonophobia and photophobia. In 88% of the patients, the majority of attacks occurred during the day (from 6 AM to 6 PM) on Monday through Wednesday, and physical activity precipitated the migraine.

In migraine with aura, children have difficulty describing their aura, so again, drawing is a way to express their feelings (Reference 6). The aura occurs less than 30 minutes before the migraine, lasts for 5–20 minutes, and may differ for each migraine episode. Most children experience visual auras such as blurred vision, zig-zags, stars, or field defects. Auras may also be sensory-, language-, or motor-related in order of commonality (Reference 15).

### Diagnostic Criteria

In preparing to diagnose migraines or headaches in children, information regarding the headache is needed. Specific details include frequency, duration, severity, location on the head, symptoms, and impact of the headache. Box 1 lists example questions that practitioners should ask patients as well as caregivers because caregivers may not always be aware of all the child's symptoms. Practitioners will apply the details of this information to the IHS criteria to see whether the diagnostic criteria are met for migraine without aura. If criteria are not met, other types of migraines or headaches may be evaluated. A Pediatric Migraine Disability Assessment Score (PedMIDAS) or Pediatric Quality of Life Inventory (PedsQL) evaluation should

also be completed (References 16, 17). The PedMIDAS is used in children and adolescents and focuses on assessing potential disabilities, the need for prophylactic medication, and response to therapy (Reference 9). The PedsQL evaluation assesses quality of life in the child in a disease-independent manner (Reference 9). A headache pattern should be established by creating a headache calendar and/or diary. Having the patient mark which days a headache occurs, the time of onset, the duration, and the possible precipitating factors can be very helpful. Learning the headache pattern, if one exists, is beneficial for tailoring treatment.

General medical and neurologic examinations may be completed to rule out other presentations such as meningitis and the potential for brain tumors. Patients who present with a normal neurologic examination usually do not warrant neuroimaging (Reference 3). Patients with rapid increases in headache frequency, localized neurologic signs (tingling or numbness, or lack of coordination), or headaches that awaken the patient from sleep (even though 25% of headaches awaken a child) require additional neuroimaging for assistance with diagnosis (References 1, 6).

### Course and Prognosis of Disease

By age 25, 25% of adults who had migraines in childhood are migraine free (men more than women) (Reference 10). However, more than 50% of children will still experience headaches at age 50 years. Not all treatment

#### Box 1. History-taking questions for patients and caregivers with potential headaches.

- When did the headaches start?
- How long do the headaches last?
- How many school days have you missed?
- Does the headache occur in the summer?
- What was the longest period you were headache free?
- How many different types of headaches do you experience?
- Does the headache wake you up at night or start at awakening?
- Is the headache long-term but not restricting, or does it occur sometimes and prevent normal activities?
- What relieves the headache?
- What medications have you tried, how often, and did they work?

Modified from Reference 10. Fenichel GM. Headache. In: Clinical Pediatric Neurology, 5th ed. Philadelphia: Elsevier Saunders, 2005:77–89.

options will be effective in each child with migraines. Quality of life must always be evaluated in patients with migraines because this may be among the first signs that migraines are worsening (Reference 2). Children with migraines experience twice the amount of days lost from school as those without headaches (Reference 10). Regular monitoring of change in activities is imperative in children with migraines to evaluate for worsening of the disease state.

## TREATMENT

### Therapy Goals

The American Academy of Neurology (AAN) has set several treatment goals for patients with migraines (Reference 3). The AAN's recommended nonpharmacologic and pharmacologic treatment goals are as follows. (1) Reduce the frequency, severity, and disability of the attack. (2) Decrease patient reliance on poorly tolerated, ineffective, or undesirable short-term pharmacotherapies. (3) Improve the patient's quality of life. (4) Avoid short-term headache medication escalation. (5) Educate, and enable, patients to manage their disease to enhance personal control of their migraine. (6) Lessen headache-related distress and psychological symptoms.

Specifically for an acute attack, the AAN states that the treatment goals are as follows. (1) Treat attacks rapidly and consistently without recurrence. (2) Reestablish the patient's ability to function. (3) Reduce the use of backup and rescue medications. (4) Optimize self-care and decrease the use of subsequent resources. (5) Use therapies that are cost-effective for overall management of care. (6) Ensure that the patient experiences minimal or no adverse events (Reference 3). Rescue medication is defined by the AAN as a medication used at home when other treatment has failed that results in relief of the headache without medical consultation (Reference 3). To improve efficacy, short-term treatment should be administered promptly when a patient determines the onset of a migraine.

Whenever children are experiencing more than one headache per week, the headache is interfering with their activities, or the PedMIDAS score is above 30 showing moderate disability, migraine prophylaxis should be considered (References 9, 18). Other situations that may warrant the use of preventive drugs are when short-term treatment is contraindicated, when disability from migraine occurs despite short-term treatment, when the child is experiencing an uncommon type of migraine, or when the patient prefers such drugs (Reference 19). The goals of prophylactic treatment are to reduce headache frequency to one or two a month and to have the patient experience a decrease in disability (reduce the PedMIDAS score to less than 10 for a period, preferably 4–6 months) (Reference 9).

Migraine therapies can be divided into three areas: nonpharmacologic strategies, short-term treatment, and prophylactic measures.

### Nonpharmacologic Therapy

Nonpharmacologic strategies include behavioral therapies such as biofeedback, relaxation techniques, and stress management. Visual and audio biofeedback, such as visualizing a "happy" or relaxing place or telling yourself positive reinforcements, is used to gain physiologic effects. Children are also taught thermal biofeedback, in which they raise the temperature of one of their fingers to shorten a migraine headache. Controlled studies have found positive benefits in this type of therapy (Reference 9). Biofeedback and cognitive behavioral therapies that are designed for a child should be included in the treatment plan (Reference 18). Other therapies are sleep hygiene, regular exercise routines, and dietary modifications. Regular sleep, eating, and exercising regimens are recommended as part of the biobehavioral therapy (Reference 18). Disruptive sleep or a change in sleep patterns are beginning to be recognized in children as having a major impact on migraines. In children, dietary triggers that have been associated with migraines include chocolate, cheese, and citrus fruits (Reference 20). Other food precipitants include monosodium glutamate (a preservative used commonly in Chinese food), aspartame, processed meats, yogurt, and alcohol. If a food is found to be a trigger of migraines, it is recommended that the patient use avoidance techniques. Caffeine is also a culprit in migraine occurrence. In this case, migraines may be caused by caffeine withdrawal or its impact on sleep patterns. Meal skipping can also trigger migraines. This is common in many adolescents who skip breakfast. Strong scents such as perfumes or candles can also precipitate a migraine because smell is a sensory stimulus.

All patients with a diagnosis of migraines can potentially benefit from a nonpharmacologic therapy; however, behavioral and physical interventions are typically used for preventing migraine episodes rather than for alleviating acute symptoms of an attack. Optimal management of acute migraine attacks includes the use of both nonpharmacologic and pharmacologic therapies.

### Pharmacologic Therapy

#### *Nonprescription Medication*

##### *Acute Attacks*

Acetaminophen and ibuprofen are safe and effective for short-term migraine treatment in children, but the AAN provides a higher rating of recommendation for ibuprofen than for acetaminophen (Reference 5). Acetaminophen is typically dosed at 10–15 mg/kg per dose (maximum dose: 1000 mg) every 4–6 hours (not

to exceed five doses in 24 hours, or 3 g daily). For migraines, ibuprofen should be dosed at 7.5–10 mg/kg per dose (maximum dose: 800 mg) every 6–8 hours (maximum daily dose: 2,400 mg) (References 5, 9). Although few studies exist for either drug, ibuprofen has undergone more studies than acetaminophen (Reference 5). Many children experience excellent efficacy results with these nonprescription drugs alone and do not require the use of prescription drugs. No clinical trials regarding the use of other nonprescription drugs in migraines are available. Salicylates, although effective in adults, are usually avoided in children because of the risk of Reye syndrome.

### *Prophylaxis*

Herbal products (e.g., feverfew, butterbur root, coenzyme Q<sub>10</sub>, magnesium, riboflavin) have been proposed as beneficial for preventing migraines. Their specific mechanisms of actions are unknown; however, deficiencies in coenzyme Q<sub>10</sub>, magnesium, and riboflavin in patients with migraines have been shown (References 9, 18). Supplementation with butterbur or coenzyme Q<sub>10</sub> has shown a decrease in headache frequency in children (Reference 18). However, a recent double-blind, randomized, placebo-controlled, crossover trial of coenzyme Q<sub>10</sub> did not improve headache outcomes in 120 children (Reference 21). In studies, magnesium showed a lack of efficacy versus placebo for prophylaxis of migraines in children, and riboflavin has conflicting evidence regarding its ability to decrease migraine frequency. Feverfew has not been studied in children. Because trials with herbal products are limited, well-designed, larger studies are warranted. Studies evaluating the combination of herbal products are under way. It is important to remember that herbal products are not under the U.S. Food and Drug Administration (FDA) label approvals or regulations, and caution should be exercised if they are used.

### *Prescription Drugs*

#### *Acute Attacks*

The serotonin receptor agonists, or “triptans,” are the prescription medications primarily used for moderate to severe migraines or for migraines that do not respond to nonprescription drugs (Reference 19). They are selective for the serotonin 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors found on the intracranial blood vessels, central nervous system neurons, and trigeminal nerve endings (Reference 8). Administration of these agents results in vasoconstriction and decreased inflammation in the cranial arteries, inhibition of trigeminal neurons, and interceded transmission in the trigeminal nucleus. The 2004 treatment parameters for acute migraine attacks in children and adolescents stated that nasal sumatriptan

was effective and should be considered (Reference 5). Only sumatriptan, rizatriptan, and zolmitriptan were discussed in that guideline because data were limited or lacking at that time (Reference 5). Currently, six of the seven available triptans show efficacy and safety in children (Reference 22). Of the available triptan data, nasal sumatriptan, oral rizatriptan, orally dissolving and nasal zolmitriptan, and almotriptan have more positive efficacy studies than do others in the triptan class in children. Nasal formulations of sumatriptan and zolmitriptan have provided the strongest efficacy data. In several well-designed studies, oral formulations have not been shown to be better than placebo, but positive clinical data exist, and these dosage forms may be considered for treatment. Almotriptan is the first triptan to obtain an FDA indication in adolescents 12 years and older with migraines lasting 4 hours or more. This approval was based on two studies, one large clinical trial and one very small open-label pilot study, both of which showed tolerability and safety. Naratriptan and eletriptan lack sufficient data to recommend for first- or second-line use in a pediatric patient with migraines. Frovatriptan has only one pharmacokinetic study, limiting its use in the population. Pharmacokinetic data in children and adolescents are similar to those in adults. The triptan class should be considered a first-line short-term treatment option for pediatric patients with migraines who require prescription medication. Although almotriptan is the only FDA label-approved triptan in pediatrics at this time, other triptans may be used clinically, given the data presented in the primary literature. Specific drug selection may be influenced by the route of administration, matching the pharmacokinetics of the drug with patient symptoms (i.e., longer duration if migraines recur quickly), and the cost of the product. Dosing varies according to medication and dosage form (Table 1). Efficacy from clinical trials of the pediatric population was based on data using one dose; however, most triptan medications that are FDA label approved state that a repeat dose of triptan may be administered 2 hours after the first dose with a maximum of two doses per day. Specifics on maximal daily doses vary according to product. Combining a triptan with a nonprescription medication for migraine relief has not yet been evaluated in children. The combination product of sumatriptan and naproxen sodium is effective and safe in adolescents with migraines. Other combinations of prescription and nonprescription medications for migraine relief have not yet been assessed in pediatrics.

For migraines, the AAN recommends that butalbital- and opioid-containing drugs be limited and carefully monitored if used (Reference 19). Some practitioners avoid narcotics and butalbital products because they have not been formally studied in children or adolescents. They have also been associated with drug-overuse

**Table 1.** Medication Dosing for Migraines (References 18, 22)

Medication	Pediatric Dose Used in Clinical Studies	Maximum Dose per Day
Acetaminophen (Tylenol)	10–15 mg/kg/dose (maximum dose: 1000 mg)	Five doses per day or 3000 mg
Ibuprofen (Advil, Motrin)	7.5–10 mg/kg/dose (maximum dose: 800 mg)	2400 mg
Sumatriptan (Imitrex/Alsuma/Sumavel)	Nasal: 5–18 years: 5 mg or 20 mg Subcutaneous: 6–18 years: 3–6 mg Oral: 8–17 years: 25–100 mg	40 mg 12 mg 200 mg
Rizatriptan (Maxalt/Maxalt MLT)	Oral tablet: 20–39 kg: 5 mg; > 40 kg: 10 mg Oral disintegrating: 12–17 years: 5 mg	30 mg <sup>a</sup>
Zolmitriptan (Zomig)	Oral: 12–17 years: 2.5 mg, 5 mg, 10 mg Oral disintegrating: adult: 2.5 mg Nasal: 12–17 years: 5 mg	10 mg
Naratriptan (Amerge)	Oral: 12–17 years: 0.25 mg, 1 mg, 2.5 mg	5 mg
Almotriptan (Axert)	Oral: 12–17 years: 6.25–12.5 mg <sup>b</sup>	25 mg
Eletriptan (Relpax)	Oral: 12–17 years: 40 mg	80 mg
Frovatriptan (Frova)	Oral: 12–17 years: 2.5 mg <sup>c</sup>	7.5 mg
Sumatriptan/naproxen (Treximet)	Oral: Adult: sumatriptan 85 mg and naproxen 500 mg (1 tablet)	2 tablets

<sup>a</sup>5 mg daily maximum if on propranolol<sup>b</sup>FDA approved for 12–17 years<sup>c</sup>No efficacy studies in pediatrics

headaches and withdrawal; thus, practitioners have limited their use (Reference 8). Adolescents with menstrual-related migraines can benefit from oral contraceptives or progesterone depot injections. An initial case series reported symptom benefit in six female adolescents who were administered botulinum toxin type A for migraines, but adverse effects such as burning sensations at injection sites, blurred vision, and mild ptosis did occur (Reference 23). Additional studies regarding the use of this drug in children with migraines are warranted.

Antiemetics are also used for migraine symptoms. It is believed that antiemetics with dopaminergic mechanisms (prochlorperazine, promethazine, and metoclopramide) may treat the underlying pathophysiology as well, not just the associated nausea or vomiting. One retrospective review of intravenous prochlorperazine found only a 14% failure rate in children with severe migraines in the ED setting (Reference 24). All patients were administered diphenhydramine to prevent akathisia. Caution must be used with promethazine because it has a warning of respiratory depression in children (contraindicated in children younger than 2 years) and may cause extrapyramidal adverse effects. Metoclopramide also can cause extrapyramidal symptoms. Ondansetron,

a serotonin (5-HT<sub>3</sub>) receptor antagonist, has become a popular antiemetic in children because of its safer adverse effect profile versus the phenothiazine derivatives. Ondansetron is available as an oral disintegrating tablet or as soluble film, and it may be administered intravenously when nausea or vomiting is a concern. Efficacy trials of pediatric migraine headaches with ondansetron are unavailable.

During acute attacks, alternative routes of medication (e.g., subcutaneous, intranasal, rectal) should be used when migraines are associated with severe nausea or vomiting in the patient (Reference 3). Counseling on short-term therapies is important, regardless of the specific drug prescribed. First, all patients should take the drug as soon as possible after the first symptom or when the headache begins. Next, using the drug appropriately (e.g., correct dose and interval) is important to reduce the potential of overuse or adverse effects. Finally, the patient should keep the drug available in a location where he or she usually has headaches. This may be at school, after-school day care, or work. Short-term treatment should not be used for more than three headaches per week (Reference 18).

Some patients with migraines will seek treatment in the ED because of failed home management. The antidopaminergic drugs as well as intravenous ketorolac have shown benefit in the ED setting (Reference 18). Prochlorperazine has shown superiority to ketorolac in a head-to-head study of children 5–18 years old in the ED setting (Reference 25). Combining these two drug classes has resulted in increased efficacy (Reference 18). About 6% to 7% of patients with migraines do not obtain relief from medications in the ED, so they are admitted to an inpatient service for migraines (Reference 18). A migraine that is a debilitating attack lasting more than 72 hours is termed *status migrainosus* (Reference 12). This type of migraine is severe in intensity and is usually treated in the inpatient setting (References 12, 18). Intravenous dihydroergotamine (DHE) may be used in a low- or high-dose protocol to stop an intractable migraine. Administered every 8 hours until the headache ceases or until the maximal dose (15 mg) is reached, DHE was found to be 97% effective in headache improvement and 77% effective in headache relief

in a small study of 32 children and adolescents (Reference 26). Intravenous valproic acid has also been used for this type of migraine. These are not FDA label-approved uses in children, but case reports and open-label studies have shown benefit (Reference 18).

### Prophylaxis

Most children do not require prophylactic medications for migraines. Currently, none of the drugs marketed in the United States are FDA label approved for prophylaxis use in children. In Europe, flunarizine, a calcium channel blocker, is approved because of several studies showing its efficacy (Reference 18). The AAN also supports the use of flunarizine, but availability limits its use (Reference 5). Current treatment options for prophylaxis in children include cyproheptadine, amitriptyline, propranolol, valproic acid, and topiramate (Table 2). Cyproheptadine has antiserotonergic effects and may have calcium antagonistic characteristics (Reference 18). One study has shown it to be comparable to

**Table 2.** Medications Used for Migraine Prophylaxis (References 18, 27)

Drug	Dose	Maximum Dose per Day	Contraindications/ Boxed Warnings	Drug Interactions
Antihistamine Cyproheptadine	0.25–1.5 mg/kg or 4–8 mg TID	24 mg	MAO inhibitors, acute asthma attack, GI tract obstructions, stenosing peptic ulcer	Decrease effects of SSRIs; enhance CNS depressant effects
Antidepressant Amitriptyline	10–50 mg daily at bedtime		MAO inhibitors; U.S. boxed warning: worsening of depression or suicidal ideations in children with depression	Major 2D6 and minor 1A2, 2B6, 2C19, 2C9, 3A4 substrate; weak inhibitor of 1A2, 2C19, 2C9, 2D6, and 2E1
$\beta$ -Blocker Propranolol	2–4 mg/kg/day or 10–40 mg TID	4 mg/kg/day or 120 mg	Asthma, hyperactive lung disease, sinus bradycardia, heart block greater than first degree, sick sinus syndrome	Major 1A2, 2D6 and minor 2C19, 3A4 substrate; weak inhibitor of 1A2, 2D6, P-glycoprotein
Anticonvulsants Valproic acid (VPA)	20–40 mg/kg/day	1000 mg	VPA: Liver disease or dysfunction, U.S. boxed warnings: hepatic failure (children < 2 years at greatest risk), pancreatitis	VPA: Minor 2A6, 2B6, 2C9, 2C19, 2E1 substrate. Weak inhibitor of 2C9, 2C19, 2D6, 3A4. Weak inducer of 2A6.
Topiramate (TOP)	1–10 mg/kg/day (usual 50 mg BID)	200 mg	TOP: None	TOP: Weak inhibitor of 2C19; weak to moderate inducer of 3A4

BID = two times/day; CNS = central nervous system; GI = gastrointestinal; MAO = monoamine oxidase; SSRI = selective serotonin reuptake inhibitor; TID = three times/day.

amitriptyline and propranolol. Amitriptyline has been used in children since the early 1980s, but dosing has varied (Reference 18). Propranolol has shown mixed results in its efficacy of preventing migraines (Reference 5). Both valproic acid and topiramate are effective in decreasing migraine severity, duration, frequency, and PedMIDAS scores (Reference 18). However, studies also exist showing no difference from placebo (Reference 28). Yet these two anticonvulsants have been studied the most regarding migraine prophylaxis in children. Very small, uncontrolled studies of levetiracetam and zonisamide have shown a decrease in migraine frequency, but larger studies are warranted before recommending their use (Reference 28).

When selecting preventive therapy, consider the patient's comorbid disease states and potential drug interactions. For example, although  $\beta$ -blockers may be considered in children with anxiety, they should be avoided in patients with asthma or diabetes. Valproic acid or topiramate may be considered in a child with epilepsy or bipolar disorder. Drug interactions between short-term and prophylactic therapy should be evaluated, as should interactions with the patient's long-term medications. Propranolol is a major substrate of cytochrome P450 (CYP) 1A2 and CYP2D6 and weakly inhibits CYP1A2 and CYP2D6 as well as P-glycoprotein. Valproic acid also is known for drug interactions within the CYP system. All medications should be initiated at a low dose and titrated to response while monitoring for adverse effects.

## MONITORING OF THERAPY

### Therapeutic Outcomes

The treatment goals of the AAN should continue to be evaluated on follow-up with patients. Quality of life and impact on activities should be monitored for improvement. All medications used for acute attacks have a potential risk of causing rebound of the headache, and children with migraines have a higher risk of developing analgesic overuse headaches (Reference 18). Patients, in general, should not be using pharmacologic treatments more than three times/week. If so, this may be a predictor that prophylaxis therapy is warranted. Prophylaxis should be initiated for a specific period. If headaches are controlled at 6 months of treatment, discontinue or taper the drug (Reference 19). Weaning during summertime may be done to see how school-aged children are doing with respect to migraine frequency. Some patients, however, may need long-term prophylaxis for longer periods.

## Toxicity

In general, treatment options for an acute migraine attacks are tolerated well. Ibuprofen and acetaminophen are commonly used for other indications, and most patients have previous experience with these drugs. The triptan class has been evaluated for safety in children, and adverse effects are similar to those seen in the adult population. Chest tightness, jaw tightness, or asthenia may be described by the child, but they are self-limiting (Reference 18). Taste disturbances are reported with nasal formulations, and injection site reactions are seen with subcutaneous injections (Reference 22). Serotonin syndrome is also a concern with triptan use. Educating patients regarding signs and symptoms is important so that they are aware of this possibility. The pharmacist should also evaluate the patient's medication profile for potential drug interactions. Contraindications for all triptans include ischemic heart disease, uncontrolled hypertension, basilar or hemiplegic migraine, and administration within 24 hours of ergotamine derivatives or other serotonin agonists. Most triptan studies in the pediatric population excluded patients with congenital heart disease and other cerebral vascular diseases, so caution is warranted in those patients. Adverse effects of DHE include nausea and vomiting (prophylaxis medications are administered in the DHE protocols), chest tightness, hives, facial flushing, and increased blood pressure (Reference 26). Ergotamines should not be used during pregnancy.

Adverse effects with prophylactic medications vary according to product. In general, concerns with weight gain exist with cyproheptadine and valproic acid. Drowsiness occurs with cyproheptadine and amitriptyline. Fatigue is associated with propranolol, and  $\beta$ -blockers should be avoided in patients with asthma, depression, or diabetes. Topiramate causes cognitive changes such as impaired concentration, emotional instability, and paresthesia. Adverse effects must be monitored to ensure that quality of life is not decreasing because of the preventive drug.

## FUTURE THERAPIES

Future treatment options tend to be focused on the trigeminovascular system. Currently, oral calcitonin gene-related peptide receptor antagonists and glutamate receptor inhibitors are being evaluated for migraine treatment and prophylaxis, respectively. Several drugs are being studied for new formulations or devices to administer the drug in needle-free devices, patches, or inhaled forms. After showing efficacy, these drugs will likely gain approval for use in the adult population first. It is unknown whether pediatric approval will be

sought. Several triptans are currently under investigation for their effectiveness in children (Reference 29). A few trials are also investigating topiramate for use in preventing migraines in children 12 years and older.

## CONCLUSIONS

Migraines occur commonly in the pediatric population. They can be debilitating and affect the school, social, and home life of a child. Appropriate diagnosis and close follow-up with monitoring are recommended for all patients. Nonpharmacologic and pharmacologic therapies should be used in children with a diagnosis of migraines to improve symptoms and increase quality of life. Biofeedback, relaxation techniques, and stress management are nonpharmacologic therapies to consider in children with migraines. Ibuprofen or acetaminophen is an appropriate first-line short-term nonprescription treatment option, with the triptan class considered a first-line prescription treatment option for children and adolescents. Several medications (e.g., propranolol, amitriptyline, valproic acid, topiramate) have been used for prophylaxis therapy in children. The understanding of this disease state, assessment, and treatment will continue to change as they are further studied. Migraine management will continue to expand as evidence is discovered regarding new short-term and preventive drugs as well as nonpharmacologic strategies.

# CHAPTER 28

## AUTISM SPECTRUM DISORDERS

Jose A. Rey, Pharm.D., M.S., BCPP

### LEARNING OBJECTIVES

1. Explain the clinical presentation and diagnostic criteria for autism spectrum disorder (ASD).
2. Discuss the application and efficacy of pharmacotherapeutic interventions for symptom-specific treatment and the limitations of pharmacotherapy in ASD.
3. Recommend and monitor pharmacotherapy for ASD for therapeutic outcomes and adverse drug effects, together with considerations of possible comorbid conditions.

### ABBREVIATIONS IN THIS CHAPTER

ABC-I	Aberrant Behavior Checklist— Irritability subscale
ADHD	Attention-deficit/hyperactivity disorder
ASD	Autism spectrum disorder
CARS	Childhood Autism Rating Scale
CGI	Clinical Global Impression Scale
DSM	Diagnostic and Statistical Manual for Mental Disorders
EPS	Extrapyramidal symptoms
IDEA	Individuals with Disabilities Education Act
OCD	Obsessive-compulsive disorder
PANDAS	Pediatric autoimmune neuro- psychiatric disorders associated with streptococcal infection
PDD	Pervasive developmental disorder
PDD-NOS	Pervasive developmental disorder— not otherwise specified
SSRI	Selective serotonin reuptake inhibitor

### INTRODUCTION

Pervasive developmental disorders (PDDs) often present considerable problems and challenges for patients, families, caregivers, and health care providers. The five PDDs recognized in the *Diagnostic and Statistical Manual for Mental Disorders (DSM-IV-TR)* are Asperger's disorder, autistic disorder, childhood disintegrative disorder, Rett's disorder, and pervasive developmental disorder-not

otherwise specified (PDD-NOS) (Reference 1). Autism spectrum disorders (ASDs) are a subset of PDDs that include autistic disorder, Asperger's disorder, and PDD-NOS (see Figure 1). This chapter will focus on autistic disorder as the predominant ASD.

In 1943, Dr. Kanner described children who withdrew, disregarded people, avoided eye contact, lacked social awareness, had limited language, displayed stereotyped motor movements, and showed a preservation of sameness as having a disorder called early infantile autism (References 2, 3). At the time, Dr. Kanner proposed that autism resulted from an inborn inability to form loving relationships with other people and described the parents of these children as cold and detached. Today, although the general behavioral description of the disorder has not changed significantly, the proposed causes of autism are now believed to be more neurobiologic in etiology, though they are still not definitively known (Reference 3).

The most significant clinical features of a child with an ASD often include qualitative impairments in the major domains of (1) social interaction or reciprocity, (2) communication and language, and (3) repetitive, restricted, or stereotypic behaviors. Other problematic and maladaptive behaviors that may prompt the use of pharmacotherapy include irritability, tantrums, aggression, and attention-deficit/hyperactivity symptoms (Reference 1).

### EPIDEMIOLOGY

The prevalence of ASDs has been a matter of debate in recent years. Some estimate the numbers to be 1 or 2 per 1000, whereas other reports estimate the prevalence to be as high as 1 or 2 per 100 (References 4–12). The average is reported to be 6 or 7 per 1000 children for the three ASDs combined (Reference 8). It is thought that the increased prevalence of ASDs is because of the increase in awareness through media coverage and the application of diagnostic criteria (Reference 8). Criteria for infantile autism were provided in the *DSM-III*, but the criteria have changed through the years, which may have affected how the disorder is identified. Another event that may have affected the diagnosis rate of ASDs is the passage of the Individuals with Disabilities Education Act (IDEA) in 1990 (Reference 8). With

IDEA, services could be billed for ASDs. Until IDEA was passed, autistic disorder did not become a diagnosis in which children became eligible to receive special education services (Reference 8).

The reported ratio of males to females with ASDs in the United States is approximately 4.5:1 (References 5, 8). There may be racial differences in prevalence, with non-Hispanic white children identified more often than non-Hispanic black children or Hispanic children (References 5, 13). The gender, racial, and ethnic differences may be culturally based, with less reporting in certain groups. Other countries may also have differences in prevalence because of the reporting of neuropsychiatric disorders or limited diagnostic and treatment resources. No evidence exists for a socioeconomic boundary, with similar rates across social status and cultures (Reference 8). Children having siblings with an ASD also have a higher likelihood of receiving a diagnosis of an ASD, with the risk being approximately 10-fold (References 8, 14–18).

### ETIOLOGY AND PATHOPHYSIOLOGY

The etiology of ASDs is unknown. The earliest proposed cause of autistic disorder—dysfunctional attachment as a result of parenting style—is no longer accepted. Today, the ASDs are thought to have a heterogeneous etiology that is neurobiologically based with a complex genetic, and therefore possibly heritable, component. Genetic mutations are being evaluated in research, but no specific causes have been identified (References 8, 14–21). The discovery of copy number variations, and the clinical and behavioral similarities of ASDs to other syndromes with recognized genetic deletions or mutations reinforce the proposed genetic abnormalities that may underlie ASDs (References 8, 19, 20). Syndromes such as fragile X syndrome (gene = *FMR1*), Angelman

syndrome (gene = *UBE3A*), and *Tuberous sclerosis* (genes = *TSC1* and *TSC2*) are examples of syndromes with recognized genetic mutations that also have behaviors similar to ASDs (References 8, 17, 22).

Determining the biochemical markers for the ASDs (e.g., abnormal neurotransmitter levels) in both the periphery and central cerebrospinal fluid has been extensively researched; however, data are inconclusive. A dysfunction in serotonin has the strongest support for explaining the behaviors associated with ASDs, though evidence is inconclusive (References 23–25). Earlier hypotheses that endogenous opioids or norepinephrine was implicated in the pathology of ASDs are not consistently supported (Reference 24). Dopamine dysfunction is still a target of research, given the efficacy of the antipsychotics, with both older and newer atypical agents demonstrating the ability to reduce ASD symptoms (References 23, 24). Various hormones and neuropeptides (e.g., cortisol, oxytocin, vasopressin) have also been suggested as factors in the etiology of ASDs; however, these hypotheses have minimal support (References 8, 23, 25).

Claims put forth in the early 1990s—subsequently determined to have been based on fraudulent data (and retracted by the publisher of the data, *The Lancet*)—that vaccinations were related to the development of autistic disorder have been disproved by several investigations (References 8, 26–30). Despite the evidence that vaccinations do not contribute to ASD, many parents continue to believe that vaccinations caused their child to develop ASD (References 30, 31). One hypothesis for the relationship between vaccines and ASDs was that some vaccines contained thimerosal as a preservative; however, this compound has been removed, or greatly reduced to only trace amounts, from most vaccine products. Although this action by the pharmaceutical industry took place about 10 years ago, ASD rates have not decreased since then, supporting the lack of relationship

between thimerosal exposure and ASD (References 30, 32). Exposure to heavy metals such as lead and mercury remains a potential causal factor in some cases of neurodevelopmental deficits (References 8, 33). Abnormal immune responses have also been proposed to be related to ASDs. This theory may still be connected to vaccine exposure as a form of immune system activation, though further research is needed in this area before accepting the existence of a connection between vaccinations or infections and abnormal immune responses leading to ASD (References 8, 34, 35).

Neuroimaging studies indicate the involvement, and possible dysfunction, of various areas of the brain, including the cortical, subcortical, and limbic regions, which may reflect early pathology (References 8, 36–40). Increased head circumference in early years (accelerated growth in the first year) will approach normal to below normal after childhood (deceleration) (Reference 39). Together with increased head size in 20% to 30% of children with ASDs, imaging reveals a general increased brain volume (References 8, 36–39). Certain neuronal cells (e.g., Purkinje cells in the cerebellum, forebrain cells, frontal and temporal lobe cortical mini-column cells, and cells in the area of Broca) are smaller (References 8, 37–39). Brainstem abnormalities have also been observed (References 38, 39). One explanation for the impairments in empathy, imitation, and language could be a dysfunction in mirror neurons (Reference 40).

Other proposed risk factors for ASD include maternal and fetal exposure to teratogenic medications, selective serotonin reuptake inhibitor (SSRI) antidepressants, neurotoxins, smoking, alcohol, infection, and prenatal malnutrition (References 8, 25, 33, 41, 42). These environmental factors may act as modulators to the expression of preexisting genetic factors. Older parents (older than 35–40 years) have a higher risk of having children with ASDs, which may be related to spontaneous genetic mutations, such as a copy number variant related to age (References 43–45).

## CLINICAL PRESENTATION AND DIAGNOSIS

The signs of ASDs are generally present before 3 years of age. The American Academy of Neurology and the Child Neurology Society suggest being aware of the following “red flags,” which are indicators to evaluate further and immediately for ASDs (Reference 46):

- No babbling, pointing, or other gesture by 12 months
- No single words by 16 months
- No two-word spontaneous (not echolalic) phrases by 24 months
- Loss of language or social skills at any age

The three core domains in most ASDs are social interaction, communication, and stereotypic or repetitive behaviors. The diagnosis of autistic disorder requires the presence of qualitative impairments and deficits in (1) two or more aspects of social interaction and reciprocity, (2) one or more aspects of communication and language use and development, and (3) the presence of one or more behaviors demonstrating restricted, repetitive, and stereotyped patterns, such as rocking, hand flapping when excited, bizarre gestures (hands to ears), or posturing, which are considered purposeless, though may actually be attempts to self-stimulate or avoid aversive stimuli. Children with Asperger’s disorder often present with impairments in only social interaction and repetitive, restrictive, or stereotypic behaviors, while language skills remain unimpaired (References 1, 8). The *DSM-IV-TR* criteria for autistic disorder are provided in Box 1. The *DSM-IV-TR* criteria, for a comparison to Asperger’s disorder, are provided in Box 2. Children not meeting the specific criteria for either autistic disorder or Asperger’s disorder because they have an atypical presentation or lack enough symptoms can be given the PDD-NOS diagnosis if other conditions have been ruled out (References 1, 8, 46).

Cognitive deficits that may qualify as mental retardation (IQ of 70 or less) are often present in children with ASDs (References 1, 8). Also seen commonly in this population are EEG (electroencephalogram) abnormalities and epilepsy (Reference 47). Many children with ASDs also present with comorbidities or associated symptoms of attention-deficit/hyperactivity disorder (ADHD), anxiety, and depression, together with the co-occurring maladaptive behaviors and symptoms of aggression, irritability, tantrums, poor impulse control, and self-injurious behavior (References 1–3, 8, 46). A clinical syndrome that requires more research into etiology and treatment and that may be rarely encountered with some clinical presentations similar to ASD is the group of Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal infections (PANDAS), in which the child may demonstrate new-onset stereotypic or ritualistic and obsessive-compulsive behaviors. However, PANDAS can reverse with time and antibiotic treatment whereas ASD does not (References 48, 49).

Some children with ASD may present with gastrointestinal problems such as constipation or diarrhea, whereas others may have difficulties with sleep patterns. Appropriate evaluation of these problems is recommended to rule out other reversible causes of the aforementioned problems, and appropriate symptomatic management is recommended. The clinician should also consider that the patient’s behavioral changes may be secondary to disturbances in sleep or gastrointestinal distress (Reference 50). Although pharmacotherapy is

### Box 1. Diagnostic criteria for autistic disorder.

- A. A total of six (or more) items from (1), (2), and (3), with at least two from (1), and one each from (2) and (3):
1. qualitative impairment in social interaction, as manifested by at least two of the following:
    - a. marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
    - b. failure to develop peer relationships appropriate to developmental level
    - c. a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest)
    - d. lack of social or emotional reciprocity
  2. qualitative impairments in communication as manifested by at least one of the following:
    - a. delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime)
    - b. in individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others
    - c. stereotyped and repetitive use of language or idiosyncratic language
    - d. lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level
  3. restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:
    - a. encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus
    - b. apparently inflexible adherence to specific, nonfunctional routines or rituals
    - c. stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements)
    - d. persistent preoccupation with parts of objects
- B. Delays or abnormal functioning in at least one of the following areas, with onset prior to age 3 years: (1) social interaction, (2) language as used in social communication, or (3) symbolic or imaginative play
- C. The disturbance is not better accounted for by Rett's disorder or childhood disintegrative disorder.

sometimes used for the gastrointestinal or sleep disturbances in ASD, these issues should be addressed and treated according to recommended pediatric guidelines for such symptoms. Some of the psychotropic medications selected for disturbed behaviors in this population will carry the adverse effects of sleep disturbances (sedation or insomnia) and gastrointestinal disturbances (constipation or diarrhea), and these issues should be considered during pharmacotherapy selection and monitoring.

### Box 2. Diagnostic criteria for Asperger's disorder.

- A. Qualitative impairment in social interaction, as manifested by at least two of the following:
1. marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
  2. failure to develop peer relationships appropriate to developmental level
  3. a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest to other people)
  4. lack of social or emotional reciprocity
- B. Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:
1. encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus
  2. apparently inflexible adherence to specific, nonfunctional routines or rituals
  3. stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements)
  4. persistent preoccupation with parts of objects
- C. The disturbance causes clinically significant impairment in social, occupational, or other important areas of functioning.
- D. There is no clinically significant general delay in language (e.g., single words used by age 2 years, communicative phrases used by age 3 years).
- E. There is no clinically significant delay in cognitive development or in the development of age-appropriate self-help skills, adaptive behavior (other than in social interaction), and curiosity about the environment in childhood.
- F. Criteria are not met for another specific pervasive developmental disorder or schizophrenia.

Evaluations to aid in diagnosing ASDs include neuropsychological, medical, speech-language, audiological, neurologic, and laboratory analysis to rule out other, better-explained diagnoses and environmental factors such as heavy metal exposure (e.g., lead) (References 1, 8, 46).

## TREATMENT

### Treatment Goals

The goal of treatment for any ASD is not to cure or prevent. Pharmacologic treatment strategies target a core aspect of the ASD (e.g., a disruptive behavior) that is interfering with the individual's ability to participate in

other treatments designed to achieve maximum functional ability. For example, if a child with ASD is verbally and physically aggressive toward the occupational or speech-language therapist, progress is impeded until the aggression is addressed. These disruptive, or even dangerous, behaviors may also be placing them at risk of harming themselves or others. When a child with ASD demonstrates disruptive, irritable, aggressive, or agitated behaviors that do not respond to nonpharmacologic behavioral interventions, targeted pharmacotherapy may be warranted (Figure 2) (References 50, 51). A clinically meaningful reduction in the problematic behaviors of irritability, aggression, and self-injury is the desired

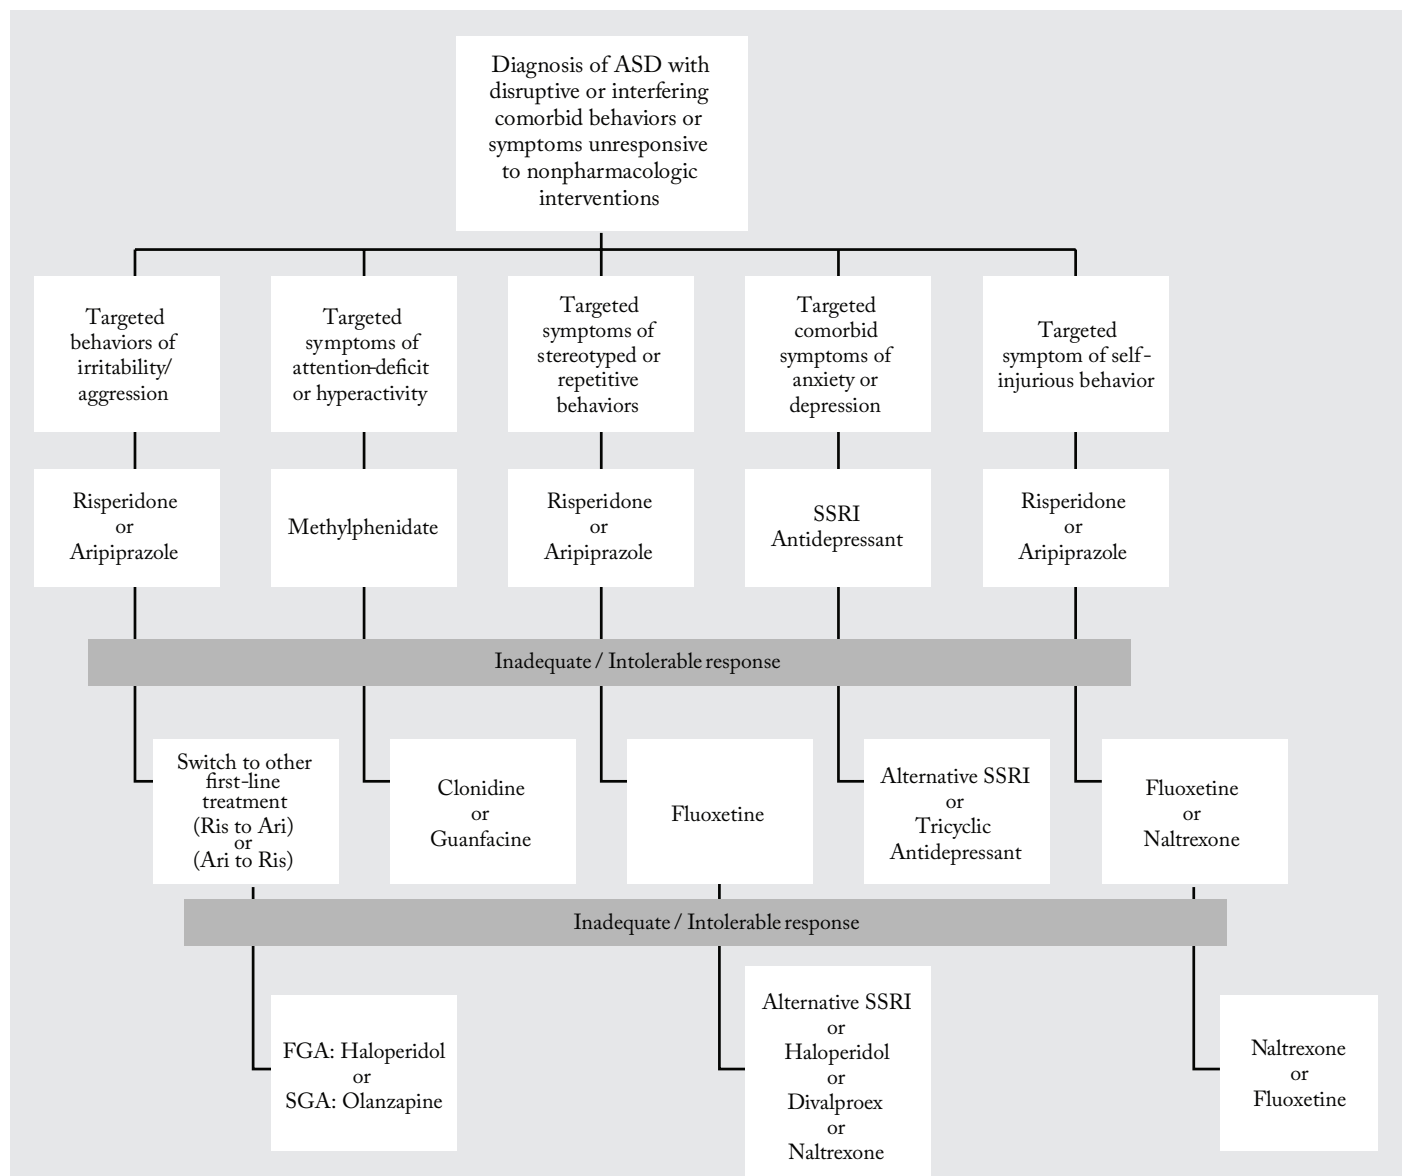

Figure 2. Pharmacologic treatment algorithm for ASD.

ARI = Aripiprazole; ASD = autism spectrum disorder; FGA = first-generation antipsychotic; RIS = Risperidone; SGA = second-generation antipsychotic; SSRI = selective serotonin reuptake inhibitor.

outcome so that the individual can then engage in the nonpharmacologic treatments intended to improve his or her overall functioning in all the affected domains and identified deficits (Reference 50).

### Nonpharmacologic Treatments for ASD

Nonpharmacologic treatments for ASD should be implemented in a coordinated manner before pharmacologic treatment (Reference 50). Therapies that may be beneficial in the management of a child with ASD include occupational therapy, physical therapy, educational interventions, behavioral therapy (e.g., applied behavior analysis), speech-language therapy, and possibly diet modification in those who are responsive to such an intervention (References 52–54). Common dietary changes include reducing or eliminating dairy protein intake (casein-free) and certain protein-containing cereals (gluten-free) (Reference 53). Dietary modifications in research provide inconsistent results; however, many parents of children with ASD will attempt this intervention, with mixed outcomes, before more costly or medically warranted interventions. Given the case-based lay and medical literature of benefit and the mixed results of dietary modification in formal research studies, this practice of dietary modification continues, and if it successfully reduces some of the problematic behaviors or symptoms in a particular child with ASD so that the child may engage in other treatments, it also then serves to empower and offer a level of control by the family and caregivers regarding the child's total treatment.

Approximately 50% of parents of children with ASDs use complementary and alternative treatments, despite the lack of evidence for their efficacy. Such treatments include the use of dietary supplements (e.g., vitamins B and C, omega-3 fatty acids, magnesium, melatonin), acupuncture, sensory integration, and aromatherapy (References 50, 54, 55).

### Pharmacotherapy of ASD

Pharmacotherapy is best used to allow the child to better engage in his or her treatment plans such as speech-language plans, occupational therapy plans, or those that are educationally, behaviorally, or socially oriented for maximum benefit to the child with an ASD. The impairments in social interaction and communication are generally unresponsive to pharmacotherapy. Even maladaptive behavioral problems should be managed without medications, if possible, with psychotropic medications being reserved for moderate to severe problems with specific behaviors such as irritability and aggression (References 50, 56, 57). Pharmacotherapeutic interventions may also be used for a comorbid symptom of the disorder such as inattention, hyperactivity, or repetitive/stereotypic behaviors that are also interfering with the child's overall

treatment plan and that are not responding adequately to the nonpharmacologic interventions. Medical treatment of comorbid diagnoses such as epilepsy, gastrointestinal problems, or sleep disorders may also be required in many children with ASD (Reference 50).

Steps to determine the need for, and implementation of, pharmacotherapy for ASD should include the following (adapted and modified from References 50, 51):

- Identify and perform a baseline assessment of target behaviors through multiple sources (e.g., parents, teachers), together with factors and triggers modifying the behaviors.
- Assess the degree of interference with functioning and consider using rating scales and clinical judgment (by the clinician) to establish baseline functioning both before the intervention and at follow-up to determine positive and negative outcomes.
- Determine the efficacy achieved with behavioral interventions and other psychosocial supports and education.
- Identify potential medical factors through physical assessment and testing that may be causing or exacerbating the target behavior(s) (e.g., pain, gastrointestinal discomfort, sleep disorders, menstruation).
- Consider psychotropic medication given the evidence that the target symptoms are interfering with learning/academic progress, socialization, and health/safety (self and others) or the patient's quality of life and that there was a suboptimal response to nonpharmacologic interventions.
- Choose a medication on the basis of known efficacy for the specific target symptoms, its potential adverse effects, formulations available, dosing schedule, and need for laboratory or other monitoring (e.g., electrocardiographic).
- Acquire informed consent from the parent/guardian and, when possible, from the patient.
- Establish a plan for monitoring and following up all treatment outcomes and the desired or expected timeframe for such outcomes, including laboratory and physical monitoring for changes in weight, glucose, lipids, and other potential laboratory values affected by the chosen medication.
- If outcomes are less than desired or expected, and adequate dosing and length of treatment was achieved, then consider alternative treatment options, including switching to another agent or augmentation with a different medication.

**Table 1.** Pharmacotherapy Options for ASD

Medication	Target Symptoms with Level of Evidence <sup>a</sup>						
	Social Interaction	Core Domains			Associated Behaviors		
		C/L	S/RB	Irritability/Aggression	Attention	Hyperactivity	SIB
<b>Antipsychotics</b>							
Risperidone	B		A	A	B	B	B/C
Aripiprazole			A	A	B	B	B/C
Haloperidol	C		C	A		B	
Olanzapine				B			
Quetiapine				C			
Ziprasidone				C			
<b>SSRIs</b>							
Fluoxetine			B				C
Fluvoxamine			D				D
Citalopram			D				D
Clomipramine			C	C/D			C/D
<b>α1-RAs</b>							
Clonidine			C/D	C		C	
Guanfacine			C/D	C		C	
<b>Psychostimulants</b>							
Amphetamine				F		F	
Methylphenidate					C	B	
<b>Others</b>							
Naltrexone	C/D		B/C	C		C	C
Divalproex			B/C				
Atomoxetine						B	

<sup>a</sup>A = Multiple DBPC studies with positive efficacy; B = one DBPC study (moderate to large N); with positive efficacy (or two small N studies); C = open-label studies with positive efficacy; D = questionable efficacy with limiting ADRs/positive efficacy through case reports/series; F = negative efficacy studies with problematic ADRs.

ADR = adverse drug event; ASD = autism spectrum disorder; C/L = communication/language impairments; DBPC = double-blind, placebo-controlled (study); RA = receptor agonist; SIB = self-injurious behavior; S/RB = stereotypy/repetitive behaviors; SSRI = selective serotonin reuptake inhibitor.

- If the patient has responded favorably for the past 6–12 months, consider tapering and discontinuing treatment to reassess the need for pharmacotherapy.

The pharmacologic management of children with ASDs includes many medications that are indicated for other disorders and are not U.S. Food and Drug Administration (FDA) approved for autistic disorder or any other PDD (see Table 1). Only two antipsychotics are FDA approved with established efficacy and safety for irritability associated with autistic disorder (References 58–69). Research indicates that most

subjects receiving pharmacotherapy for irritability can have some clinically recognized improvement. However, because a target symptom may be similar to symptoms encountered in other disorders for which these agents have established efficacy, or that are co-occurring because of another diagnosed disorder, the use of certain medications (e.g., SSRIs, psychostimulants) is accepted practice. Published research also supports the use of certain medications for targeted symptom management. These behaviors or symptoms may include repetitive or stereotyped behaviors that resemble the symptoms of obsessions and compulsions and therefore may respond to the medications approved for obsessive-compulsive

disorder (OCD), such as some of the SSRIs (References 70, 71). Symptoms of inattention and hyperactivity may respond to prescribed psychostimulant medications, though these agents may exacerbate irritability and agitation (Reference 72). In addition, other agents used in attention-deficit disorder and ADHD (e.g., clonidine, guanfacine) may be beneficial for certain targeted symptoms such as hyperactivity and aggression (References 73–76).

The use of various medications for ASD management has been increasing during the past 2 decades. A 1995 study indicated approximately 30% of children with ASD were receiving a psychotropic medication. More recently, a study of children with ASD in a Medicaid population sample indicated that up to 56% of the children with ASD were receiving at least one psychotropic medication, and 20% of the children were receiving three or more medications concurrently. Antipsychotic medications were reported as the most commonly prescribed class of psychotropics in this population, with antidepressants and psychostimulants being the second and third most commonly used, respectively (References 77–79).

### *Antipsychotics*

Historically, first-generation antipsychotics have been used in the management of maladaptive behaviors associated with ASD. Although not approved for treating ASD, haloperidol was the most commonly used and studied agent before the atypical antipsychotics were developed. And although haloperidol has been shown to be efficacious in treating the irritability, aggression, and even stereotypes associated with ASD in several small studies, its risk of extrapyramidal adverse effects such as dystonias, tremors, and the potentially irreversible tardive dyskinesia significantly limits its use today (References 80–85). In 40 autistic children 2–7 years of age, haloperidol was effective in reducing behavioral symptoms and producing general clinical improvement (Reference 80). Based on published research, the optimal dose may be no more than 1–2 mg/day. In addition to extrapyramidal symptoms (EPS), other adverse effects including increased appetite, weight gain, and sedation may also limit its use in this population. Sustained and higher-than-average prolactin levels secondary to antipsychotic use may have untoward effects on development in both females and males (References 60, 86). Clinically, manifestations of high prolactin levels can include gynecomastia, galactorrhea, amenorrhea, and possibly osteoporosis; thus, monitoring for these adverse effects is warranted.

In 2006, risperidone became the first FDA-approved medication for the treatment of irritability associated with autistic disorder in children and adolescents 5–16 years of age. It has well-established efficacy in multiple

double-blind, placebo-controlled, and open-label trials (References 50, 58–65). The two principal double-blind, placebo-controlled trials used for FDA approval established the efficacy of risperidone using the outcome measurements of the Clinical Global Impression Scale (CGI) and the Aberrant Behavior Checklist (ABC) (References 58, 61, 62, 66). Up to 75% of subjects in the trials had a CGI score of either 1 (“very much improved”) or 2 (“much improved”) compared with only 11% of subjects receiving placebo. At least 50% of the subjects had a reduction in the ABC-Irritability subscale (ABC-I) of at least 25%. The mean reduction in the ABC-I for risperidone was 57% compared with the mean reduction in the placebo group of 14% (Reference 61). The maladaptive behaviors of irritability, aggression, tantrums, and self-injury are the principal targets when using risperidone; however, research indicates that other symptoms, such as hyperactivity and stereotypy, may improve as well. The core domains of communication impairment and problems with social interaction are not considered principal targets of pharmacotherapy with risperidone, though these symptoms may occasionally improve with pharmacotherapy. The manufacturer-recommended dosage range is 0.25–3 mg/day, with higher doses sometimes needed for individuals weighing more than 45 kg. The recommended starting dose and range are based on weight (0.01–0.06 mg/kg/day), with 0.25 mg/day for children weighing less than 20 kg and 0.5 mg/day for children weighing 20 kg or more. Titration up to the effective dosage should take place every 2 weeks in increments of 0.25–0.5 mg/day, with a target dose of 0.5 mg/day for children weighing less than 20 kg and 1 mg/day for children weighing 20 kg or more (References 65, 66). Commonly reported adverse effects that were reported during the clinical trials include fatigue (42%), somnolence (67%), increased appetite (49%), weight gain (5%), hypersalivation (22%), and EPS (7% to 12%) such as dystonias, tremors, and dyskinesias (References 58, 61, 62, 64, 66). Increases in prolactin levels have been observed during clinical trials and should be monitored for in children and adolescents receiving risperidone, together with possible clinical manifestations of hyperprolactinemia such as gynecomastia and galactorrhea (References 60, 86).

In 2009, aripiprazole became the second FDA approved agent for the treatment of irritability associated with autistic disorder in children and adolescents 6–17 years of age (Reference 67). Like risperidone, the approval was based on two studies, with results indicating that aripiprazole was superior to placebo in reducing the symptom of irritability associated with autistic disorder in children and adolescents, 6–17 years of age, by at least 25% as well as in achieving a “much-improved” or “very much-improved” score on the CGI for more than 50% of the subjects taking medication compared

with only 16% of the subjects receiving placebo who achieved a “much-improved” or “very much-improved” rating. The mean reduction in the ABC-I for aripiprazole was 44% compared with the mean reduction in the placebo group of 16% (References 68, 69). The recommended treatment dosage range is 2–15 mg/day. A once-daily dose of 2 mg is the recommended starting dose; 5–10 mg/day is the recommended treatment dose; and 15 mg/day is the maximum recommended dose for children 6–17 years of age (Reference 67). Common adverse events reported during the trials included sedation (21%), fatigue (17%), vomiting (14%), tremor (10%), hypersalivation (9%), decreased appetite (7%), dizziness, and EPS (6%). Although comparison data are lacking, aripiprazole appears to have a lower risk of significant weight gain than other atypical antipsychotic agents that may be used in ASD (References 66, 67, 87, 88).

Other atypical antipsychotic agents have also been researched in ASD. In one placebo-controlled, double-blind study, olanzapine was shown to have positive efficacy for the treatment of aggression and irritability in children and adolescents with a PDD (n=11 [6: autistic disorder; 1: Asperger disorder; 4: PDD-NOS], 6–14 years of age) (Reference 89). Clozapine, ziprasidone, and quetiapine have been evaluated in small open-label studies or case reports, with modest efficacy in reducing irritability, aggression, and tantrums reported (References 90–92). Further research is required with these agents and with the more recently approved atypical antipsychotics (paliperidone, asenapine, iloperidone, lurasidone) to establish their potential roles in treating children with ASD.

On the basis of early experiences with antipsychotic medications in ASD and the established efficacy and approval of risperidone and aripiprazole, these two agents should be considered first-line treatment; after treatment failure or the inability to use one of these two agents because of intolerability, other antipsychotics should be considered.

### *Antidepressants*

Stereotypic behaviors present with symptoms similar to obsessions and compulsions. The SSRIs have been studied and used in clinical practice for the repetitive behaviors in ASD; however, their overall efficacy appears inconsistent. Medications such as clomipramine, fluoxetine, sertraline, escitalopram, and fluvoxamine have been evaluated for their ability to reduce repetitive behaviors with limited and mixed results (References 70, 71, 93–95). Although fluoxetine has proved to have some efficacy in reducing the repetitive behaviors associated with ASD when using the CY-BOCS (Child-Yale Brown Obsessive Compulsive Scale), agents such as fluvoxamine have shown minimal efficacy in children (References 70, 71, 89).

Other SSRIs such as sertraline and paroxetine have only been studied in case reports and open-label trials, which do not consistently support their use in children with ASD (Reference 71). Citalopram was studied at a mean dose of 16.5 mg/day in a relatively large placebo-controlled, double-blind trial (n=149) of children and adolescents 5–17 years of age with ASD. Citalopram was no different from placebo in clinical outcomes, yet it caused significant adverse events including activation, impulsiveness, hyperactivity, stereotypies, diarrhea, and insomnia (Reference 95). If the decision is made to use an SSRI, the prescriber should consider using agents with established safety and tolerability in children and adolescents from data generated from other approved indications such as OCD or depression. These agents include fluoxetine, sertraline, escitalopram, and fluvoxamine.

Clomipramine, a highly serotonergic tricyclic agent, was the first agent approved in U.S. adults for OCD. Clomipramine has been studied in trials (dosage range 25–250 mg/day; mean 150 mg/day) of both child and adult populations and has shown modest efficacy compared with desipramine (n=24 subjects 6–18 years of age and showing superior efficacy to desipramine) and haloperidol (n=36 subjects 10–36 years of age and showing efficacy similar to haloperidol). The areas of improvement were generally related to obsessive-compulsive behaviors and stereotypies, but they also included reductions in anger and hyperactivity, as well as an overall general improvement, as reflected in the CGI-Improvement Scale of the subjects. However, the tolerability and general adverse effect profile of clomipramine suggest it should be used after other agents such as antipsychotic agents and SSRIs have failed (References 81, 94).

### *Psychostimulants*

For ADHD-like symptoms that accompany ASD, psychostimulants such as methylphenidate have been used with mixed results (References 96–98). The response to psychostimulants in the ASD population may be less than that experienced by someone with ADHD without ASD. In addition, the response to psychostimulants may be better for children with Asperger’s disorder than for children with autistic disorder or PDD-NOS (Reference 97). The amphetamines also have limited efficacy data, with no controlled studies since the 1970s, which is before current diagnostic criteria were used. Results indicated minimal benefit with potential adverse effects, including a worsening of ASD symptoms (Reference 50).

Both clonidine and guanfacine were recently FDA approved for ADHD treatment. Both agents have been studied in children and adolescents with ASD with reports of moderate efficacy in reducing symptoms of

stereotypy, hyperactivity, and irritability (References 73–76). Sedation and fatigue are frequent adverse effects of  $\alpha_2$ -agonists. Other agents with limited research include divalproex for reducing repetitive behaviors and atomoxetine for effectiveness in reducing hyperactivity (References 99, 100). Naltrexone continues to be questionable in efficacy and utility. Many studies have been done, both open label and placebo controlled, and the results are mixed. Although naltrexone may not be very effective for self-injurious behaviors and social interaction, as originally postulated, it may have some effect on hyperactivity and is generally well tolerated (References 72, 101, 102).

## MONITORING OF THERAPY

Monitoring of ASD in clinical practice is generally through parental and observer reports, together with teacher and other caregiver input. Assessment tools such as the ABC, Childhood Autism Rating Scale (CARS), or CGI are used in research, but not commonly in practice. The ABC-I is a 15-item parent-rated or primary caregiver-rated assessment focusing on agitation, aggression, tantrums, self-injury, and unstable mood with a possible 0–45 score; higher scores indicate greater severity of symptoms. In research, a common outcome goal is achieving at least a 25% reduction in symptoms of irritability compared with baseline. The CARS is a clinician assessment tool to assist with both diagnostics and the monitoring of individuals with ASD. The CARS has 15 items assessing several areas including social interactions and relationships, communication, and behaviors. The CGI is rated (1 = not at all ill up to 7 = extremely ill) for severity or improvement, with 1 = very much improved versus 7 = very much worse, and clinicians generally use these versions in research to provide a simplified and global rating of severity or level of change at baseline and follow-up, respectively (References 103–105).

Specialty-specific outcomes (e.g., speech-language), other than a general improvement from baseline and on follow-up, are both individualized and different, depending on the type of deficits or behaviors being addressed through treatment and the type of treatment or therapy being used (References 8, 50, 51). When the previous scales are used in research, improvements can be observed sometimes within 1 week of treatment; however, an adequate trial of the appropriate medication at the appropriate daily dose may require up to 8 weeks or more before that intervention is declared a success or failure, unless it must be discontinued early because of intolerable adverse effects to the patient. In addition to clinical monitoring for efficacy outcomes, the use of the antipsychotics and other psychotropics warrants the monitoring of laboratory values that assess

metabolic parameters such as lipids and glucose control. Prolactin levels should be assessed at baseline and periodically, together with observable manifestations of hyperprolactinemia such as gynecomastia and galactorrhea. Regular monitoring for weight changes in patients taking antipsychotics, psychostimulants, mood stabilizers, and antidepressants is also recommended. Many agents for treating ASD may also cause movement disorders in the form of EPS (dystonic reactions, pseudoparkinsonism, akathisia, tardive dyskinesia), motor tics, or tremors. Consider a baseline assessment of clinical symptoms, laboratory values, and physical parameters, with a follow-up in 1 month; then, provide a quarterly assessment as indicated unless caregiver or patient input or monitoring parameters warrant assessments more frequently.

## Pharmacotherapeutic Outcomes

The desired outcomes of pharmacotherapy are best described as reductions in the maladaptive and problematic behaviors so that the child with ASD can then engage in nonpharmacologic treatments such as speech-language therapy or educational treatment plans (Reference 51). The sometimes limited efficacy of the psychotropics discussed in this chapter should be considered, together with their liabilities of adverse effects such as weight gain, sedation, or even the possible worsening of some of the behaviors of ASD. Given that the ASDs are not considered reversible, some children with ASD may require long-term treatment with medications, and the risks of long-term exposure to some of the medications discussed are not well known. Nonpharmacologic interventions should be the first-line treatment with psychotropics held in reserve for more severe cases (References 50, 51). The atypical antipsychotic medications risperidone and aripiprazole, which have been approved for use in autistic disorder, were only approved for use in 2006 and 2009, respectively. Some adverse effects of medications may take years to manifest, such as problems secondary to significant weight gain or the development of tardive dyskinesia with antipsychotics or, yet undetermined, the long-term negative effects with other psychotropics such as the SSRIs or psychostimulants. The type of symptom identified as problematic, disruptive, and thus targeted to be addressed with pharmacotherapy will influence the medication selected. The antipsychotics are best suited for the disruptive behaviors of aggression, irritability, tantrums, and stereotypic/repetitive behaviors. If there is a recognized comorbid attention deficit or hyperactivity, a psychostimulant may be warranted, though caution should be taken not to exacerbate preexisting irritability or agitation. If comorbid anxiety or depression is occurring, an antidepressant that is FDA approved for child and adolescent use is recommended. Self-injurious behaviors may respond not only to antipsychotics, but also

to SSRIs and possibly naltrexone. Some practitioners, who may associate the repetitive behaviors with obsessive-compulsive symptoms, could prescribe an SSRI or clomipramine for said behaviors, given their efficacy for OCD. Again, it is important to consider pharmacotherapy as a targeted, symptomatic treatment approach to assist in the patient's total treatment plan to maximize functioning that may be inhibited by his or her disruptive and aggressive behaviors, thereby making the patient unable to engage in the equally important nonpharmacologic interventions designed to address the other core areas of ASD.

## CONCLUSIONS

The use of medications to treat the maladaptive behaviors and comorbid symptoms of ASD is a common practice, according to surveys of prescribers and parents (References 77–79). With only two medications currently FDA approved for the treatment of irritability related to autistic disorder, most pharmacologic agents are being used off-label, though with some research supporting their use and, thus, with evidence for their positive benefit in reducing certain behavioral problems. The prescriber should keep in mind, and discuss with the patient's caregivers and family, that pharmacotherapy in ASD is for symptomatic management only. Because improvements in the core features of ASD can be made through other interventions and over time, the need for pharmacotherapy should be reassessed periodically. If the maladaptive and other co-occurring problematic behaviors such as irritability, tantrums, agitation, and hyperactivity are addressed, then ideally, the child with ASD can better engage in the other treatments and therapies that can address the core domains of the ASD and improve overall outcomes.

# CHAPTER 29

## PEDIATRIC BIPOLAR DISORDER

Raymond A. Lorenz, Pharm.D., BCPP

### LEARNING OBJECTIVES

1. Describe the etiology and pathophysiology of pediatric bipolar disorder (PBD).
2. Explain the signs and symptoms and diagnostic criteria for bipolar disorder in pediatric patients.
3. Describe the treatment goals of PBD.
4. Evaluate pharmacologic therapy for the treatment of bipolar disorder and determine the best treatment for specific patients, including mood stabilizers, antipsychotics, and adjunctive treatments.
5. Discuss common monitoring parameters for the pharmacologic treatments of bipolar disorder.

### ABBREVIATIONS IN THIS CHAPTER

ADHD	Attention-deficit/hyperactivity disorder
Bipolar disorder NOS	Bipolar disorder not otherwise specified
BMP	Basic metabolic panel
CBC	Complete blood cell count
CYP	Cytochrome P450
DA	Dopamine
DSM-IV TR	Diagnostic and Statistical Manual of Mental Disorders (4th ed., text rev.)
ECG	Electrocardiogram
FDA	U.S. Food and Drug Administration
GABA	$\gamma$ -Aminobutyric acid
LFTs	Liver function tests
PBD	Pediatric bipolar disorder

### INTRODUCTION

Bipolar disorder (or manic depression) is a serious mental illness that includes severe mood fluctuations and changes in behavior. Bipolar disorder differs from major depressive disorder; in bipolar disorder, manic, hypomanic, or mixed mood episodes occur in addition to depressive episodes. The diagnosis of bipolar disorder in children and adolescents remains controversial leading

to revised diagnostic criteria discussed below. In fact, many clinicians feel pediatric bipolar disorder is over diagnosed and has become a “catch-all diagnosis” for children with even mild behavior problems. Although bipolar disorder is a lifelong illness, treatments (pharmacologic and nonpharmacologic) are available that can improve functioning and provide short- and long-term mood stabilization. The pharmacologic treatment of bipolar disorder is perhaps even more controversial than the diagnosis. Efficacy and safety of pharmacologic treatments have been questioned by lawmakers and clinicians alike. Many unknowns are present when treating pediatric bipolar disorder with pharmacotherapy and some of these are addressed throughout the chapter.

### EPIDEMIOLOGY

Diagnosis of bipolar disorder in children and adolescents has increased in recent years, possibly because of a better recognition of symptoms in this population (Reference 1). Other factors that may contribute to a higher rate of diagnosis include a better understanding of the difference in presentation between children and adults and a greater acceptance of the diagnosis in children (removing the stigma from diagnosis). However, the diagnosis of bipolar disorder in children and adolescents is still controversial. Pediatric bipolar disorder (PBD) is estimated to occur in 1% of children and adolescents, with equal occurrence in boys and girls (Reference 2). In addition, adult patients given a diagnosis of bipolar disorder retrospectively identify symptoms in childhood (Reference 3).

### ETIOLOGY

Pediatric bipolar disorder is likely the result of a combination of various genetic and biologic abnormalities and environmental stressors or insults. The adult literature has found a genetic association in patients with bipolar disorder and their families. Patients having a first-degree relative with bipolar disorder are 4–6 times more likely to have the illness (Reference 4), and several twin and adoption studies verify this (Reference 5). Neurochemical theories on the pathophysiology of PBD involve the monoaminergic system (serotonin, norepinephrine, and dopamine [DA]),  $\gamma$ -aminobutyric acid (GABA), intracellular secondary messenger system, and neuronal membrane calcium and/or sodium (Reference 6). The

monoamine theory states that an imbalance of the neurotransmitters serotonin (5-HT), norepinephrine, and DA causes mania and depression. Evidence for this theory is that medications that decrease these neurotransmitters (antipsychotics) relieve mania, whereas medications that increase these neurotransmitters (antidepressants) relieve depression. Another, related theory states that a deficiency of GABA or an excess of glutamate may also contribute to mania and depression. This theory is evidenced by the efficacy of certain antiseizure medications, which act to increase GABA or decrease glutamate. The intracellular secondary messenger system and neuronal cations may be important in “kindling,” in which the exaggerated and spontaneous firing of neurons occurs because of imbalances in these systems. The kindling theory is similar to the pathophysiology theories in epilepsy and is important in rapid cycling bipolar disorder and mixed states (Reference 7). Kindling theory states that, when patients who are predisposed to bipolar disorder experience stressful life events or take certain medications or illicit substances, the “threshold” at which mood changes occur decreases. Eventually, the decrease in threshold becomes so low that mood episodes begin occurring without any identifiable cause. Evidence for this theory is that many anticonvulsants used in bipolar disorder have efficacy in rapid cycling and mixed states. Other pathophysiologic theories include dysfunctions in the hypothalamic-pituitary-thyroid axis and increased cholinergic tone in the central nervous system (Reference 6). Environmental factors such as psychosocial stress (illicit drug use, family discord, school difficulties, etc.) or changes in the seasons, which disrupt the circadian cycle and the amount of light exposure, also play a role in precipitating manic or depressed episodes (Reference 6).

## CLINICAL PRESENTATION AND DIAGNOSIS

Before a diagnosis of mania is made, secondary causes of mania need to be ruled out (Table 1) (References 8, 9). The medical conditions and medications that cause secondary depression appear in the Pediatric Depression chapter. The clinical workup for pediatric patients with suspected bipolar disorder includes a thorough psychiatric interview and mental status examination. Additional information should be obtained, including personal and family psychiatric and medical history and medication history. A questionnaire that helps a clinician diagnose PBD is K-SADS, or the Kiddie-Schedule for Affective Disorders and Schizophrenia (Reference 10). Other tests that can rule out secondary causes of mania include a physical and neurologic examination; laboratory tests such as thyroid function, basic metabolic panel (BMP), urine drug screen, complete blood cell count (CBC), and liver function tests (LFTs); and psychological testing. Brain imaging (computed

tomography or magnetic resonance imaging), lumbar puncture, or electroencephalogram may be obtained; however, they are only for ruling out secondary causes, not in the diagnosis of PBD.

Differential diagnosis of PBD includes cyclothymia (hypomania and dysthymia), attention-deficit/hyperactivity disorder (ADHD), posttraumatic stress disorder, pervasive developmental disorders, oppositional defiant disorder, conduct disorder, reactive attachment disorder, and abuse of or withdrawal from recreational drugs. Many of these diagnoses may be common comorbidities as well. For example, ADHD has been described in up to 90% of patients with PBD (References 5, 11). Distinguishing PBD from other diagnoses can be difficult and may take more than one interview with a patient. This difficulty is very apparent when trying to differentiate between PBD and ADHD because their diagnostic criteria have some overlap; however, some guidance exists to help clinicians with the diagnosis. Although patients with ADHD will have short, impulsive bursts of anger because of not reaching a goal, their underlying mood between outbursts is described as “happy” or “angry” but rarely “sad” or “overly elated,” as seen in PBD. Patients with PBD tend to have constant irritability that can appear as openly hostile, vicious, or dangerous, which is not present in ADHD. In addition, patients with PBD often have episodes of unpredictable rage and an episodic illness characterized by mood

**Table 1. Other Causes of Mania (References 8, 9)**

### Medical conditions that may cause mania

- Thyroid disorders
- Infections
  - Neurosyphilis, sepsis, encephalitis
  - Central nervous system conditions
- Tumor, seizures, Huntington disease, stroke, lupus, multiple sclerosis, head trauma
- Addison or Cushing disease

### Drugs that may cause mania

- Withdrawal from substances of abuse
- Alcohol intoxication
- Antidepressants
- Dopamine agonists
- Hallucinogens
- Steroids
- Thyroid replacement medications
- Caffeine or theophylline
- Pseudoephedrine
- St. John’s wort

changes over time. Normally, ADHD does not manifest with changes in mood. Elated mood, grandiosity, flight of ideas, and decreased need for sleep more likely indicate PBD than ADHD (References 5, 12).

The defining characteristic of bipolar disorder is mania or hypomania. Table 2 summarizes the diagnostic criteria for mania and hypomania in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, text rev (DSM-IV TR) (Reference 8). The main difference between hypomania and mania is the level of impairment the patient shows. If the patient is still able to function in everyday life or does not require hospitalization, but still has symptoms consistent with a manic episode, he or she would be given a diagnosis of hypomania. A manic episode is necessary for a diagnosis of bipolar disorder type I, whereas a hypomanic episode with a history of depression indicates bipolar disorder type II. Bipolar disorder not otherwise specified (NOS), however, accounts for a large portion of PBD diagnosis. Bipolar disorder NOS describes patients who may not meet full criteria for bipolar type I or II, but still display signs and symptoms consistent with the diagnosis of bipolar disorder. Many pediatric patients who do not have a classic adult bipolar disorder presentation are given the diagnosis of bipolar disorder NOS. During any mood episode, except for hypomania, a patient may have psychotic symptoms such as hallucinations, delusions, or paranoia. Patients have rapid cycling bipolar disorder when four distinct mood episodes (any combination of depressive, hypomanic, or manic episodes) occur within a year. Although these criteria are for adult patients, they have been extrapolated successfully to the pediatric population. However, there is controversy surrounding whether the adult diagnostic criteria adequately describe or include all the symptoms related to PBD. This controversy has led some clinicians and researchers to use the term *juvenile mania* to describe manic symptoms that do not meet classic adult mania criteria (Reference 5).

For example, adolescents with a diagnosis of bipolar disorder may have a more chronic illness course, which is refractory to treatment, in addition to markedly labile moods. Mixed states (having symptoms of mania and depression in the same episode) and psychotic episodes are also more common in patients receiving a diagnosis in adolescence. Younger children (younger than 12 years) may have a quite different presentation. Mood changes, energy level changes, and behavioral symptoms are often not consistently present, but rather, they wax and wane frequently. Instead of a euphoric or excessively happy mood, younger patients may have irritability, anger, and/or mixed features. Other symptoms of mania that may be more pronounced in younger patients are grandiosity, flight of ideas, and decreased need for sleep. Their long-term prognosis is often worse than that of adults because patients may be refractory to medication (Reference 5).

Depressive symptoms in PBD are similar to adult symptoms, with some exceptions. Many patients experience irritability, which may be mistaken for mania. The occurrence of fatigue, anhedonia, and suicidal ideation should be screened for in patients presenting with irritability to differentiate whether the irritability is caused by mania or depression. Further complicating the diagnosis of depression in patients with PBD is the high incidence of mixed episodes in this population.

**Table 2.** DSM-IV TR Mania and Hypomania Diagnostic Criteria (Reference 8)

---

**Mania**

- Duration of 1 week of an irritable, expansive, or elevated mood with at least three of the following symptoms (four if mood is irritable)
    - Distractibility (poor attention and concentration)
    - Excessive involvement in pleasurable activities (increased sexual activity, spending sprees, increased recreational drug use)
    - Inflated self-esteem
    - Racing thoughts
    - Increased goal-directed activity or agitation
    - Decreased need for sleep
    - Increase in talking (rapid, pressured speech)
  - Impairment in everyday functioning or need for hospital admission
  - Manic episode not caused by medications or medical conditions
- 

**Hypomania**

- Duration of 4 days of an irritable, expansive, or elevated mood with at least three of the following symptoms (four if mood is irritable)
    - Distractibility (poor attention and concentration)
    - Excessive involvement in pleasurable activities (increased sexual activity, spending sprees, increased recreational drug use)
    - Inflated self-esteem
    - Racing thoughts
    - Increased goal-directed activity or agitation
    - Decreased need for sleep
    - Increase in talking (rapid, pressured speech)
  - Hypomanic episode not caused by medications or medical conditions
-

Pediatric patients with bipolar disorder are at a high risk of suicide attempts and completion of suicide, substance abuse, and nonadherence to medication (Reference 13). Many (65.3%) patients with PBD do not “outgrow” their illness and continue to have symptoms into adulthood. In fact, patients with a diagnosis of PBD tend to have worse symptoms during adulthood and are more difficult to treat to remission (Reference 14). Patients with PBD also are at a high risk of relapse of their illness. Even when adherent to medications, patients are placed at a higher risk of relapse into mania or depression because of differences in hormonal regulation, self-medication through recreational drug use, and the kindling phenomenon (Reference 5).

## TREATMENT

### Treatment Goals

The treatment goals in PBD are to treat the current mood episode, prevent future mood episodes, minimize adverse effects, treat co-occurring conditions, and maintain or return to normal the patient’s psychosocial function and quality of life. Individualized treatment is paramount, with both nonpharmacologic and pharmacologic treatments used to achieve euthymia. Although patient education is important, in PBD, parent or guardian education is equally important.

### Treatment Algorithm

Treatment guidelines published by the American Academy of Child and Adolescent Psychiatry (References 5, 15, 16) exist to help clinicians determine appropriate treatment options. In addition, bipolar disorder treatment guidelines for adults are published by the American Psychiatric Association (Reference 9). Pharmacologic treatment is divided into acute treatment and maintenance treatment. Acute treatment medications are helpful in reducing symptoms of acute mania or depression. Maintenance treatment medications are helpful in preventing future mood episodes. As described below, some medications are used for both acute and maintenance treatment in PBD. In the treatment of PBD, combination medication treatment is the rule rather than the exception, but unwarranted polypharmacy should be avoided by using the least number of medications at the lowest possible dose. Recognition that pediatric patients may be more sensitive to the adverse effects of medication and that combining medications would compound these adverse effects is essential. In addition, there are relatively few (compared with the adult literature) large placebo-controlled trials and even fewer long-term studies of medications in PBD. As such, although the current recommendation is for combination treatment, individualized pharmacotherapy

based on tolerability, efficacy, and patient (or caregiver) preference is of utmost importance. Because of the relative lack of data for the treatment of PBD, the adult literature is often extrapolated to the pediatric population. For acute mania, antipsychotics and mood stabilizers are used, and for acute depression, antidepressants may be added to a mood stabilizer. Both antipsychotics and mood stabilizers can be used in the long-term prevention of mood episodes. During acute treatment, medications are added to a patient’s medication regimen and may be discontinued once euthymia is reached. If at any point psychosis is present, an antipsychotic should be used. Patients with PBD should continue mood stabilizer treatment indefinitely (References 5, 9, 15). See Table 3 for a summary of U.S. Food and Drug Administration (FDA)-approved medications used to treat PBD and Table 4 for other treatments that may be beneficial in PBD despite lacking FDA approval.

Nonpharmacologic treatment includes lifestyle modifications and psychosocial strategies. Stress reduction can decrease mood lability and improve quality of life. Ensuring adequate sleep through appropriate sleep hygiene and minimization of caffeine before bedtime can help prevent manic episodes. Daily exercise and adequate nutrition can also help prevent mood episodes. Eating well-balanced meals with appropriate intake of essential fatty acids, amino acids, and vitamins can help prevent mood episodes. Individual and family psychotherapies (using cognitive behavioral techniques) have also proven useful in helping improve the living environment, communication skills, problem-solving skills, and overall family dynamic. Academic and occupational functioning should be addressed, with involvement from the patient’s school or job, which can improve long-term outcomes. Although minimal data exist in pediatric patients, ECT (electroconvulsive therapy) may be used for severe mania or depression (Reference 5). Other community resources are available such as the National Alliance on Mental Illness (NAMI) or Mental Health America. (See additional resources at end of chapter.)

Treatment of acute mania or mixed episode associated with PBD (ages 10–17) should be initiated with lithium, divalproex, or an FDA-approved atypical antipsychotic as monotherapy. If no response is seen, switching to monotherapy with another first-line agent is appropriate. If a partial response is seen, augmentation with another first-line agent is warranted (e.g., lithium or divalproex with an atypical antipsychotic). Combination therapy may be required in many patients, but a systematic approach should be used. Use of a medication for 4–6 weeks at therapeutic blood levels is considered an adequate trial. Patients who have psychosis (hallucinations, delusions) should be initiated on an atypical

**Table 3. Medications FDA Label Approved for Pediatric Bipolar Disorder (References 15, 18–21)**

Generic Name	Brand Name	Indications	Formulations	Dosage and Administration	Common Adverse Effects
<b>Atypical Antipsychotics</b>					
Aripiprazole	Abilify, Abilify Discmelt, Abilify IM	Acute treatment of mania or mixed episodes as monotherapy in children and adolescents 10–17 years old Irritability associated with autistic disorder in children and adolescents 6–17 years old Adolescent schizophrenia in patients 13–17 years old IM injection not approved for use in children or adolescents	Oral tablet: 2, 5, 10, 15, 20, 30 mg Orally dissolvable tablet: 10, 15 mg Oral solution: 1 mg/mL Short-acting IM injection: 9.75 mg/1.3 mL	Titration schedule: 2 mg/day for 2 days, 5 mg/day for 2 days, and then 10 mg/day. Increase by 5-mg increments when needed. Target dose: 10 mg/day Maximal dose: 30 mg/day	Somnolence, nausea, extrapyramidal symptoms, fatigue, weight gain
Olanzapine	Zyprexa, Zyprexa Zydis, Zyprexa IM, Zyprexa Relprevv	Acute treatment of mania or mixed episodes as monotherapy in children and adolescents 10–17 years old Adolescent schizophrenia in patients 13–17 years old IM injections not approved for use in children or adolescents	Oral tablet: 2.5, 5, 7.5, 10, 15, 20 mg Orally dissolvable tablet: 5, 10, 15, 20 mg Short-acting IM injection: 10-mg vial Long-acting IM injection: 210, 300, 405 mg	Starting dose: 2.5–5 mg/day, titrate by 5-mg increments Target dose: 10 mg/day Maximal dose: 20 mg/day	Weight gain, increased appetite, sedation, fatigue, dry mouth, headache
Quetiapine	Seroquel, Seroquel XR	Acute treatment of mania or mixed episodes as monotherapy in children and adolescents 10–17 years old Adolescent schizophrenia in patients 13–17 years old	Oral tablet: 25, 50, 100, 200, 300, 400 mg Oral tablet, extended release: 50, 150, 200, 300, 400 mg	Titration schedule: Using immediate-release formulation. Day 1, 25 mg BID; day 2, 50 mg BID; day 3, 100 mg BID; day 4, 150 mg BID; day 5, 200 mg BID. Increase by not more than 100 mg/day thereafter. Target dose: 400–600 mg total daily dose Maximal dose: 600 mg/day	Somnolence, dizziness, increased appetite, weight gain, dry mouth, tachycardia, fatigue
Risperidone	Risperdal, Risperdal M-tab, Risperdal Consta	Acute treatment of mania or mixed episodes as monotherapy in children and adolescents 10–17 years old Irritability associated with autistic disorder in children and adolescents 5–16 years old Adolescent schizophrenia in patients 13–17 years old IM injection not approved for use in children or adolescents	Oral tablet: 0.25, 0.5, 1, 2, 3, 4 mg Orally dissolvable tablet: 0.25, 0.5, 1, 2, 3, 4 mg Oral solution: 1 mg/mL Long-acting IM injection: 12.5, 25, 37.5, 50 mg	Starting dose: 0.5 mg/day, titrating by 0.5- to 1-mg increments Target dose: 2.5 mg/day Maximal dose: 6 mg/day	Sedation, dizziness, fatigue, nausea, extrapyramidal symptoms, weight gain
<b>Mood Stabilizers</b>					
Lithium	Lithium carbonate, lithium citrate, Eskalith CR, Lithobid	Acute manic episode or maintenance of bipolar disorder in adolescents 12 years and older	Oral capsule, as lithium carbonate: 150-, 300-, 600-mg capsule Oral tablet, extended release as lithium carbonate: 300, 450 mg Oral syrup, as lithium citrate: 8 mEq/5 mL	Starting dose: 300 mg BID, titrating by 300-mg increments Target dose, acute mania and maintenance: 900–1,800 mg/day, based on target lithium level of 0.6–1.2 mEq/L Maximal dose: 1,800 mg/day or blood concentration of 1.2 mEq/L	Nausea, tremor, diarrhea, weight gain, sedation

BID = twice daily; CR = controlled release; IM = intramuscular; XR = extended release.

Table 4. Other Medications with Potential Uses in PBD (References 15, 26–28)

Generic Name	Brand Name	Indications	Formulations	Dosage and Administration	Common Adverse Effects
<b>Antipsychotics</b>					
Clozapine	Clozaril, Fazaclo	Adult-refractory schizophrenia or schizoaffective disorder	Oral tablet: 25, 50, 100, 200 mg Orally dissolvable tablet: 12.5, 25, 100, 150, 200 mg	Starting dose: 12.5 mg at night, titrated according to package insert Target dose: 300 mg/day Maximal dose: 900 mg/day	Sedation, weight gain, hyperlipidemia, hyperglycemia, orthostatic hypotension, agranulocytosis (rare)
Paliperidone	Invega, Invega Sustenna	Adolescent schizophrenia in patients 13–17 years old Adult bipolar mania IM injection not approved for use in children or adolescents	Oral tablet, extended release: 1.5, 3, 6, 9 mg Long-acting IM injection: 39, 78, 117, 156, 234 mg	Starting dose: 3 mg/day, titrating by 3-mg increments Target: 6 mg/day Maximal dose: 6 mg/day if < 51 kg, 12 mg/day if > 15 kg	Sedation, dizziness, fatigue, nausea, extrapyramidal symptoms, weight gain
Ziprasidone	Geodon, Geodon IM	Adult bipolar mania IM injection not approved for use in children or adolescents	Oral capsule: 20, 40, 60, 80 mg Short-acting IM injection: 20 mg/mL	Starting dose: 20–40 mg BID, titrating by 20-mg increments Target dose: 40–60 mg BID Maximal dose: 80 mg BID	Sedation, headache, QT prolongation, weight gain, prolactin elevation
<b>Anticonvulsants</b>					
Carbamazepine	Tegretol, Tegretol XR, Carbatrol, Equetro	Adult manic or mixed episode	Oral tablet: 200, 400 mg Oral chewable tablet: 100 mg Oral suspension: 100 mg/5 mL Oral tablet, extended release: 100, 200, 400 mg Oral capsule, extended release: 100, 200, 300 mg	Starting dose: 100–200 mg BID, titrated by 100 mg every week Target dose: Titrate to desired effect. Maximal dose: 1000 mg/day	Drowsiness, dizziness, nausea, weight gain, hyponatremia
Divalproex sodium, valproic acid	Depakote, Depakote ER, Depakene, Stavzor	Adult bipolar mania or mixed episodes, maintenance of bipolar disorder in adults	Oral tablet, divalproex sodium: 125, 250, 500 mg Oral tablet, divalproex sodium, extended release: 250, 500 mg Oral sprinkle capsule, divalproex sodium: 125 mg Oral capsule, valproic acid: 250 mg Oral capsule, delayed release: 125, 250, 500 mg Oral syrup, valproate sodium: 250 mg/5 mL	Starting dose: 10–15 mg/kg/day, increasing by 5–10 mg/kg/week as needed Target dose: titrated to clinical response Maximal dose: 60 mg/kg/day	Nausea, diarrhea, tremor, sedation, weight gain
Lamotrigine	Lamictal, Lamictal XR	Prevention of mood episodes in adult patients with bipolar disorder	Oral tablet: 25, 100, 150, 200 mg Orally dissolvable tablet: 25, 50, 100, 200 mg Oral tablet, chewable: 2, 5, 25 mg Oral tablet, extended release: 25, 50, 100, 200 mg	Starting dose, monotherapy titration: 25 mg/day for 2 weeks, 50 mg/day for 2 weeks, 100 mg/day for 1 week; then 200 mg/day Starting dose, with divalproex: 25 mg every other day (or 12.5 mg/day) for 2 weeks, 25 mg/day for 2 weeks, 50 mg/day for 1 week; then 100 mg/day Starting dose, with carbamazepine or other enzyme-inducing agents: 50 mg/day for 2 weeks, 100 mg/day for 2 weeks, 200 mg/day for 1 week; then 400 mg/day Target and maximal dose, monotherapy: 200 mg/day Target and maximal dose, with divalproex: 100 mg/day Target and maximal dose with carbamazepine or other enzyme-inducing agents: 400 mg	Headache, drowsiness, nausea, rash, dizziness
Oxcarbazepine	Trileptal	Adult manic or mixed episode	Oral tablet: 150, 300, 600 mg Oral suspension: 300 mg/5 mL	Starting dose: 150 mg BID, titrate by 150-mg increments every week Target dose: Titrate to desired effect. Maximal dose: 60 mg/kg/day	Drowsiness, dizziness, nausea, fatigue, tremor, hyponatremia

BID = twice daily; IM = intramuscular(ly); PBD = pediatric bipolar disorder; XR/ER = extended release..

antipsychotic (References 5, 15, 16). In general, tolerability seems to be better with atypical antipsychotics despite metabolic adverse effects such as weight gain, dyslipidemia, and glucose intolerance (Reference 17).

Limited data exist regarding maintenance therapy and prevention of symptom relapse for PBD. In general, if a patient had acute remission with a specific treatment modality, extended therapy with this treatment seems most likely to sustain remission. After 12–24 months of sustained remission, discontinuation of medications can be considered using a slow taper. Patients with a significant history of suicidality, aggressive behavior, or psychotic symptoms should be taken off medications with great caution. As mentioned previously, many patients require lifelong pharmacotherapy (References 5, 15, 16).

## MEDICATIONS FOR PBD

### Antipsychotics

Aripiprazole, olanzapine, quetiapine, and risperidone are all FDA approved as monotherapy to treat acute manic or mixed episodes in children and adolescents aged 10–17 years (References 17–20). Based on extrapolation from adult data, aripiprazole and olanzapine have FDA approval for maintenance treatment as well (References 17, 18). Ziprasidone does not have a current approval for PBD, even in light of several positive open-label trials. The lack of approval may be because the drug manufacturer did not follow generally accepted practices and protocol when conducting the initial placebo-controlled studies (References 22–25). Although paliperidone, the active metabolite of risperidone, has no approval for PBD, it is approved for schizophrenia in patients 12–17 years old. Moreover, it shows a tolerability profile similar to its parent compound in adolescent patients (References 21, 26). Also approved for adolescent schizophrenia (ages 13–17 years) are aripiprazole, quetiapine, risperidone, and olanzapine (References 18–21). Clozapine has significant adverse effects that require frequent monitoring, and it is not FDA approved for PBD or adolescent schizophrenia but may be useful in the treatment of refractory patients who have a firm diagnosis of PBD (Reference 5). In general, lower doses of atypical antipsychotics are used in pediatric patients than in adult patients, and dose titration is more conservative. Asenapine, iloperidone, and lurasidone are newer atypical antipsychotics that currently have no indications in pediatric patients, and no literature is available to guide clinicians in their use. Long-acting injectable formulations are available for risperidone, paliperidone, and olanzapine. Although the long-acting formulations are not approved for use in pediatric patients, they may be appropriate for a small subset of patients with adherence difficulties. First-generation or

typical antipsychotics have been useful for the treatment of mania, but they are not recommended because of their significant adverse effects, such as their greater propensity to cause tardive dyskinesia and extrapyramidal symptoms.

The mechanism of action of atypical antipsychotics in the treatment of PBD is not fully understood, but it is likely that dopamine (DA<sub>2</sub>) and serotonin (5-HT<sub>2A</sub>) receptor antagonism contribute to their efficacy in the acute treatment of mania or mixed states. This antagonism results in decreased DA<sub>2</sub> transmission in the mesolimbic pathway and increased DA<sub>2</sub> transmission in the mesocortical pathway. Atypical antipsychotics in general are well absorbed when administered orally; they are also highly lipophilic and highly bound to plasma proteins. In addition, they have long half-lives, which allow once-daily administration, except for quetiapine and ziprasidone, which are dosed twice daily. Most atypical antipsychotics are metabolized in the liver by the cytochrome P450 (CYP) pathways through CYP2D6 (risperidone major pathway, aripiprazole minor pathway), CYP3A4 (aripiprazole major pathway, quetiapine major pathway, olanzapine minor pathway, clozapine minor pathway, ziprasidone minor pathway), or CYP1A2 (clozapine and olanzapine major pathway). Only ziprasidone has no major pathway through the CYP system because it is primarily metabolized by aldehyde oxidase. Paliperidone is primarily excreted unchanged through the urine. Atypical antipsychotics rarely affect the metabolism of other medications through the CYP system. Other medications are more likely to affect the blood concentrations of the atypical antipsychotics through induction (decreased concentrations that may lead to decreased efficacy) or inhibition (increased concentrations that may lead to increased adverse effects) of the CYP system. When combined with lithium or valproate, as is often done in the treatment of mania associated with PBD, these medications do not affect the metabolism of the antipsychotics, but additive adverse effects may be seen (References 5, 15, 18–21).

Major adverse effects for each atypical antipsychotic are listed in Table 3 and Table 4. Although the atypical antipsychotics have similar adverse effects overall (sedation and weight gain), certain medications may be more likely to cause specific adverse effects. For example, risperidone and paliperidone are more likely to cause increases in prolactin (leading to gynecomastia, amenorrhea, and sexual dysfunction) and extrapyramidal symptoms. Olanzapine is more likely to cause increased weight, increased appetite, hyperglycemia, and hyperlipidemia and is recommended only after other medications have been tried. Olanzapine also has a warning for inducing ketoacidosis or hyperosmolar coma. Quetiapine is more likely to cause dizziness or sedation, and aripiprazole is more likely to cause nausea

and restlessness. Ziprasidone may also cause prolactin elevation as well as QT-interval prolongation. A baseline electrocardiogram (ECG) is recommended for pediatric patients before initiating treatment with ziprasidone. Clozapine causes significant weight gain, hyperlipidemia, hyperglycemia, sedation, and orthostatic hypotension. In addition, patients receiving clozapine need to be monitored for agranulocytosis weekly for the first 6 months, every other week for the next 6 months, and then once a month. Although rare, all atypical antipsychotics confer some risk of tardive dyskinesia and neuroleptic malignant syndrome, and the long-term risks of these adverse effects have not been fully examined in pediatric patients (References 18–21, 26–28).

## Mood Stabilizers

### *Carbamazepine*

Although data are limited with carbamazepine in PBD, some data exist regarding its use in adult patients. Carbamazepine has a tricyclic antidepressant-like structure and, as a result, has many adverse effects and is poorly tolerated overall. Carbamazepine also causes many drug interactions (e.g., with oral contraceptives) because it is a CYP3A4 inducer. In addition, it induces its own metabolism, and frequent dosage adjustments may be needed. As such, it is recommended only for patients whose other options in the management of their PBD have failed (Reference 15). Therapeutic levels of carbamazepine are 6–10 mcg/mL for the treatment of bipolar disorder. See the Seizure Disorders chapter for more information on carbamazepine.

### *Divalproex Sodium*

Divalproex sodium has been studied in PBD with generally positive results, but it has no FDA approval for PBD (References 29, 30). Divalproex is recommended for acute mania and maintenance therapy because of its efficacy in adults. Divalproex also seems to be effective in the treatment of mixed states or rapid cycling patients because of its antikindling effect. Valproic acid, the non-enteric-coated dosage form, may also be used, but it may cause more adverse effects than divalproex. The mechanism of action of divalproex in PBD is unclear, but it may be related to its modulating effect on sodium and calcium channels and its enhancing action on GABA. More information on the mechanism of action of divalproex and its pharmacokinetics and drug interactions is available in the Seizure Disorders chapter.

Adverse effects commonly seen in pediatric patients can be found by exploring the pediatric epilepsy data and include sedation, nausea, dizziness, tremor, and weight gain. Less common adverse effects include alopecia, thrombocytopenia, and polycystic ovarian syndrome. Divalproex also has black box warnings for

hepatotoxicity, pancreatitis, and increased suicide risk. Hepatotoxicity risk decreases considerably in older groups of children (older than 2 years), but divalproex should be discontinued if significant hepatic dysfunction is detected. Further information on adverse effects is available in the Seizure Disorders chapter.

Divalproex has a narrow therapeutic window, but monitoring of levels is not mandatory, unlike with lithium, because controversy exists regarding what the appropriate levels should be. In general, the therapeutic range for PBD is thought to be 50–125 mcg/mL (References 5, 15). Dosing is based on weight and is shown in Table 4.

### *Lamotrigine*

Lamotrigine has FDA approval in the adult population to delay the time to mood episodes in patients with bipolar disorder. Data for using lamotrigine in PBD are sparse, but positive (Reference 31). Lamotrigine is not used for the treatment of acute episodes of depression or mania, but it can be useful in long-term mood stabilization. Lamotrigine has a specific dosing titration to help prevent severe cutaneous reactions from occurring (e.g., Stevens-Johnson syndrome, toxic epidermal necrolysis) (see Table 4). This reaction is more common in pediatric patients younger than 16 years, and an extended titration schedule has been proposed to decrease the risk (Reference 32). In addition, lamotrigine titration schedules are different if the patient is receiving divalproex, carbamazepine, or other enzyme-inducing agents. For more information on lamotrigine, see the Seizure Disorders chapter.

### *Lithium*

Lithium, considered the classic mood stabilizer, is FDA approved in adolescents 12 years and older for the acute and maintenance phase of PBD (References 5, 15). Much of the data regarding the efficacy and safety of lithium in pediatric patients are extrapolated from the adult literature. Favorable double-blind, placebo-controlled trials regarding the use of lithium in PBD are lacking, but open-label trials show some efficacy (References 33–38). Compared with the atypical antipsychotics, lithium in trials shows less efficacy and more adverse effects, in addition to requiring close monitoring of levels. As such, lithium is seldom used in clinical practice compared with the atypical antipsychotics.

Lithium's mechanism of action in the treatment and prevention of mania and depression is largely unknown, but lithium may have a positive effect on many of the proposed pathophysiologies in PBD such as normalizing second-messenger systems and regulating neurotransmitters and gene expression. Lithium is a monovalent cation that is rapidly absorbed when

administered orally. It has no protein binding or metabolism and is excreted unchanged through the urine. The half-life of lithium depends on renal function, but it is generally about 24 hours. Even though lithium has a half-life that would dictate once-daily dosing, it is divided two or three times/day to improve tolerability when administered as immediate-release lithium. Extended-release lithium can be dosed one or two times/day. Drug interactions occur owing to changing the elimination of lithium from the kidney. Medications such as NSAIDs (nonsteroidal anti-inflammatory drugs), thiazide diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers may cause an increase in lithium concentration because of the reduced renal excretion of lithium. When concomitant administration cannot be avoided, frequent monitoring is recommended to determine the effect of these medications on lithium concentrations. Medications such as loop diuretics and acetaminophen are less likely to cause this interaction. Other medications such as caffeine, theophylline, and acetazolamide may cause a decrease in lithium levels because of increased renal excretion.

Adverse effects of lithium are usually dose related and most common when it is first initiated and 1–2 hours postdose. Nausea, sedation, diarrhea, tremor, headache, confusion, poor concentration, polydipsia, polyuria, and weight gain are the most common adverse effects. Other, less common adverse effects include nephrogenic diabetes insipidus, flattening or inversion of the T-wave on an ECG, and leukocytosis. Lithium has negative effects on the kidney as well, with up to 20% of patients developing morphologic changes with long-term use. These changes can lead to increased serum creatinine and decreased water reabsorption in the kidney. Another organ affected by long-term lithium administration is the thyroid gland because lithium can decrease thyroid hormone synthesis and cause the formation of antibodies to the thyroid. This effect may be especially problematic for pediatric patients because thyroid hormone is essential to proper growth and development. However, long-term effects of lithium in pediatric patients have not been fully evaluated.

Lithium has a narrow therapeutic window, and blood concentrations should be monitored often. A blood concentration of 0.6–1.2 mEq/L at steady state is generally thought to be adequate for achieving therapeutic success. For acute mania, the target concentration is the upper end of this range (0.9–1.2 mEq/L); for prevention of mood episodes, the target concentration is the lower end of this range (0.6–0.9 mEq/L). A higher concentration of lithium (greater than 1.5 mEq/L) in the blood can lead to mild toxicity, as evidenced by increased or more severe adverse effects such as nausea, vomiting, ataxia, coarse tremor, or confusion. A lithium level above 2.0 mEq/L constitutes severe toxicity,

and patients taking this level would have severe gastrointestinal effects, decreased coordination, seizures, slurred speech, muscle twitching, kidney failure, and cardiac arrhythmias. Administering intravenous fluids and monitoring of kidney function are important steps in managing acute lithium toxicity. Dialysis is recommended if the lithium level is above 3.0 mEq/L. To avoid toxicity, patients should have consistent noncaffeinated fluid intake, avoid activities that cause excessive sweating, and monitor their sodium intake (References 9, 15).

### *Oxcarbazepine*

Oxcarbazepine is a structural analog of carbamazepine that was originally touted to have fewer adverse effects and drug interactions than carbamazepine. This claim is controversial, and there are more data with carbamazepine for adult bipolar disorder than with oxcarbazepine. Nevertheless, oxcarbazepine is listed on the adult guidelines for the treatment of bipolar disorder and recommended whenever carbamazepine could be used. There has been only one PBD trial, which showed no difference from placebo in the treatment of mania (Reference 39). As such, its use is not currently recommended in PBD. See the Seizure Disorders chapter for more information on oxcarbazepine.

### *Adjunctive Treatments*

When clinicians treat patients with PBD in the depressed phase, they have little evidence to draw on in the PBD population to help make treatment decisions. Antidepressants, lamotrigine, quetiapine, olanzapine/fluoxetine combination, and lithium have been used in adults to treat bipolar depression with success, but data in pediatric patients are lacking (References 9, 15, 16). Extrapolating from the adult data, certain antidepressants such as tricyclic antidepressants (e.g., amitriptyline, imipramine) and serotonin and norepinephrine reuptake inhibitors (e.g., venlafaxine, duloxetine) seem more likely than selective serotonin reuptake inhibitors (e.g., citalopram, paroxetine) and norepinephrine and DA reuptake inhibitors (bupropion) to induce mania. Combining antidepressants with mood stabilizers in PBD is a prudent strategy to help reduce the risk of a potential switch to mania (References 5, 15). Lamotrigine and lithium have been studied in PBD in open-label trials with positive results, but more data are needed before they can be routinely recommended (References 40, 41). A study investigating the use of quetiapine in PBD showed no difference from placebo (Reference 42). For more information on antidepressants, see the Pediatric Depression chapter.

Benzodiazepines have also been used in adults as short-term treatment for acute mania or mixed episodes as a sedative-hypnotic. This strategy may not be optimal in pediatric patients because disinhibition and agitation may occur as adverse effects more often in this population than in adults. In addition, established guidelines do not mention the use of benzodiazepines in PBD, and data are lacking in the pediatric population on this topic (References 5, 15).

Other therapies that have been studied include omega-3 fatty acids and flaxseed oil. Omega-3 showed modest efficacy in an open-label trial, but flax oil failed to separate from placebo in a randomized controlled trial (References 43, 44).

## MONITORING PARAMETERS

When monitoring patients for efficacy, the Young Mania Rating Scale (YMRS) has been used successfully in pediatric patients. The YMRS can be useful in tracking specific symptoms and responses to medications over time (Reference 45). Close follow-up (within 4–6 weeks) to assess efficacy, adverse effects, and adherence is recommended when the drug is initiated (Reference 15).

Metabolic monitoring for atypical antipsychotics in adult patients is described in a consensus document (Reference 46), and when using these medications in pediatric patients it seems prudent to follow the same guidelines. Baseline measurements include weight, height, blood pressure, fasting glucose and lipids, waist circumference, and personal and family medical history. Weight should be monitored monthly for the first 3 months and then every 3 months. Fasting glucose and lipids as well as blood pressure should be monitored after 3 months and then every year. Waist circumference is monitored yearly, together with a reassessment of personal and family medical history. Additional baseline laboratory assessments should include a CBC, LFTs, thyroid function tests, and a BMP, which are then monitored periodically throughout treatment. Adolescent girls who have reached menarche should also have a urine pregnancy test at baseline. A baseline ECG is recommended before ziprasidone use, and prolactin levels may be obtained as clinically warranted. When monitoring for tardive dyskinesia, administration of an AIMS (Abnormal Involuntary Movement Scale) is recommended every 6 months (References 5, 15).

Lithium levels are recommended every week for the first month, monthly for the first 3 months, and then every 3 months. A minimum of 5 days on lithium therapy should elapse before drawing levels to ensure attainment of steady state. Lithium levels are most accurate before the morning dose, 12 hours after the evening dose. As mentioned above, a lithium level of 0.6–1.2 mEq/L is considered therapeutic. Baseline

safety monitoring of lithium consists of a BMP, a CBC, thyroid function tests, a measure of weight, a reading of fasting glucose and lipids, an ECG, and a pregnancy test in female adolescents of childbearing potential. These parameters should be obtained after 3 months on lithium and then, if normal, every 6–12 months (References 9, 15).

Anticonvulsant monitoring parameters are available in the Seizure Disorders chapter, but generally, LFTs, weight, fasting glucose and lipids, BMP, CBC, and a pregnancy test should be obtained at baseline and then periodically throughout treatment. Divalproex and carbamazepine levels reach steady state after 3 and 4 days, respectively, but are not required to be drawn as frequently as lithium levels. Although monitoring levels for divalproex and carbamazepine is prudent, the level itself should not become the therapy goal; levels should be viewed as part of the overall treatment response, with symptom resolution or prevention being the primary goal.

## Special Populations

Female adolescents who have reached menarche should be counseled on the risk of birth defects from medications used to treat PBD. Lithium can cause fetal heart abnormalities (Ebstein anomaly), and divalproex and carbamazepine can cause neural tube defects. Recently, the FDA updated the package labeling for atypical antipsychotics to include more consistent risks in pregnancy (Reference 47). Adequate contraception is recommended to females who are sexually active or who may become sexually active. Furthermore, carbamazepine reduces the effectiveness of oral contraceptives, and patients should be counseled to use another method of birth control while being treated with this medication. Treatment of PBD during pregnancy should be discussed with the patient and obstetrician and is usually handled by physicians who specialize in high-risk pregnancy.

In addition, ADHD and PBD commonly occur together. Treatment of ADHD can be especially difficult in patients with PBD because stimulants may precipitate a manic episode. Stimulants should be used cautiously and only when ADHD symptoms fail to resolve with adequate bipolar disorder treatment. Atypical antipsychotics should not be used to treat ADHD symptoms in patients without bipolar disorder, but they have shown some efficacy in co-occurring ADHD and bipolar disorder (Reference 17).

## CONCLUSIONS

Pediatric bipolar disorder is a serious mental illness that can be treated successfully with a combination of psychosocial interventions and medications. Although data are lacking for the acute and long-term management of

PBD, there are FDA-approved treatments. Lithium is FDA approved for maintenance treatment of PBD, and aripiprazole, olanzapine, quetiapine, and risperidone are approved for acute treatment of mania. Other treatments such as divalproex, lamotrigine, and other anticonvulsants have not been FDA approved, but they may prove useful in PBD. Careful diagnosis and appropriate treatment of PBD can result in improved outcomes and better quality of life for patients and families affected by PBD.

# CHAPTER 30

## ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Joshua Caballero, Pharm.D., BCPP

### LEARNING OBJECTIVES

1. Describe the signs and symptoms of attention-deficit/hyperactivity disorder.
2. Identify the primary mechanisms of action of stimulants and non-stimulants.
3. List common adverse events among pharmacologic agents.
4. Identify rare, life-threatening adverse events of pharmacologic agents.
5. Discuss advantages and disadvantages among pharmacologic agents.

### ABBREVIATIONS IN THIS CHAPTER

ADHD	Attention-deficit/hyperactivity disorder
ADHD RS-IV	ADHD Rating Scale-IV
CRS-R	Conners Rating Scales-Revised
<i>DRDs</i>	Dopamine receptor genes
<i>DAT1</i>	Dopamine transporter gene
DSM-IV-TR	Diagnostic and Statistical Manual for Mental Disorders (4th ed., text rev.)
<i>HNMT</i>	Histamine degradation gene
MAOIs	Monoamine oxidase inhibitors
SNAP-IV	Swanson, Nolan, and Pelham-IV questionnaire
TCA	Tricyclic antidepressants

### INTRODUCTION

Attention-deficit/hyperactivity disorder (ADHD) is one of the most commonly diagnosed childhood psychiatric disorders. In general, ADHD may display two types of symptoms: inattentive and hyperactive/impulsive types (see Table 1). Those with inattentive symptoms may display careless mistakes or can be easily distracted by external factors. Patients with ADHD who display symptoms of hyperactivity/impulsivity may have difficulty sitting still, may be unable to play quietly, or may blurt out answers before the teacher has finished asking the question.

Consequences of ADHD can include poor school and social functioning for the child. If left untreated, ADHD may lead to increased rates of not completing high school, unemployment, unwanted pregnancy,

sexually transmitted diseases, traffic accidents, and incarceration (References 1–3). In addition, increased rates of substance abuse and diagnosis of a major psychiatric disorder (e.g., bipolar, anxiety) have been cited in adults with ADHD (Reference 4). Having a child with ADHD can also create a significant amount of stress among caregivers and teachers. Finding the best pharmacologic agent to treat and manage symptoms, together with educational and behavioral therapies, is of utmost importance for this patient population. With many agents available, it is crucial that practitioners select the optimal medication(s) that may serve to appropriately treat symptoms while minimizing adverse events.

### EPIDEMIOLOGY

The prevalence of ADHD ranges from 3% to 20% in school-aged children, depending on the criteria and sample population used (Reference 5). However, it is estimated that the worldwide prevalence is 5%, although it appears to be almost 9% in the United States (References 6, 7). The differences in prevalence may be because of the ways in which studies classify “functional impairment” in their patients (Reference 8). Persistence into adolescence and adulthood may reach 85% and 31%, respectively (References 9, 10). The adult prevalence is estimated at 2.5% because it is believed that some patients “outgrow the disease,” undergo neurobiologic maturation, or find better coping mechanisms to adapt to the environment as they grow older (Reference 11). However, caution is warranted because some believe that patients do not really “outgrow the disease,” but rather, outgrow the diagnostic criteria set forth by the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed., text rev.) (DSM-IV) (References 12, 13).

### ETIOLOGY

There appears to be a genetic predisposition to ADHD. Studies have shown the heritability of ADHD is about 77% when at least one parent has ADHD (Reference 14). Several genetic/biologic markers in ADHD have been studied including the 480-bp allele, the dopamine transporter gene (*DAT1*), and the dopamine receptor genes (*DRDs*) (Reference 15). The gene with the strongest association in ADHD appears to be the 7-repeat allele of the dopamine receptor D4 gene (*DRD4*)

**Table 1. DSM-IV-TR Diagnostic Criteria for ADHD (Reference 21)**

“Persistent pattern of inattention and/or hyperactivity-impulsivity that is more frequently displayed and is more severe than is typically observed in individuals at comparable level of development.” Individual must meet criteria for either (1) or (2):

- 1) Six (or more) of the following symptoms of inattention have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

**Inattention**

- a) often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities
- b) often has difficulty sustaining attention in tasks or play activity
- c) often does not seem to listen when spoken to directly
- d) often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
- e) often has difficulty organizing tasks and activities
- f) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework)
- g) often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools)
- h) is often easily distracted by extraneous stimuli
- i) is often forgetful in daily activities

- 2) Six (or more) of the following symptoms of hyperactivity-impulsivity have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

**Hyperactivity**

- a) often fidgets with hands or feet or squirms in seat
- b) often leaves seat in classroom or in other situations in which remaining seated is expected
- c) often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
- d) often has difficulty playing or engaging in leisure activities quietly
- e) is often “on the go” or often acts as if “driven by a motor”
- f) often talks excessively

**Impulsivity**

- a) often blurts out answers before questions have been completed
- b) often has difficulty awaiting turn
- c) often interrupts or intrudes on others (e.g., butts into conversations or games)

- A. Some hyperactive-impulsive or inattentive symptoms must have been present before age 7 years.
- B. Some impairment from the symptoms is present in at least two settings (e.g., at school [or work] and at home).
- C. There must be clear evidence of interference with developmentally appropriate social, academic, or occupational functioning.
- D. The disturbance does not occur exclusively during the course of a Pervasive Developmental Disorder, Schizophrenia, or other Psychotic Disorders and are not better accounted for by another mental disorder (e.g., Mood Disorder, Anxiety Disorder, Dissociative Disorder, or a Personality Disorder).

Note: A new, highly anticipated version, the DSM-V, is expected in 2013 with possible changes in ADHD diagnosis, which include changing the “age of onset” from 7 to 12 and reclassifying the subtypes of symptoms (i.e., inattention, hyperactivity, impulsivity). ADHD = Attention-deficit/hyperactivity disorder; DSM-IV = Diagnostic and Statistical Manual of Mental Disorders (4th ed., text rev.). Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision, (Copyright 2000). American Psychiatric Association.

(Reference 16). However, this has been questioned because the association was still small, and there is yet to be an actual gene associated with ADHD (Reference 17). In addition, studies suggest that a genetic predisposition in patients predicts their treatment response (Reference 18). For example, those with a 9-repeat allele show poor response to methylphenidate treatment (Reference 18). Recent data also report that copy number variants, which are submicroscopic chromosomal abnormalities, may be implicated in ADHD (e.g., excess of 16p13.11 duplications) (Reference 19).

Environmental triggers associated with ADHD are countless and may include smoking during maternal pregnancy, lead exposure, low birth weight, and severe social deprivation during early infancy (Reference 8). Certain foods (e.g., chocolate, eggs, peanuts) and artificial colors or dyes (e.g., yellow #5, red #3, blue #1) may also exacerbate hyperactive symptoms of ADHD. Of interest, it has been hypothesized that a histamine degradation gene (*HNMT*) is responsible for hyperactive responses to food dyes (Reference 20).

## DIAGNOSIS

The main types of symptoms associated with ADHD include inattention and hyperactivity/impulsivity. The DSM-IV criteria for diagnosis further describe the common symptoms of ADHD, which are listed in Table 1. The literature on ADHD may classify patients as predominantly inattentive, predominantly hyperactive/impulsive, or combined type, in which the patient displays a combination of symptoms. Common features of inattention include difficulty organizing activities, sustaining attention, and following through on instructions as well as being easily distracted by extraneous stimuli (Reference 21). For example, young Debbie sits in the classroom but does not listen attentively in class or successfully complete her assignments, and she often misplaces her pencils and books (i.e., predominantly inattentive type). Hallmark features of hyperactivity include often fidgeting with hands or feet, leaving the seat in classroom, and having difficulty engaging in leisure activities quietly. Impulsive symptoms may also be present, which include having difficulty awaiting one's turn and interrupting others. For example, young Johnny disrupts the classroom by running around at inappropriate times, answering out of turn, and constantly talking with surrounding classmates (i.e., predominantly hyperactive/impulsive type). In addition, young Jamie has difficulty following directions when spoken directly to (e.g., does not follow orders), avoids completing assignments, talks excessively with classmates, and squirms excessively in the chair (i.e., combined type). Females tend to display inattentive symptoms, whereas males tend to display hyperactive symptoms (Reference 22).

As a result, by comparing the examples above (i.e., Debbie, Johnny), teachers and parents may be more prone to refer males (3:1) for diagnosis because hyperactivity will more likely disrupt the classroom or home setting. However, for a proper diagnosis, these behaviors must be present before age 7, occur in two or more settings (e.g., home, classroom), and cause significant impairment in the child's social and academic development.

## RATING SCALES

Several scales are used to measure ADHD symptoms (Reference 23). These scales primarily identify specific symptoms that can assist in diagnosing and identifying the subtypes of ADHD. The most commonly known scales include the Conners Rating Scales-Revised (CRS-R); IOWA Conners scale; Swanson, Nolan, and Pelham-IV questionnaire (SNAP-IV); and ADHD Rating Scale-IV (ADHD RS-IV). Newer scales, including the Vanderbilt ADHD Rating Scales (VARS) and the ADHD Symptoms Rating Scale (ADHD-SRS), have been developed to capture symptoms/manifestation of conduct disorders, anxiety, or depression (e.g., VARS) and to increase the subtlety of the ways in which ADHD affects social functioning (e.g., ADHD-SRS) (References 23, 24). The time required to complete the scales varies. Some scales such as the CRS-R, SNAP-IV, and ADHD-SRS may take 20–30 minutes to complete, whereas others such as the IOWA Conners, ADHD RS-IV, and VARS may take only 5–15 minutes to complete (Reference 23). All six scales can be completed by parents or teachers. Some scales (e.g., IOWA Conners, SNAP-IV, ADHD RS-IV, ADHD-SRS) may be divided into two or three subscales, whereas other scales (e.g., CRS-R, VARS) may have four to seven subscales (Reference 23). Of note, most of these scales were derived from criteria in the DSM-IV, therefore predominantly targeting male symptoms (Reference 23). Thus, caution is needed when using these scales to evaluate females.

## PATHOPHYSIOLOGY

The pathophysiology of ADHD is complex, showing overall decreased cerebral volume. Specific regions of the brain that consistently show a reduction in size in ADHD include the caudate nucleus, prefrontal cortex white matter, and cerebellar vermis (References 25, 26). Impairment of the prefrontal cortex and anterior cingulate cortex, which are responsible for controlling appropriate behaviors and inhibitions, appears to be the primary culprit in the manifestation of ADHD (References 8, 27, 28). It is theorized that a prefrontal cortex abnormality exists that causes a dysregulation of two primary neurotransmitters: dopamine and

norepinephrine. Dopamine appears to be active in the mesocortical pathways responsible for aspects of cognitive function including verbal fluency, serial learning, executive function, and sustaining attention (References 28, 29). Norepinephrine appears to be active in the prefrontal pathway responsible for mediating energy/fatigue, motivation, moderation of behavior on the basis of social cues, and sustaining of attention (Reference 29). Of note, unlike in other psychiatric illnesses (e.g., depression, schizophrenia, bipolar disorder), serotonin does not seem to play a major role in ADHD. As a result, selective serotonin reuptake inhibitors may be given to those with ADHD who also have a psychiatric comorbidity such as major depression; however, they are clinically useless in the treatment of ADHD.

## TREATMENT

### Nonpharmacologic Treatments

The best nonpharmacologic treatment available at this time appears to be behavioral therapy, usually given concomitantly with some form of educational session. Behavioral therapy attempts to eliminate or limit inappropriate behaviors by reinforcing desired behaviors. Some short-term studies have shown that behavioral therapy can improve ADHD symptoms, especially in the home environment when used with pharmacologic agents (Reference 30). However, it is not fully clear whether using behavioral therapy as adjunctive treatment will decrease medication dosage. Long-term (3-year) studies show that behavioral therapy may decrease future incidences of delinquency or substance abuse (Reference 31). Therefore, behavioral therapy may be considered monotherapy or adjunctive treatment to pharmacologic agents (Reference 32). Behavioral therapy may be used as monotherapy if symptoms are mild, ADHD diagnosis is unclear, or parents refuse pharmacologic agents (References 8, 32). However, therapy sessions can be costly, and insurance plans may only cover a limited number of sessions. In addition, there may be a lack of trained professionals (e.g., psychologists, psychiatrists) in certain parts of the country, and identifying a qualified therapist may not be possible.

Diets and certain herbal supplements to treat ADHD have been popular through the years. The Kaiser Permanente (also known as Feingold diet) or elimination diet, which works at eliminating foods containing synthetic additives (e.g., benzoate preservatives) or dyes, has been studied to evaluate its effectiveness in treating symptoms of ADHD (References 33–35). Some trials have shown a significant decrease in behaviors (e.g., hyperactivity) when elimination diets were used (Reference 33). However, the differences might not have been clinically significant and were only noted on the parents' rating scales, with no changes noted on

the health care providers' ratings. It also appears the improvement in behaviors occurred in all children despite ADHD diagnosis, leading to the belief that artificial food dyes and preservatives should be limited in all children (References 33, 34). In addition, elimination diets cause a widely varying response among patients, which may be caused by genetic variability (e.g., *HNMT*) (References 20, 33). Therefore, future pharmacogenomic testing may identify those with a higher sensitivity (e.g., greater hyperactive response) to certain foods or additives. Elimination diets may prove highly effective in a small selection of patients; however, these treatment options should not be used to replace prescription therapy (e.g., stimulants).

Most diets rich in omega-3 fatty acids have shown no greater efficacy than placebo (Reference 36). However, recent data suggest that a combination of essential fatty acids including eicosapentaenoic acid, docosahexaenoic acid, and  $\gamma$ -linolenic acid provides some benefits for inattention (Reference 35). The benefits of these fatty acids, although small, may not be seen for 3 months. Homeopathy has also been studied, and despite showing some improvements, data appear to be inconsistent and subject to interpretation. As a result, these interventions offer minor relief of symptoms in studies with weak methodologies and prone to bias (e.g., parents vs. physician rating scales) (References 8, 36). Therefore, at this time, vitamin-rich diets and homeopathy are not generally recommended, and further studies are needed.

Vitamins and herbals such as ginkgo biloba and ginseng have been used to improve attention, whereas zinc, valerian root, and lemon balm have been used for symptoms of hyperactivity/impulsivity (References 35, 37–40). Data supporting other agents (e.g., St. John's wort, L-carnitine, Pycnogenol) are weak (References 35, 37). Despite some benefits in open-label studies (e.g., zinc), adverse events are inadequately measured in most of these studies, and most are subject to bias. In addition, they provide few benefits, and the ingredients are not standardized or monitored by the U.S. Food and Drug Administration (FDA), therefore possibly leading to undesirable consequences (References 8, 40). In conclusion, the use of herbal supplementations should be avoided in the treatment of ADHD.

### Pharmacologic Treatments

#### *Treatment Guidelines*

The Texas Children's Medication Algorithm project revised the ADHD guidelines in 2006 (Reference 32). However, as new data are disseminated, guidelines for ADHD are revised and updated. Table 2 is a guideline based on new data and differs slightly from other guidelines (Reference 32). Of note, any of these stages can be skipped, if necessary. If partial response occurs at a

particular stage, some agents may be added adjunctively, as previously discussed. In addition, remember that behavioral therapy may be added during any stage. Primary comorbidities of other psychiatric conditions (e.g., Tourette syndrome, psychosis, major depression) may require different pharmacologic treatment guidelines.

### Stimulants

Stimulants are controlled substances (C-II) that have been used extensively for many years. Stimulants are separated into two classes: amphetamines and methylphenidate products. Stimulants are considered first-line agents for the treatment of ADHD, with a response rate of 65% to 75% in double-blind placebo-controlled studies or as high as 90% in other trials (References 41, 42). When both types of stimulants are tried, efficacy rates increase to 85% to 90% (References 41, 42). Despite some minor differences in the actual mechanism of action, stimulants are theorized to work by increasing norepinephrine and dopamine concentrations through reuptake inhibition. Methylphenidate is believed to occupy dopamine transporters, resulting in dopamine reuptake inhibition, which causes  $D_1$ -receptor activation (References 43, 44). In addition, recent data indicate that methylphenidate occupies norepinephrine transporters, thereby increasing norepinephrine and dopamine (norepinephrine transporters actually have more affinity toward dopamine) in the prefrontal cortex (Reference 45). Amphetamines increase

the release of dopamine through an exchange mechanism (sodium-dependent transport protein) and by binding to dopamine transporter proteins on the exterior of the cell membrane, causing dopamine reuptake inhibition (Reference 44). In addition, amphetamines presynaptically block the reuptake of norepinephrine, thereby increasing the concentration in the synaptic cleft (Reference 44).

At this time, no clinical preference exists regarding the stimulant that should be initially selected. Stimulants exist in a variety of formulations, and generics are readily available (see Table 3). Therefore, the selection of an agent will depend on these characteristics. Onset of action with stimulants can range from 15 to 120 minutes, and duration ranges from 3 to 12 hours, depending on the formulation (References 8, 46). When selecting an agent, the formulation should be carefully considered. Children weighing less than 16 kg should be routinely initiated on short-acting stimulants (References 41, 46). Overall, if symptoms are targeted that occur mostly in school, a short-acting agent is preferred. If problems persist after school (e.g., difficulty studying, completing homework), another dose of the short-acting agent can be used. However, this may cause medication burden on teachers or caregivers, especially if the child has difficulty taking the medication in the first place (References 8, 24). Therefore, it is usually better to change to an intermediate-acting formulation. If ADHD symptoms occur at all times, then a long-acting

**Table 2.** Pharmacologic Treatment Guideline

Stage 1	Stimulants: Methylphenidate or amphetamine products
	Note: Although some may prefer to start with methylphenidate because of its possibly lower adverse effects, others may choose to start with amphetamines because of more favorable kinetics.
Stage 2	Stimulant class not used in stage 1
Stage 3	Atomoxetine
Stage 4	Bupropion or guanfacine
	Note: Bupropion may be preferred if a secondary comorbidity of depression exists. Guanfacine may be preferred if tics are an issue. Practitioners may prefer the extended-release formulation of guanfacine, but costs may hinder its use.
Stage 5	Agent not used in stage 4
Stage 6	TCA or Clonidine
	Note: A TCA may be preferred if a secondary comorbidity of depression exists. Clonidine may be preferred if tics are an issue. Practitioners may prefer an extended-release formulation of clonidine, but costs may hinder its use.
Stage 7	Agent not used in stage 6

TCA = tricyclic antidepressant.

**Table 3.** Pediatric Pharmacologic Treatment of ADHD—Stimulants (References 8, 41, 46)

	Brand Name (generic)	Dosage Forms (mg)	Duration of Action (hr)	Initial Dose (mg); Maximal Daily Dose (mg)	Daily Dosing Range (mg)
Amphetamine Products	Adderall (amphetamine/dextroamphetamine)	Tablets (5, 7.5, 10, 12.5, 15, 20, 30)	Intermediate acting (4–6)	3–5 yr: 2.5 QAM ≥ 6 yr: 5 QD or 2.5 BID Maximal dose: 40	10–40
	Adderall XR (amphetamine/dextroamphetamine)	Capsules (5, 10, 15, 20, 25, 30)	Long acting (8–12)	6–17 yr: 10 QAM Maximal dose 6–12 yr: 30	5–30
	Dexedrine Spansule (dextroamphetamine)	Spansules (5, 10, 15)	Intermediate acting (5–8)	≥ 6 yr: 5 QAM-BID Maximal dose: 40	5–40
	Dextrostat/Dexedrine (dextroamphetamine)	Tablets (5, 10)	Short acting (3–5)	3–5 yr: 2.5 QAM ≥ 6 yr: 5 QAM-BID Maximal dose: 40	0.1–0.5 mg/kg/dose
	Vyvanse (lisdexamfetamine)	Capsules (20, 30, 40, 50, 60, 70)	Long acting (10–12)	≥ 6 yr: 30 QAM Maximal dose: 70	30–70
Methylphenidate Products	Ritalin (methylphenidate)	Tablets (5, 10, 20)	Short acting (3–5)	≥ 6 yr: 5 BID Maximal dose: 2 mg/kg or 60	10–60
	Ritalin SR (methylphenidate SR)	Tablets (20)	Intermediate acting (3–8)	≥ 6 yr: 20 QAM Maximal dose: 60	20–60
	Ritalin LA (methylphenidate LA)	Capsules (10, 20, 30, 40)	Long acting (8–12)	≥ 6 yr: 20 QAM Maximal dose: 60	20–60
	Methylin (methylphenidate)	Solution 5 mg/5 mL, 10-mg/5-mL Tablets (5, 10, 20) Chewable tablets (2.5, 5, 10)	Short acting (3–5)	≥ 6 yr: Tablet: 5 mg BID before breakfast and lunch Solution: 0.3 mg/kg/dose BID Chewable tablet: 2.5 BID Maximal dose: 2 mg/kg/day or 60	Tablet: 10–60 Solution: 10–60 Chewable tablet: 0.5–1 mg/kg/day
	Methylin ER (methylphenidate ER)	Tablets (10, 20)	Intermediate acting (3–8)	≥ 6 yr: 10 QAM Maximal dose: 60	10–60
	Metadate ER (methylphenidate ER)	Tablets (20)	Intermediate acting (3–8)	≥ 6 yr: 20 QAM Maximal dose: 60	20–60
	Metadate CD (methylphenidate CD)	Capsules (10, 20, 30, 40, 50, 60) Bimodal drug release 30% IR, 70% ER	Long acting (8–12)	≥ 6 yr: 20 QAM Maximal dose: 60	10–60
	Concerta (methylphenidate OROS)	Tablets (18, 27, 36, 54) Bimodal drug release (OROS) 22% IR 78% ER	Long acting (8–12)	≥ 6 yr: Not currently taking methylphenidate: Concerta 18 QAM Currently taking methylphenidate 5 BID-TID or 20 ER QAM: Concerta 18 QAM Currently taking methylphenidate 10 mg BID-TID or 40 ER QAM: Concerta 36 QAM Currently taking 15 BID-TID or 60 ER QD: Concerta 54 QAM Currently taking 20 BID-TID: Concerta 72 QAM	6–12 yr: 18–54 13–17 yr: 18–72
	Daytrana (methylphenidate)	Transdermal patch 10 mg/9 hr, 15 mg/9 hr, 20 mg/9 hr, 30 mg/9 hr	Long acting (12) wear for 9 hr only	6–17 yr: 10-mg patch daily—wear for up to 9 hr Maximal dose: 30 mg/9 hr	10–30 patch/9 hr
	Focalin (dexmethylphenidate)	Tablets (2.5, 5, 10)	Short acting (3–5)	2.5 BID Maximal dose: 20	5–20
Focalin XR (dexmethylphenidate)	Capsules (5, 10, 15, 20, 30) Bimodal drug release 50% IR, 50% ER	Long acting (8–12)	5 QAM Maximal dose: 30	10–30	

BID = twice daily; CD= controlled delivery of the modified release formulation; CR = controlled release; hr = hour(s); ER/XR = extended release; IR = immediate release; LA = long acting; OROS =osmotic release oral system; QAM = every morning; QD = every day; SR = sustained release; TID = three times/day; yr = year(s).

formulation is preferred (Reference 24). In addition, if a child cannot tolerate short-acting formulations, he or she may be changed to an intermediate- or long-acting formulation because either of these would provide lower peak concentrations and/or possibly decrease the number or severity of adverse effects (e.g., tics, nausea). However, the intermediate- and long-acting formulations may take about 1 hour longer than the short-acting agents before efficacy is seen. Therefore, short-acting agents can sometimes be combined with long-acting formulations to provide extra coverage during a specific period (e.g., school hours) (Reference 46). Conversely, if a child is taking a long-acting formulation and he or she is having difficulty sleeping or eating properly, he or she may be changed to an intermediate- or short-acting agent dosed in the morning; therefore, the medication will be mostly eliminated by evening. This should allow the child to eat a large-calorie meal for dinner and sleep better. Stimulants are usually initiated at low doses and titrated to appropriate efficacy for 2–4 weeks or until unwanted adverse effects occur (Reference 24). After selecting a stimulant, careful dose evaluation over time must be noted as the child grows older. If discontinuing stimulants, tapering is usually not required.

Drug interactions among stimulants exist. Because stimulants increase the amount of monoamines (e.g., dopamine, norepinephrine) into the synaptic cleft, they should not be administered concomitantly or within 2 weeks of discontinuing a monoamine oxidase inhibitor (MAOI) (Reference 47). Amphetamines are primarily metabolized by cytochrome P450 (CYP) 2D6 (References 8, 47). Therefore, caution is warranted if strong CYP2D6 inhibitors are used (e.g., desipramine, paroxetine, fluoxetine) because they may increase amphetamine concentrations and increase the potential for cardiac complications (References 8, 47). Conversely, methylphenidate is metabolized by de-esterification and does not undergo oxidative metabolism. However, the combination of methylphenidate and tricyclic antidepressants (TCAs) may lead to an increase in TCA concentrations through an unknown mechanism (Reference 47). The literature mainly focuses on increased imipramine concentrations with methylphenidate; however, no interactions between desipramine and methylphenidate have been reported (References 47, 48).

### *Adverse Events*

Common adverse effects among stimulants include headaches, dizziness, nausea, reduced appetite, weight loss (about 3 kg during the first year; about 1 kg during the second year), stomach pain/cramps, irritability, and insomnia. When addressing appetite suppression/weight loss, it is recommended to give a high-fat meal in the evening when stimulant effects are lower. Giving a high-fat meal (e.g., during the day) with a stimulant

may also be a way to decrease stomachache or nausea; however, certain formulations may have altered kinetics when given with food (Reference 49). For example, amphetamine/dextroamphetamine (e.g., Adderall) may show more than a 50% reduction in plasma concentrations when given with a high-calorie meal (Reference 49). Overall, increases in blood pressure (about 2–7 mm Hg) and heart rate (about 5 beats/minute) are also noted with stimulants in the literature (References 50–53).

Rare but severe adverse events include increased blood pressure and tics. These adverse events may be treated by lowering/splitting the dose or switching agents. Black box warnings for stimulants include sudden death caused by heart-related problems and new/worsening psychiatric manifestations (References 54, 55). Sudden death has been reported in around 35 pediatric patients (Reference 41). Unknown structural defects are believed to have accounted for these deaths. The risk of sudden death is estimated at 0.2 and 0.5 per 100,000 children for methylphenidate and amphetamine products, respectively (Reference 56). The risk of sudden death in the general untreated population is 0.6–6 (Reference 57). There is debate on whether baseline electrocardiograms should be required. However, at this time, the American Academy of Pediatrics recommends that practitioners obtain the patient's history and physical examination before initiating therapy (Reference 55). Psychiatric complications such as mania, hallucinations, aggression, anxiety, and dysphoria are rare but potentially dangerous. The FDA recommends that children who display any psychiatric complications be discontinued on or tapered off the stimulant as quickly as possible.

Growth suppression is highly noted among stimulant use. Among 29 studies, estimated growth suppression of 1 cm/year during the first 3 years occurs with stimulants (Reference 58). It is suggested that amphetamines cause a slightly greater effect on growth suppression than methylphenidate (Reference 59). A drug holiday (e.g., during the summer) may be recommended, but an assessment of risk versus benefit for the child should be done (Reference 8). If a drug holiday is initiated, do not reinstate treatment at the beginning of the school year. Instead, start a few weeks before to allow the child and parent to readjust and make any dosing changes, if necessary. Remember, the child may grow/gain weight during the drug holiday and therefore may need a dose adjustment.

### *Amphetamine Products*

Amphetamine products include amphetamines, dextroamphetamines, and lisdexamfetamine, which is a prodrug to dextroamphetamine. Short-acting amphetamine products include Dextrostat and Dexedrine. Intermediate-acting products include Adderall and

Dexedrine Spansule. Long-acting formulations include Adderall XR and Vyvanse (References 8, 46). Advantages over methylphenidate products may include more predictable kinetics. In addition, formulations such as Dexedrine Spansule, Adderall XR, or Vyvanse can be opened if the child cannot swallow tablets (References 8, 46). However, the contents should not be poured over hot food. Vyvanse, a prodrug of dextroamphetamine, may have less abusive potential than other amphetamines because of its longer onset of action (Reference 60). General disadvantages of amphetamines over methylphenidate products include possible greater abuse potential, slightly higher rate of causing/worsening tics, and greater growth suppression.

### *Methylphenidate Products*

Methylphenidate products include methylphenidate and dexmethylphenidate. Short-acting methylphenidate products include Ritalin, Methylin, and Focalin. Intermediate-acting products include Ritalin SR, Methylphenidate SR, Methylin ER, and Metadate ER (References 8, 46). Long-acting formulations include Concerta, Metadate CD, Ritalin LA, Focalin XR, and Daytrana. Daytrana (patch) should be rotated daily at different sites. Advantages over amphetamines may include less likelihood to suppress appetite, worsen tics, and cause insomnia. Formulations such as Ritalin LA, Metadate CD, and Focalin XR may also be opened (Reference 8). General disadvantages of methylphenidate products may include more erratic kinetics, especially with short-acting agents, and greater differences reported between brand and generic formulations (Reference 46). In addition, caution with gastrointestinal obstruction may be needed with Concerta, and parents should be counseled that the capsule will appear intact in the stool (Reference 46).

### *Non-stimulants*

#### *Atomoxetine*

Atomoxetine is a non-stimulant, non-controlled agent that is FDA approved for the treatment of ADHD (Reference 61). It acts by selectively inhibiting the presynaptic reuptake of norepinephrine. Clinical trials have shown that atomoxetine is between 63% and 80% effective and can treat all symptoms of ADHD (References 61, 62). It also appears to be around 55% effective in patients whose stimulant therapy has failed (Reference 63).

Atomoxetine is usually initiated at 0.5 mg/kg/day and titrated to reach a target daily dose of 1.2 mg/kg (see Table 4). Titration should occur over a minimum of 3 days, with most waiting at least 1–2 weeks before titrating. Dosing can be increased to a maximum of 1.8 mg/kg/day. Efficacy may not be seen for 2–4 weeks, and some data suggest 6 weeks is needed for optimal

benefits (References 41, 61, 62). Some patients may respond to the lower doses, whereas others may benefit from higher doses. Therefore, patience is warranted when this agent is titrated. Atomoxetine is considered a second-line agent after stimulants have failed. It can be used as monotherapy or in combination with other agents (Reference 32). It may also be preferred in those who have high abuse potential, those who are afraid of using stimulants, and those with the possible comorbidity of anxiety (Reference 41).

Atomoxetine can be administered once or twice daily. When considering once-daily dosing, there is debate regarding whether to administer in the morning or at bedtime (Reference 42). Single bedtime dosing may be used for those who are having difficulties with adverse effects (especially sedation); however, drug concentrations may be low by the morning, thus limiting its efficacy. Morning doses will provide higher concentrations in the morning, thereby increasing efficacy, but they may predispose patients to higher adverse effects. Therefore, most providers choose twice-daily dosing because of more stable plasma concentrations and possibly better tolerability. Atomoxetine can also be taken with or without food and can be discontinued without tapering.

Atomoxetine is highly metabolized by the CYP2D6 pathway (Reference 61). The half-life of atomoxetine is about 5 hours, but in poor metabolizers, it can be as long as 20 hours. As a result, plasma concentrations can increase 5- to 10-fold in poor metabolizers, and dose adjustment is warranted (Reference 61). In addition, dose adjustment or slower titration may be needed with the coadministration of other potent CYP2D6 inhibitors such as paroxetine and fluoxetine (Reference 61). Of note, atomoxetine is highly protein bound (98%); therefore, interactions with other highly protein-bound drugs are possible, although data are lacking in this area. Finally, atomoxetine should not be administered with MAOIs, and a minimum of 2 weeks is needed before initiating atomoxetine after MAOI discontinuation or vice versa.

Common adverse events of atomoxetine include abdominal pain (18%), decreased appetite (16%), vomiting (12%), somnolence (10%), irritability (7%), fatigue (7%), dizziness (5%), and dyspepsia (5%) (Reference 61). Somnolence, fatigue, and dizziness are more common with atomoxetine than with a stimulant. An increased heart rate of about 8 beats/minute and mild increased blood pressure (around 2–3 mm Hg) are also noted with atomoxetine (Reference 61). However, studies show the adverse effects are usually mild and well tolerated, with discontinuation rates caused by adverse events between 4% and 10% (Reference 61). Growth suppression is about 0.4 cm during a 2-year period, which is smaller than that with stimulants (Reference 64). Black box warnings for atomoxetine include hepatic failure (two cases occurred: one adult, one

**Table 4.** Pediatric Pharmacologic Treatment of ADHD—Non-stimulants (References 8, 41, 46, 61, 69–71, 74)

	Brand Name (generic)	Dosage Forms (mg)	Initial Dose (mg); Maximal Daily Dose (mg)	Daily Dosing Range (mg)	Special Notes
NE Selective Agonist	Strattera (atomoxetine)	Capsules 10, 18, 24, 40, 60, 80, 100	≥ 6 yr ≤ 70 kg: 0.5 mg/kg/day; maximum: 1.4 mg/kg/day > 70 kg: 40 QD; maximal dose: 100	≤ 70 kg: 1.2 mg/kg/day > 70 kg: 80	FDA approved, norepinephrine reuptake inhibitor. Carry less weight/growth concerns vs. stimulants.
DA/NE Antidepressant	Wellbutrin (bupropion)	Tablets 75, 150 Extended release 150, 300 Sustained release 100, 150, 200	≥ 6 yr: 1.4–6 mg/kg/day; maximal dose: 300	50–300	Dopamine and norepinephrine reuptake inhibitor. Can worsen tics, irritability.
α <sub>2</sub> Adrenergic Agonists	Intuniv (guanfacine)	Tablets, extended release 1, 2, 3, 4	≥ 6 yr: 1 AM; maximal dose: 4	1–4	FDA approval for Intuniv/Kapvay. Adjust Intuniv in increments of no more than 1 mg/week. Intuniv and Kapvay are long-acting formulations. Sedation may be helpful for sleep. Agents helpful for tic comorbidities. In children, wearing patch for 5 days = 7 duration of action.
	Tenex (guanfacine)	Tablets, short acting 1, 2	≥ 6 yr: 0.5–1 HS; maximal dose: 27–40 kg: 2 41–45 kg: 3 > 45 kg: 4	1–3	
	Kapvay (clonidine)	Tablets, extended release 0.1	0.1 HS; maximal dose: 0.4	0.1–0.4	
	Catapres (clonidine)	Tablets 0.1, 0.2, 0.3 Patch (TTS) 0.1/24 hr, 0.2/24 hr, 0.3/24 hr	≥ 6 yr: < 45 kg: 0.05 HS > 45 kg: 0.1 HS; maximal dose: 27–40 kg: 0.2 41–45 kg: 0.3 > 45 kg: 0.4	0.1–0.4	
Tricyclic Antidepressants	Pamelor (nortriptyline)	Capsules 10, 25, 50, 75	≥ 6 yr: 0.5 mg/kg/day; maximal dose: 100	50–100	Give in divided doses with higher dose at bedtime. Sedation may be helpful for sleep. Sudden death reported with desipramine (consider TCAs last line).
	Tofranil (imipramine)	Capsules 75, 100, 125, 150 Tablets 10, 25, 50	≥ 6 yr: 1 mg/kg/day; maximal dose: 200	75–200	
	Norpramin (desipramine)	Tablets 10, 25, 50, 75, 100, 150	6–12 yr: 1 mg/kg/day; > 12 yr: 25–50 maximal dose: 150	25–150	

DA = dopamine; HS = at bedtime; NE = norepinephrine; QD = every day; TCA = tricyclic antidepressant.

teenager, both fully recovered), new-onset suicidal ideations (0.4%), and sudden death caused by heart complications (risk 0.5/100,000) (References 41, 62). Abuse potential is also much lower than with stimulants.

Atomoxetine is only available in capsule form, and at this time, no generic formulation exists. Although the manufacturer of atomoxetine (Eli Lilly) states the capsule cannot be opened, the data on file suggest the contents

may be dissolved in 60 mL of juice (i.e., Tropicana 100% apple juice, Welch's 100% grape juice, fruit punch-flavored Gatorade). After waiting 5 minutes for dissolution to occur, it may be stable at room temperature for 6 hours. However, atomoxetine has a very bitter taste that, despite attempts to mask, may cause an increase in gastrointestinal complications. In addition, atomoxetine is an ocular irritant, so extreme caution is warranted when handling.

### *Bupropion*

Bupropion is a norepinephrine and dopamine reuptake inhibitor used off-label for the treatment of ADHD. The usual starting dose for ADHD treatment is about 1.5 mg/kg/day, with titration over 7 days to a target dose of 3 mg/kg/day; however, it may be titrated to 6 mg/kg/day not to exceed 300 mg/day (see Table 4) (References 8, 65). Efficacy rates range from 60% to 70%, mostly treating symptoms of hyperactivity. Bupropion can be given once or twice daily; however, data suggest twice-daily dosing is more tolerable and efficacious (Reference 66). Most common adverse events reported include nausea, irritability, and insomnia (References 8, 67). In addition, rash has been reported in a few cases (Reference 67). There are some reports of decreased appetite, but they appear to be less severe compared with stimulants. However, tremors (e.g., tics) may also manifest, and seizures may occur in doses exceeding 400–450 mg/day (Reference 46). Efficacy is not seen for a minimum of 2 weeks at the therapeutic doses, and it may take up to 6 weeks for optimal results to be seen. Bupropion is contraindicated in those with seizure or eating disorders (e.g., bulimia, anorexia), and it carries a black box warning for new-onset suicidality (Reference 46). Bupropion may have utility in those who have a comorbidity of depression or in patients who are high-risk substance abusers (Reference 32). It can be used adjunctively or as monotherapy after first- and second-line agents have failed. Currently, it may be preferred over TCAs because of its safer cardiovascular profile and better tolerability compared with TCAs.

Bupropion is available as immediate release, and various extended-release formulations and generic alternatives exist. Bupropion, similar to other antidepressants, should not be administered with MAOIs, and a minimum of 2 weeks is needed before initiating bupropion after MAOI discontinuation or vice versa. Tapering of bupropion is recommended if it is being discontinued.

### *Tricyclic Antidepressants*

Antidepressants known as TCAs have been studied for ADHD. Even though TCAs are serotonin and norepinephrine reuptake inhibitors, the primary neurotransmitter involved in the treatment of ADHD with these agents is norepinephrine (Reference 44). Recall that serotonin does not play a role in ADHD, which is why selective serotonin reuptake inhibitors are ineffective. Imipramine, nortriptyline, and desipramine are the most commonly used TCAs. However, desipramine has been associated with cardiac-related sudden death in pediatric patients and is generally avoided (Reference 41). The usual starting dose for treatment of ADHD is 0.5–1 mg/kg/day with titration to 2–3 mg/kg/day up to a maximum of 2–4 mg/kg/day (see Table 4) (Reference 41). Therapeutic range is usually between 50 and 150

mg/day, and doses are usually divided into two or three daily doses. Efficacy rates among TCAs are about 70%, mostly targeting symptoms of hyperactivity. Benefits are not seen for at least 2 weeks, and maximal efficacy may not be reached for at least 4 weeks.

The most common adverse effects are sedation, dizziness, constipation, and weight gain (References 41, 44). Caution with heart complications (e.g., increased heart rate) and cardiac toxicity is warranted. As a result, an electrocardiogram should be done at baseline and with each dose increase (Reference 41). Tricyclic antidepressants also carry a black box warning for new-onset suicidality, similar to all antidepressants. Because of the adverse event profile of TCAs, they are usually reserved as third-line agents. They may be used adjunctively and may have utility in patients with comorbidity of tic disorders, depression, or enuresis. Tricyclic antidepressants are available as capsules, tablets, and solution. These agents should not be administered with MAOIs, and a minimum of 2 weeks is needed before initiating a TCA after MAOI discontinuation or vice versa. If discontinuing, tapering of these agents is recommended.

### *$\alpha_2$ -Adrenergic Agonists*

Guanfacine and clonidine are the two most commonly used  $\alpha_2$ -agonists used to treat ADHD (see Table 4). Most data suggest that these agents primarily block norepinephrine presynaptically; however, some studies also support the postsynaptic blockade of norepinephrine (Reference 44). These agents may also increase blood flow to the prefrontal cortex (Reference 68).

Guanfacine and clonidine have been used for many years with documented efficacy. Extended-release tablet formulations have recently become available in an attempt to offer greater adherence, less kinetic fluctuations, and better tolerability (References 69, 70). Even though the extended-release formulations are supposed to offer greater tolerability than the immediate-release formulations, adequate studies are lacking to compare the formulations of these agents (Reference 71). Currently, both guanfacine (i.e., Intuniv) and clonidine extended release (i.e., Kapvay) have FDA indications as monotherapy or adjunctive therapy for ADHD. Of note, deaths have been reported with the coadministration of clonidine and immediate-release stimulants; this coadministration should therefore be avoided (Reference 46). Optimal efficacy may not be reached for at least 2–4 weeks with these agents (Reference 69). Despite data showing efficacy in all symptoms of ADHD, there appears to be more efficacy toward hyperactivity/impulsivity. These agents may be especially useful in those who have a comorbidity of tics and aggressive/oppositional disorders. In addition, these medications should be tapered by weekly increments if they are to be discontinued (Reference 69).

## GUANFACINE

Guanfacine is metabolized and eliminated equally (50/50) by hepatic and renal elimination (References 71, 72). It is primarily metabolized by CYP3A4. Immediate-release formulations may be initiated at 0.5 mg/day or twice daily and may be increased to 1–4 mg/day in divided doses (References 8, 69). The extended-release formulation is initiated at 1 mg/day and titrated weekly by 1 mg/day to a target of 2–4 mg/day (Reference 71). Even though the extended-release formulation of guanfacine should not be crushed, the short-acting formulation may be crushed. High-fat meals should be avoided with the extended-release formulation because of increased exposure. Efficacy rates range from 60% to 80%, and adverse effects include somnolence (about 40%), headache (about 25%), fatigue (about 15%), upper abdominal pain (about 10%), hypotension (about 8%), irritability (6%), nausea (about 6%), and dizziness (about 6%) (References 69, 71). Serious less-frequent adverse events include syncope (2%) and convulsions (0.4%). Most of the adverse events appear to be dose related (References 69, 70, 73). Guanfacine may be theoretically preferred to clonidine because of its longer half-life and its higher selectivity at the  $\alpha_{2a}$ -receptor, thereby leading to less dizziness and sedation (Reference 8). However, no comparison studies exist at this time.

## CLONIDINE

Clonidine is 40% to 50% hepatically metabolized and 50% to 60% renally eliminated. Immediate-release formulations may be initiated at 0.05 mg/day and titrated weekly by 0.05 mg/day to a target of 0.1–0.4 mg/day in divided doses two to four times/day. The extended-release formulation is initiated at 0.1 mg and titrated weekly by 0.1 mg to a target of 0.2–0.4 mg/day (Reference 74). Twice-daily dosing is still needed for extended-release clonidine, especially with doses greater than 0.1 mg, with the higher dose given in the evening (Reference 75). Efficacy rates range from 60% to 70%; adverse events are similar to those of guanfacine and appear to be dose related. The short-acting formulation of clonidine may be crushed; however, the extended-release formulation should not be crushed or chewed. Food has no effect on any formulation. Moreover, be aware that the weekly patch is effective for 5 days in children compared with 7 days in adolescents.

### *Miscellaneous Agents*

Other agents for the treatment of ADHD have been used, including modafinil, mood stabilizers, and antipsychotics. Modafinil (commonly used for narcolepsy) at 300 mg (dose daily or in divided doses) has shown some benefits over placebo, but the quality of the data is regarded as low (Reference 36). In addition, adverse

effects such as severe rashes and psychiatric complications make this agent a last-line alternative. Those with a comorbidity of bipolar or severe aggressive behaviors may be treated with divalproex or carbamazepine (Reference 8). Low-dose antipsychotics may also be used; of these, most of the literature is focused on haloperidol, risperidone, and quetiapine. These agents should be used with caution and reserved as last-line agents.

## CONCLUSIONS

Behavioral therapy used with educational sessions appears to be the best nonpharmacologic treatment. Elimination diets may be useful in a few patients; however, such diets should not be used to replace pharmacotherapy. Studies with vitamins and herbal products have shown some possible benefits; nevertheless, most trials are subject to bias, and adverse events have not been adequately addressed or evaluated. As a result, the primary treatment of ADHD focuses on pharmacotherapy with prescription medications. There are many pharmacologic agents and formulations (e.g., short, long acting) to choose from in the treatment of ADHD. Stimulants (i.e., amphetamines, methylphenidate) are considered first line and have a much faster onset and higher efficacy rates than non-stimulants. Atomoxetine is a non-controlled agent that may be used as an alternative in those whose response to stimulants is partial or has failed or in those who refuse to use a controlled substance. Literature suggests antidepressants (e.g., bupropion, TCAs) can be considered treatment options, especially in those with depressive symptoms. However, bupropion is preferred because of its tolerable and safer adverse effects. An increase in data indicates that  $\alpha_2$ -agonists, especially with long-acting formulations, have shown good efficacy and may be considered alternative agents in ADHD. Among  $\alpha_2$ -agonists, it appears guanfacine is the preferred agent because of its higher selectivity to receptors and the availability of a daily formulation. Miscellaneous agents (e.g., mood stabilizers, antipsychotics) may be used if the comorbidity of other psychiatric illnesses is present. Despite the agent chosen, careful monitoring is recommended for any changes in efficacy or for the development of rare but potentially serious adverse events.

# CHAPTER 31

## EATING DISORDERS IN CHILDREN AND ADOLESCENTS

Cherry W. Jackson, Pharm.D., FASHP, BCPP

### LEARNING OBJECTIVES

1. Outline the clinical presentation of anorexia nervosa, bulimia nervosa, and binge eating disorder.
2. Describe medical complications associated with eating disorders.
3. Outline diagnostic criteria for eating disorders.
4. Discuss pharmacologic and nonpharmacologic treatments for eating disorders.
5. Understand the limitations of current diagnostic criteria and eating disorder research.

### ABBREVIATIONS IN THIS CHAPTER

AN	Anorexia nervosa
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
CBT	Cognitive behavioral therapy
DSM-IV-TR	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , Fourth Edition, Text Revision
DSM-V	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , Fifth Edition
EDNOS	Eating disorder not otherwise specified
FBT	Family-based therapy
GI	Gastrointestinal
IPT	Interpersonal psychotherapy
SSRI	Selective serotonin reuptake inhibitor

### INTRODUCTION

Eating disorders in children and adolescents are complex disease states associated with high rates of morbidity and mortality. The number of children and adolescents with eating disorders has increased steadily during the past 60 years (References 1–3), whereas the age of onset has steadily declined (References 1, 4, 5). Hospitalizations for children younger than 12 years with diagnoses of eating disorders have increased by 119% since the late 1990s (Reference 5). The typical patient with an eating disorder

has changed as well. At one time, eating disorders were considered an illness seen primarily in wealthy young white women; now, these disorders are increasingly seen in minorities (References 6–8), in males (References 9, 10), and in countries where eating disorders were once relatively unknown (References 11, 12).

### Epidemiology

Recognizing and treating eating disorders at their earliest stage is imperative to achieve positive outcomes in these disorders. According to NHANES (the National Health and Nutrition Examination Survey), the 12-month prevalence rate of eating disorders, based on the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR), is 0.1% (Reference 13). The prevalence of the two most common eating disorders, anorexia nervosa (AN) and bulimia nervosa (BN), was equivalent (0.1%).

A challenge to the current prevalence data is that most children and many adolescents do not meet the DSM-IV-TR criteria for eating disorders, so they are either undiagnosed or are given a diagnosis of eating disorder not otherwise specified (EDNOS). The prevalence of EDNOS is between 0.8% and 14% (Reference 14). The EDNOS is not a lesser form of the eating disorders, and it should be treated promptly and aggressively, if necessary. Interventions occurring at an earlier stage of these potentially life-threatening disease states are associated with an improved prognosis (Reference 15).

### Etiology

The etiology of the various eating disorders is still unknown, but it appears certain that many factors contribute to the development of an eating disorder (Reference 16). Although debated, dieting, especially severe dieting, may lead to the onset of these disorders (References 15, 17). Other etiologic factors include genetics, biologic and psychological predispositions, and environmental, social, and cultural factors.

Social, cultural, and environmental factors regarding what an ideal weight and shape are and their relationship to what is culturally considered beautiful often influence the way females think and feel about their bodies. Dieting is not uncommon in industrialized countries; in fact, most women admit that they have attempted a diet. Although diet is considered an

entry point into the development of an eating disorder, less than 3% of all females will actually develop an eating disorder (Reference 17). In one study, severe dieters were 18 times more likely to develop an eating disorder than were non-dieters (Reference 18). In nations that are less industrialized and less exposed to Western culture, the prevalence of eating disorders is much lower (Reference 19).

Studies of twins and families with at least one member having an eating disorder suggest a genetic link in the development of eating disorders. Studies of monozygotic and dizygotic twins have shown high concordance rates, although the studies themselves have shown differing results. Some studies have shown that the greatest concordance is between monozygotic twins, whereas others have shown higher rates with dizygotic twins (References 20–23). In families having at least two members with either AN or BN, genomic studies show initial linkage regions on chromosomes 1, 3, and 4 in AN and on chromosome 10p in BN. Additional genomic studies are being conducted (Reference 24). Together with the genetic risk, it is believed that psychological factors may influence eating disorder development. Traits such as perfectionism, inflexibility, a drive to be thin, a need for control, and interpersonal distrust have all been proposed as factors that affect the onset of eating disorders (Reference 25). Traits that are common in eating disorders are also associated with several psychiatric conditions. The incidence of depression and other mood disorders is 50% to 80% in patients with both AN and BN. There is a 30% to 65% incidence of anxiety, especially obsessive compulsive disorder, and a 20% to 80% incidence of personality disorders, especially borderline personality disorder, in patients with AN and BN (Reference 22).

The neurotransmitters serotonin, dopamine, and norepinephrine increasingly appear to play a role in the etiology of eating disorders. Serotonin is known to play a role in appetite, mood, and stress response. Serotonin antagonists increase food cravings and intake, which leads to weight gain. The serotonin metabolite 5-hydroxyindoleacetic acid is often found to be low in those who are underweight, but the level corrects itself once normal weight is achieved (References 26–28). In patients who have recovered from AN, norepinephrine is lower than the level that exists in control populations (Reference 29). Dopamine may also be related to eating disorder etiology. Common symptoms that may be linked to dopamine dysregulation include distortion of body image and obsessive compulsive behaviors (References 30, 31).

Leptin, a hormone produced in adipose tissue, is related to weight regulation and energy balance. In addition, leptin appears to play a significant role in mediating eating disorders. Patients with AN tend to have a

decrease in leptin levels because of low levels of circulating fat. These low leptin levels signal low energy levels to the brain. Patients who have recovered from eating disorders continue to have lower levels of serum leptin based on their body mass index (BMI). It is possible that both leptin and norepinephrine serve as trait markers for patients with eating disorders, but more research needs to be completed to confirm this association (References 32, 33).

## Medical Complications

Eating disorders have the highest mortality rates of all the psychiatric disorders at a rate of 4% (References 34, 35). Medical complications associated with these disorders are especially lethal in children and adolescents. Suicidality is a risk factor associated with eating disorder-related mood changes and dissatisfaction with body image (Reference 35).

According to the Agency for Healthcare Research and Quality, the hospitalization rate because of malnutrition for children younger than 12 rose by 119% between 1999 and 2006 (Reference 5). There are frequently long-term consequences associated with eating disorders, even once resolution of disordered eating behaviors has occurred. These consequences include osteopenia, structural changes to the gray and white matter of the brain, growth retardation, and pubertal delay (Reference 36). With time, the body is unable to compensate for long-term nutritional deficits, causing metabolic rate declines and inhibition of temperature regulation. Ultimately, almost all organ systems are affected by the effect of malnutrition on the body (References 37–39).

Malnutrition and starvation lead to dysfunction of the endocrine system including hyperactivity of the hypothalamo-pituitary axis. These changes have effects on thyroid function and the reproductive system, leading to hypothyroidism, hypogonadism, hypercortisolism, and amenorrhea. In addition, endocrine dysfunction can lead to growth retardation and a delay in the onset of puberty in children and adolescents. These effects on the hypothalamo-pituitary axis as well as the inability of growth hormone to bind to insulinlike growth factor-1 may all be part of the mechanism of growth retardation (References 36–39). Unfortunately, the effects on growth, especially on short stature, may be a permanent manifestation of malnutrition (Reference 40).

Weight loss causes a decrease in the volume of the gray and white matter of the brain and cerebrospinal space (Reference 41). Cognitive dysfunction often occurs in patients with eating disorders secondary to hypercortisolism and hypogonadism (Reference 42). Magnetic resonance imaging has shown changes in

brain activity. From neuroimaging, it appears that volumetric decreases in gray matter caused by malnutrition may be permanent, whereas white matter may improve with refeeding (References 42, 43).

Hypogonadism, amenorrhea, and nutritional deficiencies lead to low bone marrow density. This is a significant problem for children and adolescents because this period of growth is important for bone mineralization. It is unclear whether refeeding will reverse these changes on bone mineral density (References 44, 45).

Eating disorders cause significant damage to the gastrointestinal (GI) tract. The effects on the GI tract include delays in gastric emptying, gastroesophageal reflux, and GI bleeding. Constipation is a common occurrence caused by nutritional deficits. Enlargement of the salivary glands is associated with hyperemesis (Reference 46). Self-induced vomiting can cause a callus on the dorsum of the hand called Russell's sign. Repeated forced emesis can also cause a separation of the mucosal membrane between the esophagus and stomach that may lead to extensive bleeding called a Mallory-Weiss tear. Stomach acid from hyperemesis may also cause dental erosion.

Dehydration from purging behaviors leads to imbalances in fluid and electrolyte status. In addition, hyperemesis may lead to a hypochloremic metabolic alkalosis because of the loss of hydrochloric acid. The body's attempt to conserve fluid in the face of dehydration can lead to hypokalemia-causing cardiac arrhythmias. Hypomagnesemia from malnutrition can lead to sudden cardiac death. Likewise, malnutrition and/or laxative abuse can induce hypoproteinemia, which can lead to significant edema and, potentially, congestive heart failure. Dehydration caused by laxative abuse may induce a hyperchloremic metabolic acidosis. Dilutional hyponatremia may be seen in patients who attempt to improve their weight before visiting their health care provider (References 38–40, 46, 47).

Finally, malnutrition can lead to stomatitis; dry, cracked, scaly skin; and hair and nail changes. The development of lanugo, a fine soft hair that covers the body, and yellow skin coloring are not uncommon in patients with eating disorders (References 38–40).

### Patient Assessment

Eating disorders can have an adverse effect on every organ system, so a thorough medical and psychosocial evaluation should be completed for patients with these disorders. In addition to a complete physical examination, laboratory measures should be taken, including an electrolyte panel, liver function tests, a complete blood cell count, thyroid function tests, and glucose, calcium, and magnesium concentrations. In patients with amenorrhea, a serum pregnancy test, serum estradiol, serum prolactin, and follicle-stimulating hormone should be

measured. In addition, in female patients with amenorrhea, a bone scan should be completed to check for osteopenia. An electrocardiogram should be considered for those with electrolyte abnormalities or cardiovascular symptoms. Neuroimaging of the brain should be considered for those with severe malnutrition (Reference 48).

It is important for the clinician to recognize that laboratory results may be normal in patients with eating disorders and that normal laboratory results should not exclude either the diagnosis or the treatment of an eating disorder. Patients should be assessed on the basis of their symptoms because medical instability can be overlooked by clinicians who base their decisions on laboratory results alone. Clinicians also need to be aware that patients with AN and BN tend to be ambivalent about treatment, and it is common for them to hide their illness. Thus, denial by the patient does not exclude the possibility of an eating disorder. With time, these disorders can become egosyntonic, meaning that the behaviors provide positive reinforcement for the patient, and changing the behavior is more frightening than living with it (References 48, 49).

Psychosocial evaluations should include an assessment of how the patient views food, nutrition, and their current body image. Social factors such as their relationships with significant others, including parents, siblings, friends, and other support systems, should be assessed. Because eating disorders often co-occur with other psychiatric conditions such as mood, anxiety, and personality disorders, these psychiatric disorders should be assessed as well. A complete medical history, including use of illicit drugs and over-the-counter medications such as laxatives, stimulants, and diuretics, should be obtained. It is important to discuss with the patient if there is any history of sexual, physical, or emotional abuse because these can play a role in the development of eating disorders. It is not uncommon for patients with an eating disorder to complete a suicide, so evaluating the patient's risk is an important part of an initial patient evaluation and ongoing clinical care (Reference 49).

### Standardized Rating Scales

A variety of assessment measures exist for evaluating eating disorders. Some of these measures include semi-structured interviews, self-reporting, symptom checklists, and clinical rating scales. The most commonly used assessment measures are the Eating Disorders Examination, the Yale Brown Cornell Eating Disorder Scale, the Eating Attitudes Test, the Eating Disorder Inventory, and the Eating Disorder Questionnaire. Any member of the eating disorder treatment team, including psychiatrists, psychologists, pharmacists, dietitians, nurses, or social workers, can be trained to provide interviews for the various scales.

The Eating Disorders Examination is a semi-structured interview with four subscales (restraint, eating concern, shape concern, and weight concern). The advantage of this examination is that it allows the clinician to develop a diagnosis, which is selective for certain eating behaviors such as binge eating. A disadvantage to using this scale is that it should be administered by a trained interviewer, and it can take up to 1 hour to complete (Reference 50).

The Yale Brown Cornell Eating Disorder Scale is also a semi-structured interview with a 65-item checklist and questions that cover ritualistic and obsessive behaviors sometimes seen in patients with eating disorders. This scale takes 15 minutes to complete (Reference 51).

The Eating Attitudes Test is a self-report measure that includes a full-scale 50-item test and a brief 26-item measure that evaluates for global eating disorder symptoms. The Eating Attitudes Test is sensitive to treatment effects (Reference 52). The Eating Attitudes Test for children is called the Children's Eating Attitudes Test. It contains 26 items, and scores greater than 20 are considered associated with developing an eating disorder (Reference 53).

Another standardized self-report measure, the Eating Disorder Inventory, evaluates patient attitudes and their behaviors around food, body image, and weight. The Eating Disorder Inventory also measures patient attitudes concerning perfection, effectiveness, trust, and maturity. The Eating Disorder Inventory is sensitive to treatment effects (Reference 54). The Eating Disorders Questionnaire is also a self-report measure. It covers eating disorder symptoms and demographic information (Reference 55).

Self-reports are simple and take a minimal amount of time to complete. They are inexpensive and objective, avoiding rater bias. The primary disadvantage of these scales is that they may be less accurate than the semi-structured interviews.

## ANOREXIA NERVOSA

Anorexia nervosa is one of the most serious psychiatric disorders that can occur in children and adolescents. The presentation of anorexia has occurred in children as young as 7 years old (Reference 56). Patients with anorexia are often perfectionists and high achievers who, under stress-induced situations, use caloric restriction as a means of controlling situations in which they otherwise have no control (Reference 57). Initially, this weight loss may be reinforced by positive comments from friends and family admiring it. Continued weight loss is associated with obsessions and compulsions that provide secondary reinforcement, which then becomes a vicious cycle (Reference 57).

### Epidemiology

The incidence of AN in adolescent females between age 15 and 19 years is 0.48% to 0.7% (Reference 58). Early-onset AN, the occurrence of anorexia in prepubertal children or children younger than 14 years, occurs in 5% of

all cases (References 56–60). Although we tend to think of AN as being a disease of females, in the prepubertal population, boys and girls have an equal incidence of this disorder, with some thought that at very young ages, boys may actually show a greater incidence of anorexia (Reference 61). At least one-third of the individuals with AN develop a chronic disorder that is marked by relapse and recurrent hospitalizations (Reference 62).

### Clinical Presentation

The core feature of AN involves a refusal to maintain body weight of at least 85% of the optimal weight for age and height. Body dysmorphism, a distortion in one's body image, is a primary reason for the refusal to maintain weight. Once weight is lost, the patient has a fear of gaining weight or becoming fat. In children and adolescents, this level of malnutrition prevents normal growth patterns, including a delay in sexual maturation, which leads to amenorrhea in females. Patients with AN may either restrict their intake of food or binge and purge. Patients with AN can meet the diagnostic criteria for BN (such as having binge/purge behaviors). However, they will retain the diagnosis of AN as long as they remain at least 15% below their ideal body weight and meet the DSM-IV-TR criteria for AN. In addition to restricting caloric intake and developing extensive food rituals, patients with AN often participate in excessive exercise to inhibit weight gain (Reference 63).

### Diagnostic Criteria

The diagnostic criteria from the DSM-IV-TR are listed in Table 1.

### Risk Factors

One risk factor for developing AN is having a family history of an eating disorder. Family studies have shown that there is a 3% lifetime risk of developing anorexia in first-degree relatives (References 21, 64). Parental eating behavior and weight may also play a role. A recent study showed that families who sat down to dinner most days in the week were less likely to develop anorexia than families who did not (Reference 65). Personality traits such as having a "type A personality" or being a perfectionist may be a risk factor. Mood symptoms in patients and their first-degree relatives may also put patients at an increased risk of developing anorexia. Many patients with anorexia were mildly overweight before developing the disorder (Reference 65).

### Course and Prognosis

Anorexia nervosa has the highest mortality rate of all the eating disorders. The mortality risk is estimated to be 10% within 10 years of an AN diagnosis and is primarily caused by starvation or suicide (References 35, 66).

Anorexia nervosa has significant comorbidity with other psychiatric disorders. In patients who restrict food intake, obsessional behaviors such as repetitive and/or intrusive thoughts, perfectionism, and inflexibility are common. In patients with AN who purge, suicidality and self-harm are common. Mood disorders and anxiety disorders are common to both anorexia subtypes (Reference 67).

If the disorder is treated in the early stages of development, especially in prepubertal adolescents in whom weight restoration is achieved, outcomes appear to be good. In patients with anorexia who continue to refuse to maintain minimum weights, there is a tendency to initiate bingeing and purging behaviors that may evolve into a diagnosis of BN (References 67, 68).

### Treatment of AN

The initial treatment goal in AN is to restore the patient's nutritional status and treat the medical complications. The degree of malnutrition dictates how to best medically manage the patient. In the initial approach, it is imperative to determine the degree of electrolyte and nutrient loss before the patient's nutritional status can be appropriately restored. Restoration of electrolytes (e.g., potassium, sodium, and magnesium) and of calcium, folic acid, zinc, and iron must occur early in the process of refeeding (Reference 69). Once patients are less than 75% of their ideal body weight, are medically unstable, or have a heart rate less than 50 beats/minute, they should be hospitalized (Reference 69).

Because these patients have been in starvation mode, it is important to improve the energy deficits early by slowly titrating energy calories. Restoring deficits in children is of greater concern than in adolescents and adults. Children may have lower energy or fat stores, and they may dehydrate more rapidly. Body mass index is unreliable in children and young adolescents who have not finished growing. Growth may be stunted, and assessing appropriate weight gain in the still-growing youth is difficult (References 69, 70).

The initial goal for inpatients is to gain 0.3–0.4 lb per day, and the initial goal for outpatients is to gain 1–2 lb per week. Recommendations on how to achieve this weight gain vary, but it is considered reasonable to start refeeding with between 1000 and 1600 calories daily and to titrate upward slowly as tolerated. Most patients will begin to achieve an adequate level of weight gain with an intake of between 2200 and 2500 calories daily. As energy requirements are replaced and the level of physical activity resumes, the metabolic rate will normalize, and the rate of weight gain will decline (References 69, 70).

The clinician must take care not to cause refeeding syndrome. Refeeding syndrome occurs when an individual is fed normal quantities of food too quickly after a long period of starvation. When a patient is in starvation mode, insulin secretion declines because of a reduced intake of carbohydrates. Protein stores are broken down first, followed by fat stores to provide energy to the individual. During this level of starvation,

**Table 1.** DSM-IV-TR Criteria for Anorexia Nervosa (Reference 63)

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected)
- B. Intense fear of gaining weight or becoming fat, even though underweight
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight
- D. In postmenarchal women, amenorrhea (i.e., the absence of at least three consecutive menstrual cycles). (A woman is considered to have amenorrhea if her periods occur only after hormone therapy [e.g., estrogen administration].)

*Specify type:*

**Restricting Type:** During the current episode of anorexia nervosa, the person has not regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

**Binge Eating/Purging Type:** During the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

DSM-IV-TR = *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision.

intracellular electrolytes are reduced. Intracellular phosphate levels are at particular risk of depletion, although extracellular phosphate, which is typically measured in laboratory results, appears normal. Once normal feeding resumes, the body shifts from breaking down fat to breaking down carbohydrates once again. The cycle is reversed, insulin is secreted, and phosphates are shifted intercellularly. This leads to a profound extracellular hypophosphatemia. The serum phosphate concentration, usually less than 0.5 mmol/L, causes refeeding syndrome. Refeeding syndrome is characterized by hypotension, arrhythmias, seizures, cardiac failure, respiratory failure, rhabdomyolysis, coma, and sudden death. Refeeding syndrome can occur with not only oral feeding, but also parenteral or enteral feedings (Reference 71).

Once patients have stopped losing weight, their weight has started to trend upward to at least 75% of their ideal body weight, and their laboratory results have normalized, they can go to a supportive home, where they can continue to work with a dietitian and therapist on a regular basis. If a supportive environment is not available, patients may go to a day treatment program, where they can be monitored for progress toward their weight gain goals.

### Nonpharmacologic Treatment

Once the patient is stabilized medically, the next stage in treatment is to focus on developing new dietary habits as well as changing cognitive response to eating, weight, and the underlying psychopathology that led to the eating disorder.

At one time, environmental factors in families were thought to be the cause of eating disorders, but this theory has been dismissed. In the past decade, research suggests that family therapy is the most beneficial treatment for AN. In family therapy, called family-based treatment or family-based therapy (FBT), parents initially take responsibility for the child's or adolescent's eating behaviors. It is the family's job to ensure that the patient is eating adequately and avoiding eating disorder behavior. Once patients have regained at least 85% of their normal weight, children or adolescents slowly become responsible for their own eating. In the last treatment phase, the patient and family work toward resuming what would be a normal developmental stage for the child or adolescent (Reference 72).

At least five controlled trials of FBT show promise for this treatment, especially in children or adolescents with a short illness (References 72–77). Family-based therapy typically takes 6–12 months to complete, and the outcomes have been durable at the 5-year follow-up (References 73–78).

Family-based therapy is typically advised for intact, supportive families. In families where the affected child has been abused, or in the most nutritionally and medically compromised patients, FBT would not be the treatment of choice (Reference 72). In these patients, cognitive behavioral therapy (CBT) or interpersonal psychotherapy (IPT) should be considered.

Cognitive behavioral therapy teaches the patient strategies to cope with feelings and events that initially led to the eating disorder. In addition, CBT improves self-esteem and helps the patient correct body image distortions (Reference 79). Interpersonal psychotherapy typically focuses on interpersonal problems that may play a role in eating disorder behaviors.

### Pharmacologic Treatment

There are no randomized controlled trials of any pharmacologic agent for the treatment of AN in children or adolescents alone. Some trials have been completed in adolescents and adults, but most of these studies were either too short or used medication doses that today would be considered insufficient for the treatment of an eating disorder. In addition, studies that have been published typically do not have the statistical power required to make evidence-based decisions.

If medications are used in AN, they should be considered for the co-occurring psychiatric conditions frequently seen with AN, rather than for treatment of the eating disorder alone.
