Pharmacologic treatments for AN have included antidepressants, antipsychotics, cyproheptadine, hormones, and zinc. Most randomized controlled trials completed in adults have been with the antidepressants. The tricyclic antidepressants clomipramine and amitriptyline have been studied for the treatment of AN. Clomipramine caused increased appetite, which did not carry over to weight gain in patients (Reference 80). Amitriptyline has been studied in two trials. In the first, there was no significant difference between amitriptyline and placebo, although patients experienced adverse effects with amitriptyline (Reference 81). In a second trial, amitriptyline was compared with cyproheptadine and placebo. The patients taking amitriptyline had no improvement in weight gain or depression scores. Patients taking cyproheptadine had improvement in both areas (Reference 82). Tricyclic antidepressants may cause several cardiac adverse effects including prolongation of the QT interval and sudden death in children and adolescents, so they should be used cautiously under direct medical supervision only.

The selective serotonin reuptake inhibitors (SSRIs) fluoxetine and citalopram have been studied in randomized controlled trials for AN. The SSRIs have efficacy for depression and obsessive compulsive disorder symptoms in children and adolescents, and they are

safer than the tricyclic antidepressants, but no studies using the SSRIs have shown patient improvements in weight restoration or eating disorder symptoms (Reference 59). In addition, there is a black box warning for using SSRIs in children and adolescents (see Pediatric Depression chapter), so these medications should only be used when risk outweighs benefits.

Most information regarding the use of antipsychotics for the treatment of AN has revolved around either case reports or case series. Although most studies with these agents have been completed in adults, there are some studies of atypical antipsychotics in children and adolescents. The most-studied atypical antipsychotics are olanzapine, quetiapine, risperidone, and aripiprazole.

Open-label trials and a case series have documented BMI improvements in children and adolescents taking olanzapine (References 83, 84). In addition, patient anxiety and agitation around eating meals was reduced. In randomized controlled trials using olanzapine in adults with AN, one study found improvements in weight gain and obsessional thinking. Weight gain, a common adverse effect of olanzapine, led to treatment refusal by half of the patients in the trial. Patients forced to gain weight without concomitant improvements in anxiety around gaining the weight typically have difficulty with treatment adherence. In the other trial, olanzapine and CBT did not separate out significantly from CBT alone (Reference 83).

Quetiapine has been used in two open-label studies of children (References 85, 86). In these studies, quetiapine improved depression and anxiety scores, but it did not significantly improve weight gain. In a case series of children and adolescents that used quetiapine for AN, patients reported improvements in body dysmorphism.

There are two case reports using risperidone in adolescents (References 87, 88). Patients did not show significant improvements in eating or weight gain in these reports, but they did show a decline in anxiety and obsessions surrounding food. There is currently a randomized placebo-controlled trial with risperidone for the treatment of AN in adolescents.

One case series of five patients with AN showed some improvements in anxiety and depression that may have led to improvements in BMI when aripiprazole was added to the patients' medication regimen. Patients, observed between 4 and about 40 months, seemed to have fewer obsessional symptoms and less distress around eating when aripiprazole was added (Reference 89). The National Institutes of Mental Health recently completed a clinical trial of aripiprazole for the treatment of AN.

Common adverse effects of antipsychotics include sedation and the potential for extrapyramidal adverse effects, which, in the long term, could lead to tardive dyskinesia. These agents can also cause metabolic syndrome, including hypertension, diabetes, and hyperlipidemia, and should be used with caution in children and adolescents.

Hormones have also been used in adolescents and adults for the treatment of AN. Growth hormone has been compared with placebo in adolescents with AN (Reference 90). In one study, the patients taking growth hormone became medically stabilized 10 days faster compared with patients not using growth hormone. There was no significant improvement in weight in any of these patients. Studies of testosterone use in adults with AN have shown mood improvement, but there were no specific improvements in weight compared with placebo (Reference 91).

One open trial using elemental zinc showed improvements in weight gain in patients with AN. Like the patients in the growth hormone study, patients receiving elemental zinc were hospitalized for about 7 days less than patients who did not receive zinc (Reference 92).

## Summary

Medications should not be a first-line treatment in AN. Although medications may show some benefit in treating co-occurring depression, anxiety, or obsessive compulsive symptomatology, there is insufficient evidence that they improve weight gain or eating disorder symptoms. After medical stabilization and refeeding, nonpharmacologic therapy, especially FBT, is the most appropriate line of treatment.

## BULIMIA NERVOSA

Bulimia nervosa, as opposed to AN, is often characterized by a loss of control in food intake (binge eating and purging). Whereas patients with AN attempt to take charge of their lives by limiting food intake, patients with BN often feel that they have lost control. Children and adolescents with AN who initiate binge and purge behaviors may eventually develop BN, although it typically occurs independently of AN.

## Epidemiology

Although AN may occur in children and adolescents, BN is usually seen in adolescence or early adulthood, with a peak onset between age 15.7 and 18.1 years (Reference 93). Bulimia nervosa seldom occurs in premenarchal females. The lifetime prevalence of BN is 2.3%; the incidence of BN is 1% to 2% (References 94, 95). In one national study, less than one-third of all BN cases were recognized by a clinician because of the secretive nature of the disorder (Reference 95). Mortality rates

for patients with a diagnosis of BN are much lower than for AN at 3.9% and are often associated with suicidality and medical complications, primarily electrolyte imbalances (Reference 96).

### Clinical Presentation

Bulimia nervosa is characterized by disinhibited eating of large quantities of food during a short amount of time and purging, either by self-induced vomiting, diuretics or laxatives, or all of these to reduce the potential weight gain associated with the binge. Although the amount of calories taken in a binge varies per individual, as many as 2000–5000 calories can be taken in during a discrete period. When individuals with BN binge, they typically do so until they experience significant abdominal discomfort. Vomiting helps decrease the stomach discomfort caused by the binge and, for some patients, allows them to continue the binge. Often, patients with this disorder are obese in childhood and early adolescence. The disorder itself is often not recognized by family, friends, or even health care professionals because the patient is typically within a normal weight range for age and height (Reference 56).

Patients with BN often hold over-idealistic views of what body weight and shape should be, leading them to feel conflicted about eating. Fluctuations in weight are common because of binge/purge behaviors (Reference 57).

### Diagnostic Criteria

The diagnostic criteria for BN are listed in Table 2.

### Risk Factors

Like those for AN, the risk factors for BN include having a family history of an eating disorder. Often, the parents of patients with BN are obese, and the relative risk of developing BN is 4.2% for first-degree female relatives with AN and 4.4% for first-degree relatives of patients with BN (Reference 64). A history of physical or sexual abuse and low self-esteem are also risk factors for this disorder. Personality traits such as impulsivity and self-harm are commonly seen in this population. Patients with BN often have a history of excess dieting, frequently skipping meals, and having dissatisfaction with their body image. Performers like models, actors, athletes, and jockeys in certain sports such as ballet, gymnastics, dance, running, wrestling, and racing are at greater risk of developing BN because of stringent weight and body shape requirements (References 97, 98).

### Course and Prognosis

Bulimia nervosa has a chronic course with periods of recovery and relapse. Although the 5-year clinical recovery rate is 55% (Reference 96), as many as 46% will continue to have eating disorder symptoms 6 years after treatment. As stated previously, the mortality risk

**Table 2.** DSM-IV-TR Criteria for Bulimia Nervosa (Reference 63)

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  1. Eating, in a discrete period (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period and under similar circumstances
  2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B. Recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice weekly for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify type:

**Purging Type:** during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

**Nonpurging Type:** during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

DSM-IV-TR = *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision.

Used with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed.; text rev. Washington, DC: American Psychiatric Association, 2000.

associated with BN is estimated to be 3.9% (Reference 36). Bulimia nervosa has a better outcome than AN, and a shorter illness before treatment is associated overall with improved outcomes. Premorbid obesity, poor family and peer relationships, and excessive exercise are all associated with poorer outcomes (Reference 99).

### Treatment of BN

Initial goals in the treatment of BN include addressing any medical complications and decreasing and eventually eliminating bingeing and purging behaviors. It is important to provide patient education regarding adequate nutrition and to rectify incorrect thinking regarding body shape and size, eating, and weight. Treatment of co-occurring psychiatric conditions is imperative. Support systems should be used to prevent relapse.

### Nonpharmacologic Treatment

Outside psychotherapy, much less is known about the nonpharmacologic treatment of BN compared with AN. There is much more evidence regarding the use of CBT in patients with BN. Cognitive behavioral therapy should be provided to patients on a weekly basis for 4–5 months (Reference 97). Interpersonal psychotherapy also has a role in helping patients with BN to work through interpersonal issues that may affect their eating disorder.

There are two controlled trials of FBT in adolescents and one trial of FBT in combination with CBT (Reference 100). Although the results are preliminary, they appear to be promising.

### Pharmacologic Treatment

Antidepressants are the most studied medications for the treatment of BN. The first antidepressant trials used the tricyclic antidepressant desipramine, the tetracyclic antidepressant trazodone, and the monoamine oxidase inhibitor brofaromine (References 101–104). All of these trials were randomized controlled trials, and all found improvements in bingeing and purging behaviors distinct from their treatment of mood. These studies had small sample sizes and a short duration, and they did not have adequate follow-up trials. In addition, adverse effects of these medications include sedation, dry mouth, and weight gain. Monoamine oxidase inhibitor use is limited by dietary restrictions.

Bupropion was studied in one clinical trial, and although its use decreased binge and purge behaviors, it also caused grand mal seizures in 4 of 55 patients, and an advisory against its use in eating disorders was released (Reference 105). Fluoxetine is the only medication to be U.S. Food and Drug Administration (FDA) label approved for the treatment of BN. There are six randomized controlled trials supporting

the use of fluoxetine for treating BN. Most of these trials support the use of fluoxetine 60 mg/day, a much higher dose than that used for the treatment of depression. Although binge/purge behaviors begin to respond in as few as 3 weeks, most studies suggest at least 8 weeks to allow a response, and treatment should be continued for at least 1 year (References 106–111). Both venlafaxine and fluvoxamine have shown some promise in treating BN. Use of an adequate dose for an adequate amount of time appears to be imperative for the use of any of the antidepressants in the treatment of BN (References 112–114). Topiramate, naltrexone, and ondansetron have all been used in small trials for the treatment of BN, and all three have been found successful in treating core symptoms. Further study in larger trials needs to be completed to recommend the role of these medications in the treatment of BN (References 115–118).

### Summary

Although fluoxetine has an FDA label-approved indication for the treatment of BN, the research on fluoxetine was completed primarily in adults, which may not translate to treatment response in children and adolescents. Because information on children and adolescents is limited and because of the black box warning for antidepressant use in these age groups, antidepressants should be used with caution in this population. In addition, because CBT has been found beneficial in BN, medication is not considered first-line treatment. When medications are used, they should be used to help treat eating disorder comorbidities, and the patient should be closely monitored by a clinician.

## EATING DISORDERS NOT OTHERWISE SPECIFIED

Eating disorders not otherwise specified make up around 60% of all eating disorder diagnoses in children and adolescents (Reference 119). Most of the disordered eating seen in EDNOS is subsyndromal or an early presentation of the primary eating disorders AN or BN. Some of these subsyndromal cases will never meet the full diagnostic criteria for one of the eating disorders as defined by the DSM-IV-TR.

Binge eating disorder (BED) is currently categorized as an EDNOS. Provisional criteria have already been set for this disorder, and BED will most likely be a separate disorder in the DSM-V when it is published in 2013 (References 120, 121). The diagnostic criteria for BED are listed in Table 3.

Other eating disorders fall into the category of EDNOS. Four atypical eating disorders are usually reported: selective eating, food avoidance emotional disorder, food phobias (this includes functional dysphagia), and pervasive refusal syndrome.

## Epidemiology

The prevalence of EDNOS is between 0.8% and 14%, depending on the symptoms and the way in which the disorder is defined (Reference 122). Patients who do not meet all the current criteria in the DSM-IV-TR for either AN or BN will fall into the category of EDNOS. If subsyndromal AN and subsyndromal BN were included with patients who meet the full diagnostic criteria, 45.7% of patients with EDNOS would be removed from that diagnostic group, leaving only 14.3% of patients who would actually be categorized as EDNOS. Of that 45.7%, 25.7% would be categorized as having a subsyndromal AN, and 20% would be categorized as having subsyndromal BN. Six percent of EDNOS would account for BED. The atypical eating disorders would make up 8.3% of the EDNOS. Unfortunately, insufficient research has gone into these atypical eating disorders to provide further epidemiologic characterization (Reference 122).

## Clinical Presentation

Eating disorders are common in childhood and adolescents, but determining how to define them diagnostically has been a challenge. In the DSM-IV-TR, AN and BN have been defined on the basis of specific physical, behavioral, and cognitive parameters. Children and adolescents cannot meet the same criteria on the basis of these parameters. For example, an adult with AN is fully grown, and determinations can be made given a stable height and BMI. Pubertal growth varies widely among children and adolescents. These independent variables make it difficult to determine specific DSM-IV-TR criteria related to weight on the basis of height. Currently, amenorrhea—defined as an absence of three menstrual

cycles—cannot be determined in premenarchal girls, and it is difficult to determine in adolescents because it is common for menstrual cycles to be irregular during the first years after menarche.

Other challenges with defining AN and BN in children include their verbal and cognitive skills, including their ability to use abstract reasoning, all of which are required to make a diagnosis. Until adulthood, children and adolescents typically lack the insight needed to understand the deleterious effects of dramatic weight loss, for example, and the long-term effect on health or the behavioral consequences of such behaviors (Reference 122).

Despite these difficulties in matching the current diagnostic criteria to children and adolescents, there is no meaningful clinical difference between AN and BN and subsyndromal AN and BN.

Binge eating disorder is characterized by bingeing without the commensurate purging behaviors so that patients with this disorder gain a large amount of weight and are typically obese. Unlike the sex ratios with AN and BN, the ratios of males to females with this disorder are similar. Personality traits common to BED are low self-esteem and dissatisfaction with body shape and image. In addition to obesity, depression commonly co-occurs with BED (Reference 57).

The atypical eating disorder called selective eating refers to what is commonly called the picky eater. Such choosy eaters limit themselves to a small variety of foods and refuse to try new food items. There are thought to be two types of selective eating. The most common type is believed to be caused by never providing the young child a variety of foods and food textures. The secondary form of selective eating is thought to occur because of an event such as choking or vomiting. Personality traits associated with selective eating include shyness and sensitivity. Selective eating is common with pervasive developmental disorders (e.g., autism) and later in the development of AN (Reference 123).

**Table 3.** Provisional BED Research Criteria for Children (Reference 121)

- 
- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
    - 1. Food seeking in the absence of hunger (e.g., after a full meal)
    - 2. A sense of lack of control over eating (e.g., endorses that “When I start to eat, I just can’t stop”)
  - B. Binge eating episodes are associated with one or more of the following:
    - 1. Food seeking in response to negative affect (e.g., sadness, boredom, restlessness)
    - 2. Food seeking as a reward
    - 3. Sneaking or hiding food
  - C. Symptoms persist over a period of 3 months.
  - D. Eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, excessive exercise) and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa.
- 

BED = binge eating disorder.

Used with permission from Marcus MD, Kalarchian MA. Binge eating in children and adolescents. *Int J Eat Disord* 2003;34:S47–S57.

Food avoidance emotional disorders refer to an avoidance of most or all food. Children with food avoidance emotional disorders typically have an anxiety component to their illness, which presents as somatization. Children with this disorder often complain that “my tummy hurts,” or they say they “are not hungry,” or “cannot eat.” Patients usually know that they are below weight norms and that it is not a positive experience for them. In addition to anxiety, these patients frequently experience depression, and later, they may be given a diagnosis of AN (Reference 123).

Food intake phobias usually occur in school-aged children who fear choking, vomiting, diarrhea, an allergic reaction to food, or other medical- or health-related concerns. Fear of choking associated with difficulty swallowing is called “functional dysphasia.” Children with this phobia often choke or gag while eating (Reference 123).

Pervasive refusal syndrome is an absolute refusal to eat on the part of the child. Children may also refuse to walk, talk, or care for themselves. This atypical eating disorder is rare and is typically associated with posttraumatic stress, sometimes related to abuse. It has also been associated with learned helplessness (Reference 123).

### Diagnostic Criteria

The diagnostic criteria for EDNOS are listed in Table 4.

### Risk Factors

Risk factors for subsyndromal AN and subsyndromal BN are the same as for the full-spectrum disorders. Risk factors for BED include obesity in both first-degree family members and the patient, as well as low self-esteem, unhappiness with current body weight and shape, and a history of depression. Atypical eating disorders

tend to occur in very young children and are associated with personality traits like shyness and sensitivity or emotionality; fear of choking; or vomiting, diarrhea, or an allergic reaction. Although rare, pervasive refusal syndrome may be associated with a severe stress or with physical, emotional, or sexual abuse.

### Course and Prognosis

Subsyndromal AN and BN share the same course and prognosis as full-symptom AN and BN. Of importance, clinicians should recognize that subsyndromal eating disorders are just as important and as potentially dangerous to the patient as the full-spectrum disorders.

Although research on the course and prognosis of BED is limited, the prognosis appears good. In one 5-year study, 72% of patients made a full or partial recovery without treatment (Reference 124).

Research on atypical eating disorders is very limited, but some of it suggests that many children with these disorders will develop AN in middle childhood or early adolescence.

### Treatment of EDNOS

Treatment of subsyndromal AN and subsyndromal BN should be similar to that of the full-spectrum disorders. The prepubertal onset of these disorders is usually at least as severe as the postpubertal forms of the disorders and may be more dangerous because of the lack of excess energy stores inherent in adults. Early interventions for the subsyndromal disorders provide the best outcome for patients. It is also important to remember that prepubertal forms of AN and BN are still associated with health risks, growth delays that may be permanent, and deficiencies in bone mass that lead to

**Table 4.** DSM-IV-TR Criteria for EDNOS (Reference 63).

The EDNOS category is for disorders of eating that do not meet the criteria for any specific eating disorder. Examples include:

1. For females, all the criteria for anorexia nervosa are met except that the individual has regular menses.
2. All the criteria for anorexia nervosa are met except that, despite significant weight loss, the individual's current weight is in the normal range.
3. All the criteria for bulimia nervosa are met except that the binge eating and inappropriate compensatory mechanisms occur at a frequency of less than twice a week or for less than 3 months.
4. The regular use of inappropriate compensatory behavior by an individual of normal body weight after eating small amounts of food (e.g., self-induced vomiting after the consumption of two cookies)
5. Repeatedly chewing and spitting out, but not swallowing, large amounts of food
6. Binge eating disorder: recurrent episodes of binge eating in the absence of the regular use of inappropriate compensatory behaviors characteristic of bulimia nervosa

DSM-IV-TR = *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision; EDNOS = eating disorder not otherwise specified.

Used with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed.; text rev. Washington, DC: American Psychiatric Association, 2000.

osteopenia, as well as to cognitive impairments that may be permanent without treatment (References 124–128). Atypical eating disorders are poorly classified; thus, they have not undergone significant research to find treatments. Similar to AN treatment, establishing normal weight and eating patterns, teaching children and their families about healthy eating and nutrition, and treating co-occurring psychological problems are currently the best treatments for these disorders until they are better defined with established evidence-based research.

The goal of treating BED is to eliminate bingeing and help the patient lose weight in a healthy manner.

### Nonpharmacologic Treatment

Like BN, both CBT and IPT are the most effective nonpharmacologic treatments for BED. Treatments target normalizing eating by using food diaries, problem solving, and reframing the ways in which patients view interpersonal issues.

### Pharmacologic Treatment

The SSRIs, including fluoxetine, fluvoxamine, sertraline, citalopram, and escitalopram, together with the tricyclic antidepressant imipramine, have the most studies supporting their use in BED. The SSRIs appear to help decrease binge frequency, but they do not appear to affect weight loss. Medications studied for BED have been in short-term trials (less than 12 weeks), and these trials have experienced high dropout rates. Like SSRI use in BN, doses need to be in the high-end range to have an effect. The SSRIs do not appear to be better for BED than behavioral therapy (Reference 57).

Other medications found to help with binge eating in adults include topiramate, atomoxetine, zonisamide, lamotrigine, acamprosate, and orlistat (Reference 57). Adverse effects from these agents and recent warnings added to orlistat, in addition to the lack of studies in children and adolescents, indicate these treatments are not currently recommended as first-line treatments for pediatric BED.

### Summary

Antidepressants, especially the SSRIs, improve BED by reducing binge eating. Antidepressants do not seem to cause significant long-term weight loss. Topiramate may also help with bingeing and weight loss, but further study must be completed to confirm the results of current trials.

### CONCLUSIONS

The eating disorders AN, BN, BED, and EDNOS are all complex, serious, life-threatening disorders and should be viewed as such by clinicians. The mortality associated with eating disorders ranks highest among all

the psychiatric disorders, especially regarding suicidality and starvation. Children and adolescents with eating disorders often do not meet all the diagnostic criteria in the current DSM-IV-TR. Work is being completed to remedy this in the DSM-V. Children and adolescents with subsyndromal eating disorders should be treated with the same degree of concern as individuals with full-spectrum eating disorders. Atypical eating disorders need further delineation and research to determine adequate treatments.

Medication trials are especially weak for the treatment of AN. Managing AN with medications alone is inappropriate. There is some evidence that, after medical stabilization and refeeding, FBT and CBT are beneficial and can decrease the risk of relapse.

The bingeing and purging behaviors of BN and the bingeing behaviors of BED respond to treatment with the SSRIs. Fluoxetine 60 mg/day is the only FDA label-approved treatment for BN. There is good evidence that CBT and IPT are effective for BN and BED. It is important to recognize that patients may often be non-adherent to medications because of the adverse effects associated with them.

Medication studies of the treatment of eating disorders in children and adolescents have several limitations. Many of these studies lack scientific rigor. Many studies are also poorly designed, have insufficient sample sizes, and lack sufficient power. As with most psychiatric research, there is a high dropout rate, which has an effect on study outcomes.

The long-term prognosis of eating disorders is improved if adequate treatment can be provided as early as possible. Recognition of these disorders by improving diagnostic criteria in the upcoming DSM will be a positive step toward new research for eating disorders in children and adolescents.

# CHAPTER 32

## SUBSTANCE USE AND ADDICTIVE DISORDERS

Lisa Lubsch, Pharm.D., AE-C

### LEARNING OBJECTIVES

1. Describe the problems that arise from substance use and identify risk factors for addiction in children.
2. Discuss the intoxication effects and consequences of common substances of abuse.
3. Compare and contrast treatment approaches in pediatrics for substance use and addiction.

### ABBREVIATIONS IN THIS CHAPTER

AAP	American Academy of Pediatrics
ADHD	Attention-deficit/ hyperactivity disorder
DSM-IV	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , fourth edition
GABA	$\gamma$ -Aminobutyric acid
GHB	$\gamma$ -Hydroxybutyrate
LSD	Lysergic acid diethylamide
MDMA	Methylenedioxy methamphetamine
NRT	Nicotine replacement therapy
NSDUH	National Survey on Drug Use and Health
PCP	Phencyclidine
SUD	Substance use disorder
THC	Tetrahydrocannabinol

### INTRODUCTION

The consequences of adolescent substance use disorders (SUDs) affect all realms of life. The harm to the adolescent and his or her family varies among biological, psychological, social, spiritual, and financial problems. The continuum of SUD varies between experimental use, abuse, and dependence, with the latter better referred to as addiction. Addiction is a chronic, neurobiologic disease of pathologic pursuit of reward and/or relief by substance use involving cycles of remission and relapse (Reference 1). Adolescent SUD is treatable, but it often becomes more difficult as it progresses to a chronic problem.

### Epidemiology

Although several national surveys measure differing rates of substance use among adolescents, all show widespread use of alcohol and other drugs. The Youth Risk Behavior

Survey (YRBS) is a national survey administered every 2 years to representative samples of 9th- to 12th-grade students. The 2009 survey showed that 72.5% of students had consumed at least one alcoholic drink in their lifetime. The present rate (defined as at least one drink in the previous 30 days) of alcohol use among high school students is 41.8% (Reference 2).

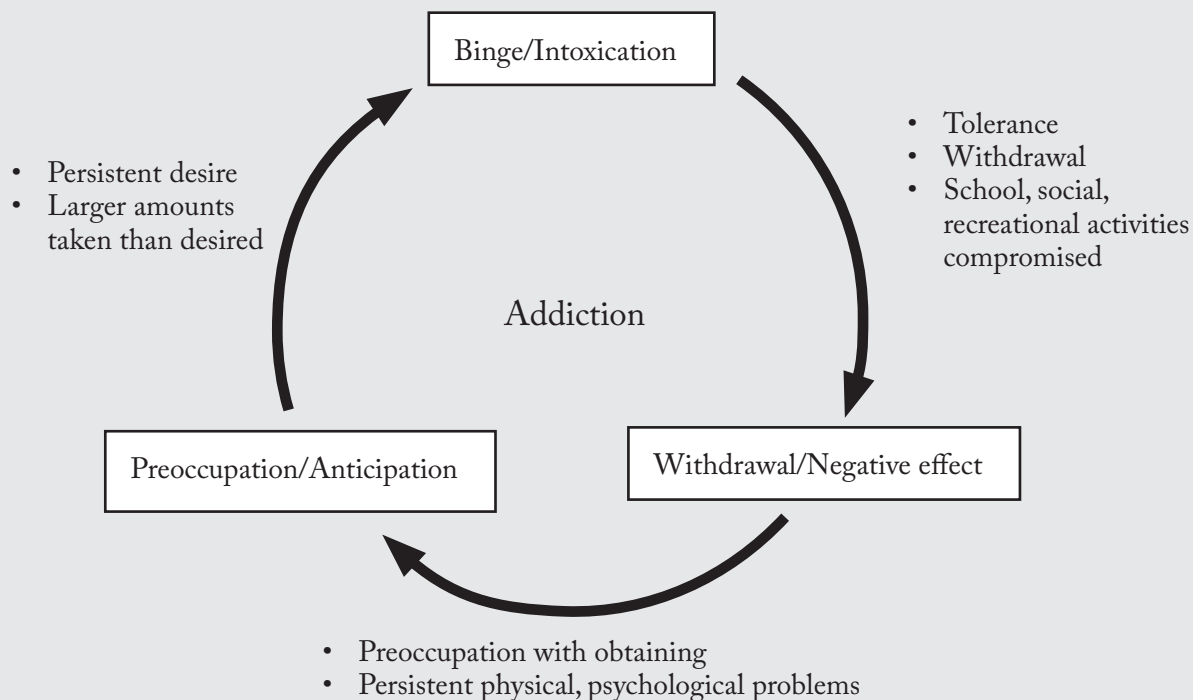

The National Survey on Drug Use and Health (NSDUH), an interview of individuals 12 years or older, has shown similar long-term trends, with lower prevalence rates compared with the YRBS. More than one-half (52.2%) of people 12–20 years old reported underage drinking at least once in their lifetime, and 27.2% consume alcohol currently. Limiting the age to 12–17 years resulted in a current alcohol use rate of 14.7% (Reference 3).

According to the NSDUH, the current drug use rate among those 12–17 years of age is lower than alcohol use at 10.0% (Reference 3). Marijuana is the most widely used substance, with a present rate of 7.3%. However, the YRBS showed a higher current use rate for marijuana of 20.8% (Reference 2). Marijuana, phencyclidine (PCP), and inhalants are drugs that adolescents often experiment with initially (Reference 3).

Another survey of students in the 8th, 10th, and 12th grades shows long-term trends similar to those in the previously mentioned studies. In the 2010 Monitoring the Future report, alcohol use continued to decline, whereas marijuana continued to rise among all three grades. The ongoing decline in cigarette use came to a halt in the lower grades, with both 8th and 10th graders showing increased smoking. About 1 in 14 (7.1%) 8th graders and up to 1 in 5 (19.2%) 12th graders are current smokers. These proportions are likely underestimated because the data do not include high school dropouts (Reference 4).

### Neurobiology of Addiction

Addiction progresses over the course of three stages, with each stage corresponding to alterations to neurobiologic circuits in the central nervous system (Figure 1). The first stage, binge/intoxication, involves a reward pathway of the ventral striatum (location of the nucleus accumbens) from the ventral tegmental area. The neurotransmitters or neuromodulators with key roles in reinforcing the effects of drugs of abuse are primarily mesolimbic dopamine together with opioid peptide,  $\gamma$ -aminobutyric acid (GABA), and endocannabinoid. A

**Figure 1.** The addiction cycle. Diagram including different criteria for substance dependence incorporated from the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed.

Adapted from Koob GF. Neurobiology of addiction. In: Galanter M, Kleber HD, eds. *Textbook of Substance Abuse Treatment*, 4th ed. Arlington, VA: American Psychiatric Press, 2008:3–16.

second stage of withdrawal/negative effect results from activation of the extended amygdala. The neurotransmitters thought to have a function in negative reinforcement are corticotropin-releasing factor, norepinephrine, and dynorphin. A widely distributed network, including the prefrontal cortex and hippocampus, mediates the third stage of preoccupation/anticipation. Glutamate is the main neurotransmitter involved in this phase of craving (Reference 5).

Adolescents may be particularly vulnerable to the exposure to alcohol and other drugs because the brain is still maturing throughout this period into young adulthood. Natural adolescent brain development involves a reduction in gray matter volume and enhancements in white matter, which are thought to support advances in cognition and behavior. Improved dopamine transmission occurs, mainly because of an increase in the density of connections in the prefrontal cortex. Neural consequences in adolescent substance users include poor white matter integrity as well as alterations in the prefrontal, hippocampal, and cerebellar structure. These are associated with deficits in neuropsychological functioning. These deficits may manifest as impairments in attention, information processing, spatial skills, learning

and memory, and complex behaviors such as planning and problem solving. Adolescent SUDs during this developmental period increase the susceptibility to negative, chronic effects in all realms of life (Reference 6).

In general, a more developed limbic system, responsible for emotional and incentive processing, together with a lower-functioning prefrontal region involved in behavioral control, puts the adolescent at risk of poor decisions (Reference 6). Other risk or protective factors affecting adolescent SUDs are listed in Table 1. With the interaction of genetic and environmental influences, the more risk factors an adolescent has, the greater the chance of his or her substance use progressing to addiction.

## CLINICAL PRESENTATION AND DIAGNOSIS

### Screening and Diagnosis

Several organizations recommend universal screening of adolescents for use of alcohol, tobacco, and other drugs at every health supervision visit and at appropriate acute care visits (References 7, 9, 10). Practice parameters (Reference 8) and consensus recommendations (Reference 11) suggest adolescents who exhibit

**Table 1. Factors Influencing SUD in Adolescents**

Risk Factors	Protective Factors
<ul style="list-style-type: none"><li>▪ Positive family history of addiction</li><li>▪ Early age of onset of regular use</li><li>▪ Drug-using peers or siblings</li><li>▪ History of mental health disorders</li><li>▪ History of sexual or physical abuse</li><li>▪ Parental crime</li><li>▪ Transition (divorce, change in school)</li><li>▪ College (alcohol use)</li><li>▪ Availability</li><li>▪ Advertising/media</li></ul>	<ul style="list-style-type: none"><li>▪ Parental approval</li><li>▪ Parental monitoring</li><li>▪ Two-parent home</li><li>▪ Family dining</li><li>▪ Perception of harm</li><li>▪ High religiosity</li><li>▪ Academic achievement</li><li>▪ College (tobacco use)</li></ul>

SUD = substance use disorder.  
Adapted from References 3, 4, 6–8.

signs and symptoms of substance use receive an appropriate, confidential screening primarily focused on use patterns. Indicators for SUDs that reveal the need for a more comprehensive assessment include (Reference 11):

- Substance use indicators
  - Use of substances during childhood or early adolescence
  - Substance use before or during school
  - Peer involvement in substance use
  - Daily use of one or more substances
- Psychosocial indicators
  - Physical or sexual abuse
  - Parental substance abuse (including driving under the influence/driving while intoxicated)
  - Sudden downturns in school performance or attendance
  - Peer involvement in serious crime
  - Marked change in physical health
  - Involvement in serious delinquency or crimes
  - HIV (human immunodeficiency virus) high-risk activities (intravenous drug use, sex with intravenous drug user)
  - Indicators of serious psychological problems (suicidal ideation, severe depression)

A validated screen is available for adolescent SUD, and the American Academy of Pediatrics (AAP) recently published a universal algorithm for substance use, brief intervention, and/or referral to treatment (Reference 7). The National Institute on Alcohol Abuse and Alcoholism (together with the AAP) also recently published a quick tool for identifying adolescents at risk of alcohol-related problems (Reference 12).

Drug testing with consent from the adolescent is also a useful adjunct to screening for SUD. A negative screening result should be followed up with a reevaluation in 6 months for adolescents at high risk of a SUD.

The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*), provides the formal criteria for adult SUDs (Reference 13). The diagnosis of substance abuse or dependence requires that a certain number of criteria be met in the previous year. These criteria do not accurately represent adolescent SUD for alcohol or cannabis, and refinement to consider abuse and dependence conjointly is expected in future editions (References 14–16). Therefore, many adolescents with SUD do not receive a diagnosis until adulthood.

Consensus recommendations (Reference 17) for adolescent SUD treatment, combined with a policy statement from the AAP (Reference 7), describe the stages of a substance use continuum. These include:

1. Abstinence
2. Use: Experimental or limited use with minimal consequences
3. Problematic use: Use in a high-risk situation (driving, babysitting), use with consequences, or use for emotional regulation (stress, depression)
4. Abuse: Regular use or abuse with several and more severe consequences
5. Addiction (dependence): Regular use for an extended period with continued severe consequences
6. Recovery: Return to abstinence, with a relapse phase in which some adolescents cycle through the stages again
7. Secondary abstinence

The coexistence of a SUD and another mental health disorder is often referred to as dual diagnosis. Common adolescent comorbidities associated with addiction are mood disorders, attention-deficit/hyperactivity disorder (ADHD), and conduct disorder. It is important to establish whether the SUD preceded the mental health condition or the reverse; the adolescent may either be experiencing a health consequence of the SUD or be self-medicating to treat the psychiatric illness, respectively.

## Common Substances of Abuse

The more commonly abused drugs, together with common “street names” and health risks, are listed in Table 2. The signs and symptoms of intoxication or withdrawal are specific to the type of substance used and are described in the section below (References 13, 18). Intoxication is defined as the maladaptive behavioral or psychological change that develops after a recent ingestion of alcohol or other drugs. The syndrome after the cessation of (or reduction in) use that is heavy and prolonged to induce intoxication is known as withdrawal.

### *Cannabinoids*

The active ingredient of marijuana, delta-9-tetrahydrocannabinol (delta-9-THC), is available from the *Cannabis sativa* plant together with other cannabinoids. The use of new synthetic cannabinoids that are marketed as herbal incense products is increasing in popularity. Delta-9-THC is a partial agonist at cannabinoid receptors, which regulate mood, motor control, perception (including pain perception), memory and cognition, appetite, sleep, reproductive function, and immune response (Reference 21).

#### Intoxicating Effects

- Conjunctival injection
- Increased appetite
- Dry mouth
- Tachycardia

#### Withdrawal Effects

- Irritability, anger, or aggression
- Nervousness or anxiety
- Insomnia
- Restlessness
- Depressed mood
- Decreased appetite or weight loss
- Stomach pain, shakiness or tremors, sweating, fever, chills, headache

The intoxicating effects of cannabis occur within 2 hours of use, and the withdrawal signs and symptoms may be apparent several days after last use.

### *Depressants*

Alcohol acts as a central nervous system depressant by activating GABA<sub>A</sub>. Opioid drugs interact with several opioid receptors, but the  $\mu$ -receptor is primarily responsible for analgesia and dependence.

### *Alcohol*

#### Intoxicating Effects

- Slurred speech
- Lack of coordination
- Unsteady gait
- Nystagmus
- Impairment in attention or memory
- Stupor or coma

#### Withdrawal Effects

- Autonomic hyperactivity (sweating or heart rate greater than 100 beats/minute)
- Increased hand tremor
- Insomnia
- Nausea or vomiting
- Transient visual, tactile, or auditory hallucinations or illusions
- Psychomotor agitation
- Anxiety
- Generalized tonic-clonic (“grand mal”) seizures

### *Opioids*

#### Intoxicating Effects

- Pupillary constriction
- Drowsiness or coma
- Slurred speech
- Impairment in attention or memory

#### Withdrawal Effects

- Dysphoric mood
- Nausea or vomiting
- Muscle aches
- Lacrimation or rhinorrhea
- Pupillary dilation, piloerection, or sweating
- Diarrhea
- Yawning
- Fever
- Insomnia

Withdrawal may develop after several hours to a few days after alcohol cessation and within a few minutes to several days after last opioid use or after administration of an opioid antagonist.

### *Stimulants*

Stimulants (amphetamines, cocaine) work by either increasing the release or inhibiting the uptake of dopamine and norepinephrine. More recently, the use of synthetic stimulants, commonly marketed as “bath salts” and “plant food,” has been increasing.

**Table 2. Common Substances of Abuse**

Substances	Street Names	DEA Schedule	Administration	Health Risks
Marijuana	Weed, blunt, chronic, dope, ganja, grass, green, herb, hydro, joint, bud, mary jane, pot, reefer, sinsemilla, skunk, smoke	I	Swallowed, smoked	Cough, frequent respiratory infections, anxiety, depression, schizophrenia
Synthetic marijuana	K2, spice, bliss, black mamba, Bombay blue, fake marijuana, fake weed, genie, Yucatan fire, skunk, moon rocks, zohai	I	Smoked	Unknown
<b>Depressants</b>				
Alcohol		Not scheduled	Swallowed	Increased risk of injuries, violence, fetal damage in pregnant women, depression, neurologic deficits, hypertension, liver and heart disease, fatal overdose
Opioids (oxycodone, hydrocodone)	Oc, ox, oxy, oxycotton, oxycet, roxy, hillbilly eroin, perc	II, III	Swallowed, snorted, smoked, injected	Respiratory depression and arrest, nausea, confusion, constipation, sedation, unconsciousness, coma
Heroin	Big H, black tar, brown sugar, chiva, dope, hell dust, horse, junk, negra, smack, thunder	I	Injected, smoked, snorted	Constipation, endocarditis, hepatitis, HIV, fatal overdose
<b>Stimulants</b>				
Amphetamines/methylphenidate	Bennies, black beauties, crosses, hearts, LA turnaround, speed, truck drivers, uppers/JIF, MPH, R-ball, skippy, the smart drug, vitamin R	II	Swallowed, snorted, smoked, injected	Weight loss, insomnia, cardiac or cardiovascular complications, stroke, seizures Also, for amphetamines: tremor, loss of coordination, irritability, anxiousness, restlessness, delirium, panic, paranoia, impulsive behavior, aggressiveness
Mephedrone/methylenedioxy-pyrovalerone (MDPV)/methylone	Bath salts, bliss, blue silk, cloud nine, drone, energy-1, ivory wave, lunar wave, meow meow, ocean burst, pure ivory, purple wave, red dove, snow leopard, stardust, vanilla sky, white dove, white knight, white lightning	I (emergently classified)	Swallowed, snorted, smoked, injected	Unknown
Cocaine	Blow, bump, C, candy, charlie, coke, crack, flake, rock, snow, toot	II	Snorted, smoked, injected	Weight loss, insomnia, cardiac or cardiovascular complications, stroke, seizures, nasal damage from snorting
Methamphetamine	Batu, bikers coffee, black beauties, chalk, chicken feed, crank, crystal, fire, glass, go-fast, hiropon, ice, meth, methlies quick, poor man's cocaine, shabu, shards, speed, stove top, tina, trash, tweak, uppers, ventana, vidrio, yaba, yellow bam	II	Swallowed, snorted, smoked, injected	Weight loss, insomnia, cardiac or cardiovascular complications, stroke, seizures, irreversible neurologic damage, impaired memory and learning, severe dental problems
Nicotine		Not scheduled	Smoked, snorted, chewed	Chronic lung disease, cardiovascular disease, stroke, cancers of the mouth, pharynx, larynx, esophagus, stomach, pancreas, cervix, kidney, bladder, and acute myeloid leukemia, adverse pregnancy outcomes

(continued)

Table 2. Common Substances of Abuse (continued)

Substances	Street Names	DEA Schedule	Administration	Health Risks
<b>Club Drugs</b>				
MDMA	Ecstasy, adam, beans, clarity, disco biscuit, E, eve, go, hug drug, lover's speed, peace, STP, X, XTC	I	Swallowed, snorted, injected	Sleep disturbances, depression, impaired memory, hyperthermia
GHB ( $\gamma$ -hydroxybutyrate)	Easy lay, G, georgia home boy, goop, grievous bodily harm, liquid ecstasy, soap, scoop, goop, liquid X	I III	Swallowed Pharmaceutical preparation	Unconsciousness, seizures, coma
Flunitrazepam (Rohypnol)	Circles, forget-me pill, la rocha, lunch, mexican valium, money drug, R2, reynolds, roach, roche, roofies, roofinol, rope, rophites, row-shay, ruffies, wolfies	IV	Swallowed, snorted	Confusion, fatigue, impaired coordination, memory, judgment, respiratory depression and arrest
<b>Dissociative Drugs</b>				
PCP (phencyclidine)	Angel dust, boat, hog, love boat, peace pill	I, II	Swallowed, smoked, injected	Memory loss, difficulties with speech and thinking, depression, weight loss
Ketamine	Cat valium, Jet K, K, kit kat, purple, special K, super acid, super K, vitamin K	III	Injected, snorted, smoked	Anxiety, tremors, numbness, memory loss, nausea
Dextromethorphan	CCC, Dex, DXM, poor man's pcp, robo, robotripping, skittles, triple C, velvet	Not scheduled	Swallowed	Hypoxic brain damage from severe respiratory depression
<b>Hallucinogens</b>				
LSD (lysergic acid diethylamide)	Acid, blotter; blue heaven, cubes, dots, mellow yellow, window pane	I	Swallowed, absorbed through mouth tissues	Flashbacks, hallucinogen persisting perception disorder
Psilocybin	Magic mushrooms, purple passion, shrooms, little smoke	I	Swallowed	Flashbacks, risk of psychiatric illness, impaired memory
Salvia divinorum	Salvia, shepherdess's herb, maria pastora, magic mint, sally-D	Not scheduled	Smoked, swallowed, chewed	Unknown
<b>Other</b>				
Inhalants	Laughing gas, gluey, huff, poppers, rush, snappers, whippets	Not scheduled	Inhaled through nose or mouth	Cramps, muscle weakness, depression, memory impairment, damage to cardiovascular and nervous systems, unconsciousness, sudden death
Anabolic steroids	Arnolds, juice, gym candy, pumpers, roids, stackers, weight gainers	III	Injected, swallowed, applied to skin	Hypertension, blood clotting and cholesterol changes, liver cysts, hostility and aggression, acne, premature stoppage of growth; in males: prostate cancer, reduced sperm production, shrunken testicles, breast enlargement; in females: menstrual irregularities, development of beard and other masculine characteristics

DEA = Drug Enforcement Agency; HIV = human immunodeficiency virus; MDMA = methylenedioxymethamphetamine. Adapted from References 19, 20.

## *Amphetamines and Cocaine*

### Intoxicating Effects

- Pupillary dilation
- Tachycardia or bradycardia
- Elevated or lowered blood pressure
- Perspiration or chills
- Nausea or vomiting
- Weight loss
- Psychomotor agitation or retardation
- Muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias
- Confusion, seizures, dyskinesias, dystonias, coma

### Withdrawal Effects

- Dysphoric mood
- Fatigue
- Vivid and unpleasant dreams
- Insomnia or hypersomnia
- Increased appetite
- Psychomotor retardation or agitation

Withdrawal may occur within a few hours (typical for cocaine) to several days (typical for amphetamines or related substances) after cessation from stimulants.

The AAP considers tobacco use a pediatric disease (Reference 22). Nicotine is primarily the addictive component in tobacco. Smoking and chewing tobacco increase the risk of pulmonary disease, cardiovascular disease, and various cancers. Withdrawal begins within 24 hours of last nicotine use and includes dysphoric or depressed mood; insomnia; irritability, frustration, or anger; anxiety; difficulty concentrating; restlessness; decreased heart rate; and increased appetite or weight gain.

Caffeine is likely the most widely used substance but is not included in the previous surveys of adolescents. Of concern are the effects of the energy drinks that contain unregulated amounts of caffeine and ingredients that lack evaluation in adolescents (Reference 23).

## *Caffeine*

### Intoxicating Effects

- Restlessness
- Nervousness
- Excitement
- Insomnia
- Flushed face
- Diaphoresis
- Gastrointestinal disturbance
- Muscle twitching
- Rambling flow of thought and speech

- Tachycardia or cardiac arrhythmia
- Periods of inexhaustibility
- Psychomotor agitation

### Withdrawal Effects

- Headache
- Marked fatigue or drowsiness
- Dysphoric mood, depressed mood, or irritability
- Difficulty concentrating
- Flulike somatic symptoms, nausea, vomiting, or muscle pain/stiffness

The withdrawal symptoms occur within 24 hours after last caffeine use.

## *Club Drugs*

Methylenedioxymethamphetamine (MDMA), commonly referred to as ecstasy, is frequently sold in combination with other drugs, often resulting in unpredictable effects when it is abused. Methylenedioxymethamphetamine works mainly by inhibiting the reuptake of serotonin. Common symptoms of intoxication include mild hallucinogenic effects, increased tactile sensitivity, empathic feelings, lowered inhibition, anxiety, chills, sweating, teeth clenching, and muscle cramping.

The other “club drugs,”  $\gamma$ -hydroxybutyrate (GHB) and flunitrazepam, are typically used as either an adjunct to sleep or date rape.  $\gamma$ -Hydroxybutyrate acts at the GHB and GABA<sub>B</sub> receptors, and flunitrazepam, like other benzodiazepines, acts at the GABA<sub>A</sub> receptor. The intoxication and withdrawal effects of these substances mimic those of alcohol.

## *Dissociative Drugs*

Although uncommon, PCP is one of the first substances with which adolescents may experiment. Phencyclidine works mainly as a glutamate receptor antagonist. Within 1 hour of use, vertical or horizontal nystagmus; hypertension or tachycardia; numbness or diminished responsiveness to pain, ataxia, dysarthria, muscle rigidity, seizures, or coma; and hyperacusis may occur. The actions of ketamine and high-dose dextromethorphan are similar to PCP in causing the dissociative feeling separate from one’s body and environment.

## *Hallucinogens*

Other hallucinogens are not separately listed for criteria in the *DSM-IV*. Lysergic acid diethylamide (LSD) is a partial agonist at serotonin receptors. Psilocybin, better known as mushrooms, has LSD-like properties. *Salvia divinorum* is a plant with potent activity at the  $\kappa$ -opioid receptors. In a state of full wakefulness and

alertness, perceptual changes occur (subjective intensification of perceptions, depersonalization, derealization, illusions, hallucinations, synesthesias) after recent use of a hallucinogen. Other signs that develop are pupillary dilation, tachycardia, sweating, palpitations, blurred vision, tremors, and incoordination.

### ***Other Substances of Abuse***

Inhalants are next to marijuana as the most common drug initially used by adolescents. Inhalants include solvents (paint thinners, gasoline, glues), gases (butane, propane, aerosol propellants, nitrous oxide), and nitrites (isoamyl, isobutyl, cyclohexyl). Intoxication from inhalants includes the following signs and symptoms: dizziness, nystagmus, incoordination, slurred speech, unsteady gait, lethargy, depressed reflexes, psychomotor retardation, tremor, generalized muscle weakness, blurred vision or diplopia, stupor or coma, and euphoria. Of primary concern is the risk of sudden sniffing death syndrome, which may occur with any use of inhalants (Reference 24).

Anabolic steroids and other performance-enhancing substances (protein supplements and creatine) have few to no intoxicating effects. However, the AAP strongly objects to the use of performance-enhancing substances because of the potential for adverse health problems and the lack of principle and fairness (Reference 25). Adolescent athletes who are “doping” are at risk of the many consequences listed in Table 2.

### ***Polysubstance Use***

The various substances previously described may become even more harmful and addictive when used in combination. Polydrug use causes additive or interactive effects. For instance, acute ingestion of marijuana and alcohol increases the effects of D-9-THC (Reference 26). A particularly dangerous combination is cocaine and alcohol because the liver combines these substances to produce cocaethylene (Reference 27). This new substance intensifies the effects of cocaine and is associated with a greater risk of sudden death than cocaine alone.

## **TREATMENT**

Of the 1.8 million 12- to 17-year-olds who needed treatment for a SUD, only 150,000 (8.4%) received it (Reference 3). Thus, more than 1.6 million adolescents remained untreated for a SUD in 2009. It is extremely helpful to be aware of the community resources available for adolescents needing evaluation for and treatment of a SUD.

An important determinant of treatment is at which stage along the substance use continuum an adolescent is in. The following is a concise description of treatment suggestions for adolescents (References 7, 17).

1. Abstinence: Positive reinforcement, anticipatory guidance
2. Use: Promote patient strengths, encourage cessation, provide education about risks of using alcohol and other drugs
3. Problematic use: As previously stated plus brief intervention; consider breaking confidentiality
4. Abuse: As previously stated plus referral for comprehensive assessment and treatment
5. Addiction (dependence): As previously stated plus referral to subspecialty treatment; encourage parental involvement
6. Recovery: Positive reinforcement, support
7. Secondary abstinence: Positive reinforcement, support

### **Nonpharmacologic Therapy**

Brief intervention may include education on the immediate consequences of even casual use, a recommendation for abstinence possibly with negotiation, and an agreement for follow-up.

The recovery stage has several treatment phases. The acute intervention motivating the adolescent to recovery may be followed temporarily by detoxification, depending on the substance(s) used and the use pattern, for managing withdrawal. The next phase of treatment is rehabilitation, in which combinations of individual, group, and family therapy and 12-step-based fellowships (e.g., Alcoholics Anonymous, Narcotics Anonymous) are strong components. Other nonpharmacologic therapies helpful to an adolescent in recovery are scheduled chores and recreational activities, school or vocational training, and contracts with outlined consequences (Reference 17). The transition period from inpatient and/or residential treatment back to home is often difficult, and treatment should include continuing care to prevent relapse. Finally, maintenance of recovery may require further therapy and 12-step work to support abstinence.

### **Pharmacologic Therapy**

Pharmacologic therapy for SUD may be divided into medications used for:

- Intoxication to stabilize the adolescent
- Detoxification to manage the signs and symptoms of withdrawal
- Maintenance of recovery

Most medications are not approved by the U.S. Food and Drug Administration for adolescent SUD; therefore, the risk-benefit must be balanced before initiating pharmacologic therapy. Limited data on SUD treatment in adolescents exist, and often, management strategies are extrapolated from adult recommendations. Available dosing information for the drug therapies reviewed below is listed in Table 3.

The management of intoxication should focus on respiratory, cardiac, and neurologic stabilization, together with administration of an antidote when indicated and available. Life support to maintain cardiorespiratory function and fluid replacement for hydration may be necessary. Comatose adolescents at risk of aspiration may require intubation and ventilation. Adolescents exhibiting psychosis may need sedation and antipsychotics. Medications recommended for reversal are naloxone, given repeatedly as needed, for acute opioid intoxication and flumazenil for acute intoxication with benzodiazepines, including flunitrazepam but not GHB. Physostigmine may have a role in GHB toxicity (Reference 28). Decontamination of the gastrointestinal tract (by activated charcoal and gastric lavage) or clothes and skin (inhalant use) may be indicated. Other substance-specific problems are methemoglobinemia from inhalant intoxication, needing methylene blue treatment (Reference 24), and hyperthermia from MDMA, requiring management with cooling blankets, acetaminophen, and benzodiazepines for shivering or seizures.

Detoxification is uncommon for most substances, but depressants may require therapy to manage the signs and symptoms of withdrawal. Long-acting benzodiazepines, although seldom needed, together with vitamin replacement, are appropriate for treatment of alcohol withdrawal. Opioid detoxification is more complicated in adolescents than in adults, and use of opioid agonists may be indicated. Methadone is a full receptor agonist with no controlled studies in adolescents. Buprenorphine is a partial agonist approved for opioid dependence in those 16 years and older. A Cochrane review provides no conclusion regarding opioid detoxification from the two controlled trials using buprenorphine (Reference 29). The findings from these trials are that 12 weeks of buprenorphine-naloxone maintenance is more effective than 2 weeks of buprenorphine alone (Reference 30), and buprenorphine is more effective than clonidine (Reference 31) for opioid treatment. Clonidine is not routinely recommended for detoxification, but it may be used early on for control of early autonomic withdrawal symptoms.

Maintenance therapies may be considered in treatment-resistant adolescents for alcohol dependence (Reference 8). Acamprosate works by activating GABA<sub>A</sub> receptors and blocking glutamate receptors. It has been shown to increase abstinence over placebo in adolescents with alcohol dependence at 90 days (Reference 32). Naltrexone, an oral opioid receptor antagonist, was found to reduce alcohol consumption and craving in

**Table 3.** Medications for Management of Adolescent SUD (References 29–33)

<b>Acute Intoxication</b>	
Flumazenil	0.01 mg/kg (maximal dose 0.2 mg); repeat every minute to maximal cumulative dose 1 mg
Naloxone	2 mg; repeat every 2–3 minutes
<b>Detoxification</b>	
Buprenorphine	6–8 mg/day; decrease by 2 mg every 7 days or up to 14 mg/day, taper to 14 days
Clonidine patch	0.1 mg on day 1; add 0.1 mg on day 2; add an optional 0.1 mg on day 4. Remove all patches on day 7 and replace with 0.2-mg doses. Remove all patches on day 14 and replace with 0.1-mg doses. Remove all patches on day 21.
Methadone	0.05–0.1 mg/kg/dose every 6 hours; increase by 0.05 mg/kg/dose. Decrease interval to every 12–24 hours at 1–2 days. Taper 0.05 mg/kg/day.
<b>Maintenance</b>	
Acamprosate	666 mg in morning, 333 mg in afternoon, 333 mg in evening for 12 weeks
Buprenorphine	Up to 24 mg/day (and naloxone 0.5 mg) for 9 weeks and then taper to 12 weeks
Methadone	Flexible dosing daily for 16 weeks
Naltrexone	25–50 mg/day for 6 weeks

SUD = substance use disorder.

an open-label trial of adolescents (Reference 33). Ondansetron (Reference 34) and disulfiram (References 35, 36) have also been evaluated in adolescents but are seldom recommended over the above therapies for alcohol dependence.

The use of pharmacotherapy in adolescents with tobacco use disorder is controversial. Although nicotine replacement therapy (NRT) is safe, a Cochrane review found little evidence that such medications are effective in promoting abstinence among adolescent smokers. Moreover, the evidence does not support the use of bupropion either alone or as an adjunct to NRT (Reference 37).

Adolescents with a SUD and a co-occurring psychiatric illness may benefit from programs that provide treatment of both disorders. Medications for mental health disorders that are considered nonaddictive would be more appropriate treatments for adolescents with dual diagnosis. For instance, atomoxetine may be considered over stimulant medications for the treatment of ADHD in an adolescent who also suffers from a SUD. Drugs used in studies of adolescents with a coexisting SUD and another mental health disorder include fluoxetine or sertraline for depression and alcohol dependence (References 38–40), lithium for bipolar disorder and alcohol or other drug dependence (Reference 41), and bupropion for ADHD and nicotine dependence (Reference 42).

## MONITORING AND PROGNOSIS

Toxicologic testing may be an important component in the ongoing assessment of substance use during and after treatment. However, the AAP does not recommend routine home- or school-based drug testing (Reference 43). The opportunity for detection from a urine drug test may be small because most substances, with the exception of marijuana, are fully excreted within 72 hours or less. Other important limitations are that standard panels do not detect some of the drugs, such as alcohol and inhalants, most often abused by adolescents, and false-positive results may occur, which require follow-up. Other monitoring parameters may include self-reported substance use, adherence to therapies, and behavioral changes.

Untreated adolescents who abuse substances will likely progress to having addiction in adulthood. Treatment may effectively lead to abstinence; however, relapse is common in adolescents. Instead of increasing shame or providing punishment, the emphasis should be on what adolescents can learn from the relapse. With continued treatment and encouragement to abstain from alcohol and other drugs, the adolescent may lead a full and healthy life.

## PREVENTION

Early-use prevention targeting children and preadolescents is thought to be essential to reducing the risk of progression to later addiction. A document, published by the National Institute on Drug Abuse, outlines the following 16 research-based principles, which are important to the structure, content, and delivery of drug abuse prevention programs (Reference 44).

### Risk Factors and Protective Factors

1. Enhance protective factors (parental support/modeling), and reverse or reduce risk factors (delay the age of initiation).
2. Address all forms of drug abuse (illegal and legal substances, over-the-counter medications).
3. Address drug abuse problem within the local community.
4. Be tailored to address risks specific to audience (age, gender, ethnicity).

### Prevention Planning

5. Enhance parent-child relationships while developing, discussing, and enforcing family policies on substance abuse.
6. Occur as early as preschool
7. Target educational (academic failure) and emotional (early aggression) awareness for elementary children.
8. Target increasing academic (study habits) and social (peer relationships) competence for middle and high school students.
9. Be aimed for a general population at key transition points (elementary to middle school).
10. Combine at least two programs (community-, school-, and family-based) to be more effective.
11. Reach many settings (schools, faith-based organizations, media).

### Prevention Program Delivery

12. Retain core elements (structure, content, delivery) while adapting to local community.
13. Be long term to reinforce content.
14. Train teachers in positive classroom management techniques.
15. Employ active learning.
16. Be cost-effective.

## CONCLUSIONS

Alcohol and other drug use is common among adolescents, but progression to later addiction may be preventable. Screening along the substance use continuum, followed by the suggested treatment of brief intervention to referral, is an appropriate management strategy

for adolescent SUD. At minimum, adolescents should be advised that even casual use of substances, regardless of amount or frequency, is likely illegal and has the potential for adverse consequences. For further information regarding adolescent SUD, visit the suggested resources listed in Table 4.

# CHAPTER 33

## PEDIATRIC DEPRESSION

Tiffany-Jade M. Kreys, Pharm.D., BCPP

### LEARNING OBJECTIVES

1. Recognize signs and symptoms of and diagnostic criteria for a Major Depressive Disorder (MDD) in children and adolescents compared to adults.
2. Identify screening tools used to detect depression in youths.
3. List the three main treatment phases of MDD and corresponding treatment goals.
4. Recognize the role of psychotherapeutic treatments for MDD in youths.
5. Compare and contrast pharmacologic treatments in regards to mechanisms of action, dosing, efficacy, and tolerability.
6. Explain the risk of new onset suicidality associated with antidepressant use in youth as well as the risk of untreated depression.

### ABBREVIATIONS IN THIS CHAPTER

AACAP	American Academy of Child and Adolescent Psychiatry
ADHD	Attention-deficit/hyperactivity disorder
CBT	Cognitive behavioral therapy
DSM-IV-TR	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , Fourth Edition, Text Revision
ECT	Electroconvulsive shock therapy
MAOIs	Monoamine oxidase inhibitors
MDD	Major depressive disorder
PHQ-9	Patient Health Questionnaire-9 Item
SNRIs	Serotonin norepinephrine reuptake inhibitors
SSRIs	Selective serotonin reuptake inhibitors
TCA	Tricyclic antidepressants

### INTRODUCTION

Major depressive disorder (MDD) can occur in children as young as preschool age and is associated with an increased risk of morbidity and mortality. Psychotherapy and pharmacotherapy are the mainstays of treatment for pediatric depression. This chapter will highlight important concepts in the diagnosis and management of depression in children and adolescents and evaluate key studies and controversies surrounding the use of antidepressant therapy in this patient population. The clinical

course and duration of depression in youths, together with a review of treatment phases and pharmacologic options, are also discussed.

### EPIDEMIOLOGY OF PEDIATRIC DEPRESSION MDD in Adolescents

According to the adolescent supplement of the National Comorbidity Survey Replication, the prevalence of *mood disorders*, a term used to describe both unipolar and bipolar disorders, in adolescents 13–18 years old is 14.3% (Reference 1). About 11.7% of those surveyed met the diagnostic criteria for an MDD or dysthymia (Reference 1). An estimated 50% of these adolescents developed a mood disorder before age 13 (Reference 1). The incidence of mood disorders was found to increase with progressing age, and it almost doubled in rate in adolescents from age 13–14 years (8.4%) to 17–18 years (15.4%) (Reference 1). Although the depression rate is equal in females and males before puberty, depression is twice as common in females as in males after puberty, which is consistent with the rates observed in adulthood (Reference 2). Although female adolescents have higher rates of mood and anxiety disorders, males show higher rates of behavioral and substance abuse issues (Reference 1). In addition, it has been found that depressive symptoms below the threshold for meeting diagnostic criteria for MDD in adolescents are predictive of a major depressive episode in adulthood (Reference 3).

### MDD in Children

Major depressive disorder may present in children as young as preschool age (Reference 4). There is a lack of current epidemiologic data available regarding the prevalence of childhood depression; however, earlier studies have described a prevalence rate for preadolescents (6–11 years old) ranging from 0.6% to 2.7% (Reference 5). According to the Centers for Disease Control and Prevention's NHANES (National Health and Nutrition Examination Survey), there is a 3.7% prevalence of mood disorders in children 8–15 years old, with higher prevalence rates in girls and older children (Reference 6).

### MDD and Suicide

Major depressive disorder is associated with an increased risk of morbidity and mortality (Reference 7). According to the National Center for Health Statistics, suicide was the fourth leading cause of death in 2007 in

children aged 10–14 years and the third leading cause of death in those aged 15–24 years (Reference 8). About 50% to 75% of children and adolescents who commit suicide have had a mood disorder, with major depression being the most common (Reference 9). Additional risk factors for suicide, as reported by the Centers for Disease Control and Prevention, include previous suicide attempts, family history of suicide, history of depression or other psychiatric disorder, substance abuse, stressful life event or loss, easy access to lethal methods, exposure to the suicidal behavior of others, and incarceration (Reference 10).

In a secondary analysis of the Adolescent Depression Antidepressants and Psychotherapy Trial (ADAPT), predictors of suicidality and nonsuicidal self-injury were evaluated during a 28-week study in adolescents with major depression. The authors concluded that family dysfunction, high levels of suicidality, and recent self-harm (suicidal or nonsuicidal) increase the risk of future suicide attempts and that recent nonsuicidal self-injury is the strongest predictor of future nonsuicidal self-injury. The presence of these patient characteristics should alert clinicians to the increased risk of future suicide attempts or self-injurious behavior (Reference 11).

Although adolescent males are more likely to complete suicide (4 males to 1 female) as a result of using more lethal methods for suicide, females have a higher rate of suicide attempts (Reference 2). Suicide attempts are also increased in those with multiple psychiatric comorbidities (Reference 12). Around 40% to 90% of children and adolescents with MDD have at least one other psychiatric condition, with dysthymia and anxiety disorders (both at 30% to 80%), disruptive disorders (10% to 80%), and substance use disorders (20% to 30%) being the most commonly occurring psychiatric comorbidities (Reference 2). Because depression is strongly associated with suicidal thoughts and behaviors, it is recommended that clinicians evaluate for the presence of these symptoms and risk factors on initial presentation and subsequent assessments (Reference 7).

## ETIOLOGY AND PATHOPHYSIOLOGY

The exact etiology of depression remains unknown but is thought to be caused by genetic, biochemical, and environmental influences (Reference 2). Twin studies support a genetic component to depression, with a concordance rate for a major affective disorder of 76% and 19% in monozygotic and dizygotic twins, respectively (Reference 2). Studies show that a family history of depression is a major risk factor for the development of depression in children (Reference 2). It was found that children of parents with an affective disorder had a 2.6 times greater rate of developing MDD than children whose parents had no disorder (Reference 13). In the STARD (Sequenced Treatment

Alternatives to Relieve Depression) Child study, the relationship between remission or amelioration of maternal depression and its impact on psychiatric and social functioning in children was assessed (Reference 14). Women 25–60 years old and their biological children between age 7 and 17 were eligible for inclusion. This analysis showed that remission in maternal depression was associated with lower levels of internalizing (e.g., depression, anxiety) and externalizing (e.g., behavioral) problems in youths. In addition, remission of maternal depression predicted changes in mothers' expressions of warmth and acceptance, which led to changes in youths' tendencies to internalize symptoms. These findings suggest that short-term treatment with an antidepressant induces maternal remission of depression, thereby affecting the mother's expression of warmth and acceptance, leading to decreased depressive and anxiety symptoms in children.

According to the “monoamine hypothesis,” one of the most researched theories on depression, depression results from a deficiency or imbalance in monoamine neurotransmitters such as serotonin, dopamine, and norepinephrine (Reference 15). Supporting this hypothesis is that antidepressant medications enhance monoamine function, thereby treating symptoms of depression (Reference 15).

The pathophysiology of depression is likely caused by a variety of factors, with recent research focusing on molecular mechanisms of depression (Reference 15). Hypercortisolemia, BDNF (brain-derived neurotrophic factor), hippocampal neurogenesis, circadian rhythm changes, and functional and structural brain imaging are among the various proposed factors contributing to the pathogenesis of depression (Reference 15).

Additional risk factors for child and adolescent depression include psychosocial stressors (e.g., childhood neglect or abuse), psychiatric comorbidities (e.g., attention-deficit hyperactivity disorder [ADHD], anxiety), chronic illness (e.g., diabetes), female sex, hormonal changes during puberty, presence of serotonin transporter gene variants, and use of certain medications (Reference 16).

## DIAGNOSTIC CRITERIA AND CLINICAL PRESENTATION

According to the *Diagnostic and Statistical Manual of Mental Disorder*, Fourth Edition, Text Revision (DSM-IV-TR), the diagnostic criteria for MDD in children and adolescents are similar to those in adults. To meet the diagnostic criteria for a major depressive episode, at least five of nine depressive symptoms must be present during the same 2-week period. At least one of the five symptoms must be depressed mood or anhedonia, defined as an inability to experience pleasure in normal pleasurable acts; however, an irritable mood may be

considered equivalent to either depressed mood or anhedonia in the pediatric patient population. Depressive symptoms should be present almost every day for most of the day and should include the following:

- Depressed or irritable mood or anhedonia
- Significant weight loss or weight gain or failure to make expected weight gains in children
- Insomnia or hypersomnia
- Psychomotor agitation or retardation
- Fatigue or loss of energy
- Feelings of worthlessness or excessive or inappropriate guilt
- Difficulty concentrating or indecisiveness
- Recurrent thoughts of death

To further meet diagnostic criteria, these depressive symptoms must cause clinically significant distress or impairment in social, occupational, or other areas of functioning. In addition, the symptoms must not be caused by illicit drug use, a medication, a general medical condition, and/or bereavement (Reference 17).

Although the diagnostic criteria for depression in children and adolescents are similar to those for adults, some differences in the clinical presentation of depression may exist based on the youth's physical, emotional, cognitive, and social developmental stage (Reference 7). Because data are conflicting with respect to the symptom presentation of depression in children and adolescents, a database study of children and adolescents who were referred to an outpatient mood and anxiety disorders clinic was conducted (Reference 18). This study evaluated clinical characteristics of depression in this patient population. Adolescents with depression showed more hopelessness/helplessness, fatigue/lack of energy/tiredness, hypersomnia, weight loss, and suicidality compared with children with depression. Comorbid substance abuse/dependence was found to be more prevalent in depressed adolescents, whereas comorbid separation anxiety, oppositional defiant disorder, and ADHD occurred more often in children. A depressed or irritable mood in children was often associated with specific events or preoccupations compared with adolescents. Other depressive symptoms, including feelings of guilt, negative self-image, anhedonia, delusions/hallucinations, weight gain, increased appetite, anorexia, psychomotor agitation/retardation, social withdrawal, and insomnia, were observed to occur at similar rates in both children and adolescents.

### Differential Diagnosis

The presence of specific medical conditions (e.g., hypothyroidism, mononucleosis, anemia, certain cancers, autoimmune disease, premenstrual dysphoric disorder, chronic fatigue syndrome) and psychiatric conditions

(e.g., anxiety, dysthymia, ADHD, oppositional defiant disorder, pervasive developmental disorder, substance abuse) that may occur with or show symptoms similar to depression should be assessed before confirming an MDD diagnosis (Reference 7). The use of certain medications that may cause symptoms of depression, such as stimulants, corticosteroids, and contraceptives, should also be evaluated (Reference 7). Patients with bipolar disorder, a cyclic mood disorder characterized by alternating episodes of mania and depression, will often experience an acute depressive episode before any periods of mania, making it difficult to distinguish between unipolar and bipolar depression. About 20% to 40% of children and adolescents initially presenting with depression develop bipolar disorder within 5 years after the onset of depression (Reference 7). Characteristics associated with an increased risk of developing bipolar disorder in adolescents with MDD include early-onset depression, depression accompanied by psychomotor retardation or psychotic features, family history of bipolar or other mood disorders, and drug-induced mania (Reference 19). Hence, it is important to monitor for the presence of hypomanic symptoms, such as a decreased need for sleep, excessive talking, distractibility, and flight of ideas, which often tend to worsen with antidepressant therapy (Reference 19). See the Pediatric Bipolar Disorder chapter for more detailed information on this disorder in children and adolescents.

### SCREENING FOR MDD

Although evidence supporting the use of depression-screening instruments in youths is limited (Reference 20), it is recommended that clinicians screen all children and adolescents for depressive symptoms using checklists derived from the DSM-IV-TR, clinician-based instruments, and/or child/parent depression self-reports (Reference 7). The patient evaluation should also include interviews with the child and parent(s) and an interview alone with the adolescent, if attainable (Reference 7). The Patient Health Questionnaire-9 Item (PHQ-9) is a self-administered depression-screening tool, based on DSM-IV-TR criteria, developed for use in adults in primary care settings (Reference 14). Its utility in screening for adolescent depression was recently highlighted. The PHQ-9 has greater sensitivity but lower specificity in detecting depression in adolescents compared with adults. Thus, the PHQ-9 is unlikely to miss detecting depression in adolescents; however, false positives, possibly caused by an overlap of symptoms among mental health disorders or subthreshold symptoms of depression combined with adjustment disorder, may occur, thereby warranting further inquiry by providers. A limitation of the PHQ-9 is that it does not include an item for irritability, a symptom of depression included

as part of the diagnostic criteria for MDD in youths but not adults. Therefore, providers may need to specifically inquire about the presence of irritability when screening for depression. Other instruments evaluated for use in adolescent depression screening in the primary care setting include the BDI-PC (Beck Depression Inventory–Primary Care Version), a 7-item self-rated questionnaire, and the PHQ-A (Patient Health Questionnaire for Adolescents), a 67-item self-rated questionnaire (References 20, 21). The SDQ (Strength and Difficulties Questionnaire) has been studied in youths 4–16 years old but has a lower sensitivity in detecting depression in youths (33% to 54% sensitivity) compared with the aforementioned instruments used to detect depression in adolescents (Reference 20). The Children's Depression Inventory, a 27-item self-rated scale, can also be used to assess for depressive symptoms in children 7–17 years old and is the most commonly used inventory for childhood depression (Reference 22). In addition, the CDRS (Children's Depression Rating Scale), a 16-item clinician-rated instrument based on parent, child, and schoolteacher interviews, can be used to determine the severity of depression in children aged 6–12 years (Reference 23).

### Clinical Course and Duration

Five major terms are used to describe the clinical course of MDD: response, remission, recovery, relapse, and recurrence. Response is defined as significant improvement, usually considered a 50% reduction in symptom severity from baseline, during the initial or acute treatment phase. Remission is a period of at least 2 weeks and less than 2 months characterized by the presence of no or very few depressive symptoms (i.e., PHQ-9 less than 5). Recovery is defined as either an asymptomatic period lasting 2 months or more or the presence of no more than one or two depressive symptoms for at least 2 months. Relapse is an episode of depression during the remission period, and recurrence is the emergence of MDD symptoms during the recovery period (Reference 7).

A major depressive episode persists for about 7–9 months in clinically referred youths. Although around 90% of major depressive episodes remit within the first 1–2 years of onset, the likelihood of recurrence is between 20% and 60% and further increases to 70% after 5 years. Risk factors for recurrence include younger age at onset, increased number of past episodes, severe current episode, psychosis, and psychosocial stressors (Reference 7).

## TREATMENT

The two main treatment options for pediatric depression include pharmacologic and/or nonpharmacologic therapy. The following factors should be considered when selecting treatment modality: age, cognitive development,

symptom severity and duration, comorbidities, family history of medication response, family and social environment, impact on functioning, and suicide risk. Service availability and patient or family preference may further guide treatment selection. For instance, cognitive behavioral therapy (CBT) may be unavailable in the patient's geographic area, or the child's parents may object to medication treatment (Reference 7).

### Psychotherapy

A meta-analysis published in 2006 of 35 randomized controlled trials showed that psychotherapy had only modest effects on adolescent depression compared with previous trials reporting substantial benefit from psychotherapy (Reference 24). The practice parameter for children and adolescents with depressive disorders published by the American Academy of Child and Adolescent Psychiatry (AACAP) in 2007 provides a brief review of studies assessing the effectiveness of psychotherapy in pediatric depression. The AACAP practice parameter states, "it is reasonable, in a patient with a mild or brief depression, mild psychosocial impairment, and the absence of clinically significant suicidality or psychosis, to begin treatment with education, support, and case management related to environmental stressors in the family and school." The American Academy of Child and Adolescent Psychiatry states that supportive therapy has been shown to be as effective as CBT or IPT (interpersonal psychotherapy). However, AACAP mentions that, in those with moderate to severe depression, chronic or recurrent depression, significant psychosocial impairment, suicidality, agitation, and/or psychosis, supportive therapy and case management are not usually effective and that specific types of psychotherapy or pharmacotherapy are warranted (Reference 7). Interpersonal psychotherapy focuses on the patient's social functioning and relationship with others, whereas CBT is centered on addressing inaccurate or negative thinking patterns or behaviors that contribute to the patient's emotional distress (References 25, 26). Although AACAP states that moderate depression may respond to CBT or interpersonal psychotherapy alone, it denotes that more severe depressive episodes generally require antidepressant treatment, either alone or in combination with psychotherapy. If monotherapy with psychotherapy or antidepressants is ineffective, AACAP recommends a combination of the two treatment modalities.

In the ADAPT study, 208 patients 11–17 years old with moderate to severe depression whose response to a psychosocial brief initial intervention failed were randomized to receive treatment with a selective serotonin reuptake inhibitor (SSRI) plus CBT or an SSRI alone (Reference 27). All patients received routine mental health services together with active clinical care. No difference in treatment effectiveness was observed at any

time. In moderately to severely depressed adolescents, the addition of CBT to an SSRI did not result in improved outcomes or prevent adverse events and was not cost-effective. The authors concluded that if psychosocial interventions do not elicit a response within 2–4 weeks, an SSRI should be prescribed. Thus, in patients with more severe depression undergoing psychotherapy but not responding to it, clinicians should have a low threshold for initiating antidepressant therapy.

### Pharmacotherapy

There are four main antidepressant drug classes. Tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) are older antidepressants that are not recommended for use in pediatrics because of their adverse effect profile, toxicity in overdose, and lack of data supporting their use in this patient population (Reference 28). The TCAs inhibit the reuptake of both serotonin and norepinephrine, thereby increasing serotonin and norepinephrine in the synapse. The MAOIs block monoamine oxidase, the enzyme responsible for the breakdown of monoamines, including serotonin, norepinephrine, and dopamine (Reference 29). Newer antidepressants include SSRIs, serotonin norepinephrine reuptake inhibitors (SNRIs), bupropion, and mirtazapine. The SSRIs block the reuptake of serotonin, whereas the SNRIs block the reuptake of both serotonin and norepinephrine (Reference 29). Bupropion is a norepinephrine and dopamine reuptake inhibitor (Reference 29). Mirtazapine increases the release of norepinephrine and serotonin through presynaptic  $\alpha_2$ -antagonism (References 29, 30). Mirtazapine also shows 5-HT<sub>2</sub> and 5-HT<sub>3</sub> antagonism, which is associated with decreased serotonin-mediated adverse effects, such as gastrointestinal disturbances or sexual dysfunction (Reference 29).

Most controlled studies have evaluated SSRIs for the treatment of pediatric depression. The U.S. Food and Drug Administration (FDA) label-approved SSRIs for acute and maintenance treatment of depression in adults including citalopram, escitalopram, fluoxetine, paroxetine, and sertraline. Although only fluoxetine and escitalopram are indicated for treatment of depression in pediatric patients, all the aforementioned SSRIs have some data supporting their use in this patient population (References 31–35). Fluoxetine is FDA approved for use in patients 8–18 years old, whereas escitalopram is FDA approved for use in patients 12–17 years old (References 36, 37). For the treatment of adult depression, recommended first-line therapies include SSRIs, SNRIs, bupropion, and mirtazapine (Reference 38). Although few studies exist evaluating the use of these agents for the treatment of depression in the pediatric population, there are some data supporting their use. In addition, although no SNRIs are FDA approved for use in pediatric depression, venlafaxine

has efficacy data supporting its use for the treatment of adolescent depression (Reference 39). Moreover, some open-label trials support the use of bupropion sustained release (SR) and mirtazapine in adolescent depression (References 40, 41).

To further assist with treatment selection and sequencing, two multisite, randomized controlled trials have been published. The Treatment for Adolescents with Depression Study (TADS) was a randomized controlled trial of 439 outpatient volunteers aged 12–17 with an MDD diagnosis. Most patients included in this study were considered to have moderate to severe depression. For 12 weeks, this study assessed the effectiveness of fluoxetine in combination with CBT compared with treatment with fluoxetine or CBT alone, as well as the effectiveness of fluoxetine or CBT alone compared with placebo. Fluoxetine in combination with CBT produced the greatest improvement in depressive symptoms. Combination therapy also elicited an earlier treatment response compared with CBT or fluoxetine alone. Fluoxetine alone was more efficacious than CBT alone, and CBT was no more effective than placebo (Reference 33). Response rates at 12 weeks for fluoxetine with CBT were 71%, whereas fluoxetine alone produced a response in 60.6% of patients. About 43% of patients responded with CBT alone compared with a response rate of 34.8% with placebo. However, by week 36 of therapy, no significant differences in response rates were observed between treatments (86% combination therapy, 81% fluoxetine, 81% CBT) (Reference 42). Although high-risk suicidal patients were excluded from the study, about 29% of patients at baseline were described as having at least minimal to severe suicidal ideation. Suicidal thinking significantly improved in all of these patients at 12 weeks, with the greatest reduction occurring in the fluoxetine plus CBT cohort. In addition, there were no completed suicides in this study. By 36 weeks of treatment, it was found that patients treated with fluoxetine alone were more likely to show suicidal ideation and treatment-emergent suicidal events than were patients receiving combination therapy or CBT alone (Reference 42). Investigators concluded that fluoxetine alone or in combination with CBT hastens the improvement of depression compared with CBT alone and that CBT added to fluoxetine decreases suicidal ideation and treatment-emergent adverse events in adolescents.

The Treatment of SSRI-Resistant Depression in Adolescent trial (TORDIA) was a randomized controlled trial of 334 patients aged 12–18 years with a primary MDD diagnosis who did not respond to an adequate dose and duration (2 months) of an SSRI. Patients were randomized to 12 weeks of (1) a different SSRI; (2) venlafaxine, an SNRI; (3) a different SSRI plus CBT; or (4) venlafaxine plus CBT. It was found that CBT plus

a switch to either an SSRI (e.g., paroxetine, citalopram, fluoxetine) or venlafaxine produced a higher response rate (54.8%) compared with either medication alone (40.5%). No significant difference in response rates existed with venlafaxine (48.2%) compared with a second SSRI (47%). Although response rates were comparable, venlafaxine was not as well tolerated as the SSRIs. Skin problems occurred more often in patients in the venlafaxine cohort. Significant increases in diastolic blood pressure and heart rate were also observed in patients receiving venlafaxine. Therefore, because SSRIs were shown to be equally effective and better tolerated than venlafaxine, investigators concluded that patients whose response to initial SSRI therapy failed should be switched to another SSRI rather than to venlafaxine. No statistically significant difference in self-harm adverse events or suicidality between treatments was observed, and no subjects in this study completed suicide. Contrary to findings from the TADS, the addition of CBT to antidepressant therapy did not reduce suicidal adverse events. This may have been because patients in the TORDIA study had higher suicidality at baseline and underwent frequent and intense safety monitoring. Overall, given the results obtained in these two trials, combination therapy with CBT and an antidepressant may produce the greatest symptom improvement in adolescents; however, studies assessing the utility of combination therapy in children are lacking.

In a follow-up study of the TORDIA sample, remission and relapse rates were evaluated at 48 and 72 weeks from intake (Reference 43). Remission was defined as 3 weeks or more with one or no clinically significant symptoms and no functional impairment, and relapse was defined as 2 weeks or more with probable or definite depressive disorder. About 61% of youths reached remission by 72 weeks. Random treatment assignment did not affect remission rate or time to remission. Factors associated with higher rates of remission included less severe depression, shorter depressive episode, lower functional impairment, less non-suicidal self-harm behavior, and less drug and alcohol abuse. Of the 130 subjects who achieved remission by week 24, about 25% relapsed by 72 weeks. No statistically significant difference was observed between random treatment assignments. Only non-white race was associated with higher rates of relapse.

### **Treatment Phases**

The three main phases of treatment for MDD are acute, continuation, and maintenance. The main goal of acute-phase treatment, which typically lasts 6–12 weeks, is to achieve symptom response and remission. Medication-related adverse effects typically occur shortly after therapy initiation, whereas symptom improvement is often not observed until at least 2–4 weeks of treatment at a

therapeutic dose. Once remission is achieved, patients enter the continuation phase of treatment, which typically lasts at least 6–12 months. Continuation-phase treatment is recommended for all patients who have responded to acute-phase treatment, with the goal of this treatment phase being relapse prevention. It is recommended that the dose used to achieve remission be continued during the continuation phase of therapy. In a study evaluating continuation treatment and relapse prevention, patients 7–18 years old with MDD and responding to fluoxetine treatment at 12 weeks were randomized to receive fluoxetine or placebo for an additional 6 months (Reference 44). Patients treated with fluoxetine had lower rates of relapse and an increased time to relapse compared with placebo. This study supports the continuation of antidepressants for at least 6 months after remission is achieved.

Patients with at least two previous depressive episodes, one severe episode, and/or chronic episodes of depression may require maintenance therapy. Other patient-specific factors that should be considered when assessing the need for maintenance therapy include comorbidities, psychosocial stressors, and family psychiatric history. During the maintenance phase of treatment, the antidepressant is continued for an additional 1–2 years or longer. The therapy goal during this treatment phase is to reduce the risk of recurrence (Reference 7).

Regardless of the treatment phase, psychoeducation, supportive management, and family and school involvement are recommended. *Psychoeducation* is a term used to describe the education that family and the patient receive regarding the cause of depression, symptoms, course of the disease, available treatment options, adverse effects, and consequences of untreated depression. Supportive management consists of psychotherapy, which entails self-reflection, problem solving, and the learning of coping skills. Through family and school involvement, the disorder will be better understood, and treatment can be monitored more closely (Reference 7).

### **Treatment Guideline**

In 2007, the Texas Children's Medication Algorithm Project published updated consensus guidelines focusing on medication management in pediatric depression, specifically in patients 6–17 years old. No recommendations for children younger than 6 years are provided, given the lack of evidence available. This publication makes no recommendations regarding combination therapies versus medication management alone, but instead, focuses on a stepwise approach to medication management in pediatric patients with depression significant enough to warrant medications, such as depressive symptoms causing impairment in social or school performance and/or risk of harm to the patient or others. Most studies have evaluated the use of SSRIs for

the treatment of pediatric depression. Therefore, it is recommended that patients receive treatment with an SSRI such as fluoxetine, sertraline, or citalopram in stage I of therapy if they have not received an antidepressant for their current depressive episode or if they have received an inadequate trial of an antidepressant. Of note, escitalopram was not yet indicated for the treatment of adolescent depression when this algorithm was created, which may explain why escitalopram is not specifically recommended for stage I treatment. Paroxetine is not recommended as first-line therapy because of the increased number of study dropouts caused by adverse effects (e.g., exacerbation of depressive symptoms, agitation, hostility, epistaxis) occurring in the children treated with paroxetine compared with placebo (References 45, 46). Most studies have evaluated fluoxetine for the treatment of pediatric depression. Therefore, fluoxetine has the most evidence to support its use, and it is thus considered the antidepressant of choice unless drug interactions, history of poor response, or family resistance preclude its use. Citalopram and sertraline are also considered reasonable treatment alternatives in stage I.

If the patient does not respond to SSRI treatment in stage I or is unable to tolerate the current SSRI, it is recommended that the patient be switched to a different SSRI, including fluoxetine, sertraline, citalopram, escitalopram, or paroxetine (adolescents only if switching to paroxetine). The new antidepressant should be cross-tapered with the initial antidepressant in patients not switching from fluoxetine. Fluoxetine does not need to be tapered because of its long half-life. Patients who experience adverse effects from the initial agent should have that antidepressant discontinued, and a new antidepressant should be initiated at a lower dose. For those showing partial response to the initial antidepressant, an augmentation agent can be added to the medication regimen. Augmentation permits partial responders to continue receiving benefit from the initial antidepressant and enables the targeted treatment of symptoms not responding to the initial agent. It is unclear which augmentation strategies are most efficacious and best tolerated in the pediatric patient population because of the lack of evidence available. Some augmentation strategies that have evidence for effectiveness in the adult population include bupropion SR and mirtazapine; thus, these agents are recommended as possible augmentation strategies for pediatric depression.

Patients who have not responded to at least two adequate SSRI trials move to stage III of therapy, during which time a different antidepressant class (e.g., bupropion, venlafaxine, mirtazapine, duloxetine) is recommended. The guidelines do not provide further recommendations for subsequent stages of treatment because of the lack of data available in the pediatric population.

In patients not responding to antidepressant therapy, the following factors should be evaluated: medication adherence, dose of antidepressant, duration of antidepressant trial, diagnosis (re-examine the appropriateness of primary diagnosis and evaluate for the presence of psychiatric comorbidities), and psychosocial stressors. It is also recommended that psychotherapy, specifically interpersonal therapy or CBT, be tried in patients who have not responded to other psychotherapeutic interventions. If psychotherapy has not previously been tried, it is advised that a trial of psychotherapy be recommended to the child and family (Reference 47).

In patients with severe depression that fails to respond to antidepressant trials, electroconvulsive shock therapy (ECT) should be considered. Electroconvulsive shock therapy entails sending electric currents to the brain to induce a seizure, which subsequently leads to neurotransmitter release. State statutes may differ regarding the age requirement for ECT. According to an executive summary published by AACAP, the administration of ECT in adolescents should be considered only if the depression is severe, persistent, and significantly disabling and if it has failed to respond to at least two adequate trials of pharmacologic agents that have been accompanied by other treatment modalities. Electroconvulsive shock therapy may be considered earlier in the treatment of patients who either cannot tolerate pharmacologic treatment or cannot physically take medications or in high-risk patients when waiting for a pharmacologic response may endanger their life (Reference 48).

The Texas Children's Medication Algorithm Project also provides information on treating pediatric depression in children with other psychiatric comorbidities including psychosis, anxiety disorders, ADHD, and other disruptive behavior disorders. A review of treatments for these conditions is beyond the scope of this chapter but can be found in the Texas Children's Medication Algorithm Project publication (Reference 47).

### **Dosing**

No dose-response studies of antidepressants have been performed in pediatric patients (Reference 49). Antidepressant dosing in the pediatric population is thought to be similar to that in adults; however, some studies report that the half-lives of SSRIs (paroxetine, sertraline, citalopram) and other newer antidepressants (bupropion) in children are much shorter than in adults (Reference 50). These studies infer that antidepressants may need to be dosed twice daily; however, more studies are required to support this dosing recommendation (Reference 49). Thus, monitoring for the presence of withdrawal symptoms should occur, specifically 8–12 hours after the last dose (Reference 47).

Most antidepressants should be initiated at a lower dose than recommended for adults to minimize the occurrence of adverse effects. The dose should subsequently be titrated on the basis of efficacy and tolerability. The SSRIs and SNRIs are typically dosed once daily in the morning or evening with or without food. Because only escitalopram and fluoxetine are FDA approved for pediatric depression, specific dosing recommendations for other antidepressants in this patient population are lacking in the literature. Adolescents being treated with escitalopram should be initiated on a dose of 10 mg/day, which can be titrated to 20 mg/day after a minimum of 3 weeks. Those treated with fluoxetine should be initiated on 10 mg/day, which can be increased after a minimum of 1 week. Because lower-weight children tend to have higher fluoxetine plasma levels, it is recommended they be initiated on 5 mg/day (Reference 50). Because of the long half-life of fluoxetine compared with that of other antidepressants, patients having difficulty with medication adherence may benefit from using this agent (Reference 49). The extended-release formulation of venlafaxine is dosed once daily compared with the two or three times/day dosing of the immediate-release formulation (Reference 51). The dose of bupropion SR should not exceed 400 mg/day because of an increased risk of seizures associated with higher doses (Reference 52). In addition, immediate- and sustained-release formulation of bupropion should be administered twice daily, with no single dose exceeding 200 mg/day, to avoid high peak concentrations. To reduce seizure risk further, a gradual dose titration should be employed. In addition, bedtime administration of bupropion should be avoided to prevent insomnia from occurring. Conversely, it is recommended that mirtazapine be administered at bedtime because of its sedating properties; however, in adults, it has been found that the drowsiness and sedation observed at lower doses diminishes in frequency and severity with higher mirtazapine doses (Reference 53). Thus, in youths receiving higher mirtazapine doses at bedtime and experiencing insomnia, a switch to morning administration of mirtazapine may be warranted.

Table 1 shows the doses and dose ranges of antidepressants studied in pediatric depression trials, as well as the major metabolic pathways and half-lives of these agents. Of the antidepressants listed in Table 1, citalopram, escitalopram, fluoxetine, paroxetine, and sertraline are available in liquid dosage form (Reference 54). Mirtazapine is available as an orally disintegrating tablet and may be beneficial for use in children unable to swallow tablets and capsules (Reference 61). In children who have difficulty swallowing and who are prescribed venlafaxine immediate or extended release, the contents of the capsule can be sprinkled on a spoonful of applesauce and swallowed immediately without

chewing (Reference 51). A glass of water should then be administered to ensure that all pellets have been swallowed. Bupropion SR is only available in tablet form and should not be crushed, divided, or chewed to minimize the risk of seizures (Reference 52).

### *Optimizing Pharmacotherapy*

Therapy response should be assessed at 4-week intervals. It is recommended that the patient receive treatment with a therapeutic dose of an antidepressant for a minimum of 4 weeks, if tolerated. If, at 4–8 weeks, the patient shows minimal to no response to medication therapy, or for those unable to tolerate the antidepressant, the antidepressant should be discontinued, and a new antidepressant should be tried. Patients showing partial response to therapy at weeks 4–8 of treatment may benefit from an increase in dose, or, if the patient is already taking the maximum recommended dose, augmentation therapy may be used. In patients who continue to be partial responders at week 12 of therapy, the next stage of treatment should be tried (Reference 7). Patients with residual symptoms at week 12 are more likely to relapse during the next 6 months of treatment compared with patients having no residual symptoms at this time (Reference 44). Thus, the treatment goal should be remission of symptoms rather than response to therapy.

### *Drug Interactions*

Fluoxetine, bupropion, and paroxetine are potent cytochrome P450 (CYP) 2D6 inhibitors, thereby predisposing these agents to significant drug interactions (Reference 62). Sertraline has been found to inhibit 2D6 in a dose-dependent manner, with doses greater than 150 mg/day causing moderate to potent 2D6 inhibition (Reference 62). Thus, plasma levels of medications metabolized by the CYP2D6 enzyme, such as TCAs and antipsychotics (i.e., risperidone or aripiprazole), may be increased, resulting in adverse effects and toxicity. Citalopram and escitalopram have minimal CYP enzyme activity and few drug interactions. The MAOIs irreversibly inhibit enzymes responsible for dopamine, norepinephrine, and serotonin metabolism. To prevent serotonin syndrome, MAOIs should not be given within 5 weeks of discontinuing fluoxetine or within 2 weeks of discontinuing other antidepressant agents. In addition, antidepressants should not be administered within 2 weeks after discontinuing an MAOI.

### *Adverse Effects*

Overall, SSRIs and other antidepressants are well tolerated by the pediatric patient population (Reference 7). Common adverse effects associated with SSRIs and SNRIs include gastrointestinal disturbances, sleep changes (insomnia,

somnolence, vivid dreams, and nightmares), restlessness, diaphoresis, headaches, akathisia, appetite changes, and sexual dysfunction. These adverse effects are usually dose-dependent and typically resolve with time (Reference 49); however, many adverse effects can be treated by either lowering the antidepressant dose or switching to a different antidepressant (Reference 38). Venlafaxine has been associated with causing dose-related increases in blood pressure; thus, routine monitoring of blood pressure is recommended. Mirtazapine may cause an increase in appetite, weight gain, and somnolence (Reference 7). The use of bupropion is contraindicated in patients with a seizure disorder, in patients with a history of anorexia/bulimia, and in patients undergoing abrupt discontinuation of alcohol or sedatives. Antidepressants have also been shown to cause behavioral activation, characterized by impulsivity, irritability, agitation, and/or silliness in about 3% to 8% of patients (Reference 49). Antidepressants may also cause rare adverse effects such as bleeding and serotonin syndrome (Reference 7).

#### Withdrawal Symptoms/Discontinuation Syndrome

After the continuation or maintenance phase of treatment is complete, and if lifelong antidepressant therapy is unwarranted, antidepressants should be slowly tapered rather than abruptly discontinued to prevent the occurrence of withdrawal symptoms. Withdrawal symptoms, also referred to as *discontinuation syndrome*, include flu-like symptoms such as nausea, headache, light-headedness, chills, and body aches, together with neurologic symptoms such as paresthesias, insomnia, and “electric shocks” (Reference 38). Some patients may develop symptoms similar to those consistent with a relapse in or recurrence of a depressive episode (Reference 7). Withdrawal symptoms can occur after receiving antidepressant treatment for only 6–8 weeks and can begin as early as 24–48 hours after treatment discontinuation (Reference 7). Symptoms typically resolve without treatment during a 1- to 2-week period (Reference 38). To prevent the occurrence of withdrawal symptoms, it

**Table 1.** Antidepressant Dosing in Pediatric Depression Trials and Pharmacokinetic Parameters

Antidepressant	Ages Studied (years)	Starting Dose (mg/day)	Dose Range (mg/day)	Major Metabolic Pathway (Reference 54)	Half-life (Reference 54)
<b>Selective Serotonin Reuptake Inhibitors (SSRIs)</b>					
Citalopram (Celexa) (References 31, 55–57)	7–18	10–20	10–40	2C19, 3A4	24–48 hours
Escitalopram <sup>a</sup> (Lexapro) (Reference 37)	12–17	10	10–20	2C19, 3A4	27–32 hours
Fluoxetine <sup>a</sup> (Prozac) (Reference 36)	8–18	10–20	10–20	2C19, 2D6 3A4 for norfluoxetine (Reference 58)	4–6 days Active metabolite: 9.3 days
Paroxetine (Paxil) (References 34, 45, 55)	7–18	10–20	10–50	2D6	21 hours (Reference 59)
Sertraline (Zoloft) (Reference 35)	6–17	25	50–200	2C19, 2D6	26 hours
<b>Serotonin Norepinephrine Reuptake Inhibitors (SNRIs)</b>					
Venlafaxine (Effexor) (Reference 39)	12–18	37.5	150–225	2D6	5 ± 2 hours Active metabolite: 11 ± 2 hours
<b>Other Agents</b>					
Bupropion SR (Wellbutrin SR) (Reference 40)	12–17	100	150–400 (administer in two divided doses if ≥ 300 mg/day)	2B6	12 ± 3 hours (Reference 60)
Mirtazapine (Remeron) (Reference 41)	12–18	30	30–45	1A2, 2C9, 2D6, 3A4	20–40 hours

<sup>a</sup>FDA approved for child and/or adolescent depression.  
SR = sustained release.

is recommended that the antidepressant dose be decreased by no more than 25% per week, with tapering usually occurring during a 2- to 3-month period (Reference 47).

### *Antidepressants and Suicidality*

In October 2004, the FDA issued a black box warning for all antidepressants, describing the increased risk of suicidal thinking and behavior in children and adolescents (younger than 18 years) with MDD and other psychiatric disorders when treated with antidepressants. This warning was extended in 2007 to include young adults up to age 25 (Reference 63). The black box warning recommends evaluating the benefits and risks associated with antidepressant therapy when considering antidepressants for use in this patient population. Because short-term studies did not show an increase in suicidality in adults older than 24 and actually showed a decrease in suicidality in adults older than 65, this warning applies only to patients younger than 25 years. Also mentioned in this warning is that depression itself is associated with an increased risk of suicide, making it difficult to determine whether suicidality is a result of antidepressant treatment or a consequence of the disease. After the first black box warning in 2004, antidepressant prescription rates decreased by 18% from July 2003 to July 2004, whereas teen suicide rates increased for the first time in more than a decade, highlighting the consequence of untreated depression (Reference 64). In a cohort study of depressed patients 10–18 years old initiated on antidepressant therapy, the risk of suicidal acts did not vary within the class of SSRIs or between antidepressant classes (SNRIs, TCAs, mirtazapine, nefazodone, trazodone), thereby supporting the inclusion of all antidepressant agents in the black box warning (Reference 65).

Regardless of whether suicidality is because of antidepressant therapy or the disease itself, health care providers should educate patients of all ages about the possibility of increased suicidal symptoms, especially early in treatment, and monitor patients for clinical worsening, suicidality, and unusual changes in behavior during the first few months of therapy and during dosage adjustments. The FDA guidelines specifically recommend that during the first 4 weeks of antidepressant treatment, the clinician should meet face-to-face with the patient at least once weekly. For the next 4 weeks of therapy, the FDA advises biweekly visits, followed by a visit at 12 weeks. Thereafter, the patient can be seen as clinically indicated. In addition, symptoms such as anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, akathisia, hypomania, and mania may be indicative of suicidality. Thus, family

and caregivers should be educated on the importance of monitoring for the presence of these symptoms and of the subsequent need to contact a health care provider, should any of these symptoms arise.

### CONCLUSIONS

Major depressive disorder can present as early as childhood and is associated with an increased risk of morbidity and mortality. To restore optimal functioning and prevent recurrence, it is necessary to identify symptoms of depression early in their course and provide effective treatment through psychotherapy and/or pharmacotherapy. More studies are required to further evaluate the efficacy and tolerability of antidepressant agents as monotherapy or in combination with psychotherapy in the pediatric patient population. Because of the risk of suicidality associated with antidepressant use, close monitoring for clinical worsening, behavioral changes, and suicidality is recommended when initiating antidepressants in patients younger than 25 years.

# CHAPTER 34

## NEONATAL SEPSIS

Jason B. Sauberan, Pharm.D.

### LEARNING OBJECTIVES

1. Distinguish the differences in the etiology and treatment strategy between early- and late-onset neonatal sepsis.
2. Describe the elements of a maternal history and clinical presentation of a neonate that would lead to a high index of suspicion for sepsis.
3. Design an appropriate individualized treatment regimen for neonatal sepsis.

### ABBREVIATIONS IN THIS CHAPTER

AMG	Aminoglycoside
ANC	Absolute neutrophil count
CLABSI	Central line-associated bloodstream infection
CNS	Central nervous system
CoNS	Coagulase-negative staphylococci
CSF	Cerebrospinal fluid
EOS	Early-onset sepsis
GA	Gestational age
GBS	Group B <i>Streptococcus</i>
GNR	Gram-negative rod
HSV	Herpes simplex virus
LOS	Late-onset sepsis
NEC	Necrotizing enterocolitis
NICU	Neonatal intensive care unit
PCR	Polymerase chain reaction
VLBW	Very low birth weight (less than 1500 g)

### INTRODUCTION

An estimated 3.1 million neonates in the world die every year (Reference 1). Of these, almost one-fourth die of severe neonatal infections such as sepsis, meningitis, and pneumonia. Improvements in the quality of and access to maternal and neonatal health care and anti-infective therapy are critical to reducing neonatal mortality rates (References 2–4). Despite such improvements, surviving the transition from fetal to neonatal life remains a challenge; the risk of death during the neonatal period is significantly higher than at any other time in childhood and throughout most of adulthood (References 1, 5) (Figure 1). An important factor in this age-related death rate disparity is the underdeveloped

fetal and neonatal immune response (Table 1). An infected neonate is insufficiently equipped to fight invading pathogenic organisms and thus can rapidly develop severe sepsis (References 6–10). The pharmacist caring for neonates must always be prepared to quickly initiate appropriate treatment when sepsis is suspected and to closely monitor the response to treatment.

### NEONATAL SEPSIS: THE BASICS

Neonatal sepsis can be defined as the presence of signs and symptoms suggestive of systemic infection together with pathogenic organisms cultured from the blood (i.e., septicemia). When systemic infection is strongly suspected but cultures are sterile, the neonate can be considered to have “clinical sepsis.” Although this general definition of sepsis is no different from that for infants, children, and adults, septic neonates present with unique signs, symptoms, and clinical histories compared with older patients (Table 2).

The classification of sepsis depends on the neonate’s day of life. Early-onset sepsis (EOS) occurs in the first 3 days of life (Reference 15). Pathogens associated with EOS are acquired perinatally from the mother’s genital-fecal flora during birth, or from a new-onset intra-uterine infection near the time of delivery. Late-onset sepsis (LOS) presents after the first 3 days of life. The infecting pathogens in LOS can also be acquired from the mother during labor and delivery, but they are more commonly acquired postnatally from parents and other caregivers and from nosocomial sources, including health care workers (References 9, 10, 16). Bacteria are the most common pathogens in EOS and LOS. Fungi are more common in LOS than in EOS, particularly in very low-birth-weight (VLBW) preterm neonates (References 17, 18). Congenital infection occurs in utero before birth from transplacental transmission of viral or bacterial pathogens (Reference 16).

Initial treatment of neonatal sepsis uses antimicrobials directed at the presumed infecting pathogen(s) on the basis of the timing of illness onset, clinical presentation, presence of important risk factors, and local patterns of pathogen prevalence and antimicrobial susceptibility. If a pathogen is identified, treatment can be tailored on the basis of sensitivity testing. Supportive treatment of sepsis can include supplemental oxygen and ventilation, cardiovascular support, parenteral nutrition, and adjunctive immunoglobulin.

**Table 1.** Deficiency and Clinical Significance of the Neonatal Immune System (References 6–8)

Immune Function	Neonatal Deficit	Clinical Significance
T cell	Decreased dendritic cellular function Low circulating numbers Defective endocytosis Decreased expression of costimulatory molecules (e.g., CD40, CD80, CD86) Reduced pathogen-induced cytokine production	Impaired cell-mediated immunity to intracellular pathogens (e.g., HSV, CMV, <i>Candida</i> , <i>Toxoplasma</i> , <i>Mycobacterium</i> , <i>Listeria</i> , <i>Salmonella</i> ) Reduced response to immunization
Humoral	Minimal plasma B-cell differentiation Limited, low-affinity IgM response to antigens Reliance on transplacental acquired IgG until 4–6 months of age Transplacental IgG minimal < 32 wk GA Decreased T cell-independent B-cell presence in marginal zone of spleen Weak response to bacterial capsular polysaccharides	Limited ability to defend against pathogen attack, particularly < 32 wk GA Increased susceptibility to <i>Streptococcus</i> , <i>Neisseria</i> , and <i>Haemophilus influenzae</i> type b infection Reduced response to immunization
Macrophage	Diminished activation from T cells Decreased production of some cytokines Decreased movement Reduced number of progenitor cells	Impaired capacity to kill intracellular pathogens
Granulocyte	Diminished precursor storage pool Reduced number of progenitor cells Decreased movement Impaired microbicidal mechanisms	Inadequate neutrophil quantity to respond to sepsis Neutropenia with severe infection because of exhausted supply Diminished activity against <i>Staphylococcus</i> and GNRs
Complement	Reduced complement levels	Limited opsonic activity
Skin	Stratum corneum and vernix caseosa absent < 28 wk GA, epidermal barrier not mature until 32–34 wk GA	Very preterm neonates vulnerable to nosocomial pathogen colonization and infection in NICU, exacerbated by routine procedures that disrupt skin

Note: Premature neonates generally have a greater degree of immune deficit in proportion to their degree of prematurity.

CMV = cytomegalovirus; GA = gestational age; GNR = gram-negative rod; HSV = herpes simplex virus; IgG = immunoglobulin G; IgM = immunoglobulin M; NICU = neonatal intensive care unit; wk = week(s).

## MICROBIOLOGIC ETIOLOGY

Different pathogens are responsible for EOS, LOS, and congenital infection (Table 3). Group B *Streptococcus* (GBS) and *Escherichia coli* are responsible for most EOS cases in the United States (Reference 15). The provision of intrapartum antibiotic prophylaxis has reduced the incidence of early-onset neonatal GBS disease in the United States to 0.34–0.37 cases per 1000 live births (Figure 2) (Reference 22). In VLBW neonates, gram-negative bacteria (mainly *E. coli*) are slightly more common, causing 54% of all EOS cases and 5.1 cases per 1000 live births. The mortality rate

in premature (younger than 37 weeks' gestational age [GA]) neonates with *E. coli* EOS is 38%. Gram-positive bacteria comprise 45% of all VLBW EOS cases, with GBS accounting for 2.1 cases per 1000 live births (References 15, 23). In the developing world, neonatal tetanus remains prevalent in EOS, affecting about 20–80 of every 1000 live births and 2% of all neonatal deaths worldwide (References 2, 9).

Nosocomial pathogens such as staphylococci, enteric gram-negative rods (GNRs), and *Candida* spp. dominate the microbiologic causes of LOS (References 17, 19, 20). In the VLBW population, coagulase-negative

**Table 2.** Relevant Infection History and Clinical Presentation in Neonatal Sepsis (References 10–14)

Maternal/Fetal History	Neonatal Features
Chorioamnionitis or other peripartum febrile illness or infection	Premature, low birth weight
Urinary tract infection	Apnea, bradycardia spells
Group B <i>Streptococcus</i> colonization	Respiratory distress, cyanosis
Prolonged rupture of membranes	Increased oxygen/ventilation requirement
Meconium-stained amniotic fluid	Feeding intolerance, emesis
Traumatic delivery	Abdominal distension, bloody stools
Fetal distress	Temperature instability
No prenatal care	Hyper- or hypothermia
	Lethargy, hypotonia
	Hypertonia, convulsions
	Hypotension, hypoperfusion, oliguria
	5-minute APGAR score < 6
	Immature-to-total neutrophil ratio > 0.2
	Platelet count < 100,000/mm <sup>3</sup>
	CRP > 1 mg/dL

CRP = C-reactive protein.

**Table 3.** Etiology by Timing of Infection (References 12, 15–17, 19–21)

<b>Early-Onset Sepsis</b>	<b>Common:</b> Group B <i>Streptococcus</i> ( <i>S. agalactiae</i> ), <i>E. coli</i> <b>Less common:</b> <i>Staphylococcus aureus</i> , CoNS, <i>E. faecalis</i> , other <i>Streptococcus</i> spp., <i>Ureaplasma urealyticum</i> , <i>Listeria monocytogenes</i> , <i>Haemophilus influenzae</i> , <i>Candida albicans</i>
<b>Late-Onset Sepsis</b>	<b>Common:</b> CoNS, <i>Streptococcus agalactiae</i> , <i>S. aureus</i> , <i>Escherichia coli</i> , <i>Enterococcus</i> spp., <i>Klebsiella</i> spp., <i>Pseudomonas aeruginosa</i> , <i>Enterobacter</i> spp., <i>Serratia marcescens</i> , <i>Candida</i> spp. <b>Less common:</b> Other gram-negative rods, anaerobes, viruses
<b>Congenital Infection</b>	Toxoplasma, <i>Treponema</i> , rubella, CMV, HSV, VZV

CMV = cytomegalovirus; CoNS = coagulase-negative staphylococci; HSV = herpes simplex virus; VZV = varicella zoster virus.

**Figure 1.** Age-specific death rates, United States, 2007 (Reference 5).

**Figure 2.** Incidence of early- and late-onset GBS sepsis in the United States (Reference 22).

GBS = group B *Streptococcus*.

staphylococci (CoNS) are the most common (48%) LOS pathogens, primarily from catheter-related infection (Reference 24). Among the GNRs, *Klebsiella* and *E. coli* are the most common (4% to 5%) (Reference 17). *Candida* and other fungi have been documented to occur in 12% to 14% of LOS cases (References 17, 18). Reported mortality rates are highest for LOS caused by *Candida* (30% to 50%) and GNRs (20% to 30%) and are lowest for CoNS and other gram-positive cocci (6% to 8%) (References 17, 25, 26). Negative neurodevelopmental outcomes such as vision and hearing impairment, cerebral palsy, and cognitive and motor developmental abnormalities are more likely to occur by 18–22 months of age in extremely low-birth-weight neonates who developed *Candida* or CoNS LOS than in noninfected controls matched for GA (References 27, 28).

Congenital infection may be caused by *Toxoplasma gondii*, cytomegalovirus, hepatitis B virus, herpes simplex virus (HSV), human immunodeficiency virus, Rubella virus, *Treponema pallidum*, *Mycobacterium tuberculosis*, and varicella zoster virus. Although newborns with congenital infections have several system disorders, some of which respond to antimicrobial therapy, their disease does not typically manifest as sepsis; hence, they will not be discussed in this chapter.

## CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

### Early-Onset Sepsis

Early-onset infection is among the most common illnesses responsible for neonatal hospitalization in the United States (Reference 29). However, the incidence of culture-proven EOS in North America is not high; there are about six or seven cases with a positive culture for every 1000 neonatal intensive care unit (NICU) admissions and one case for every 1000 live births. The incidence is highest among neonates born weighing less than 1500 g and is about 11 cases per 1000 live births (References 15, 30).

Specific maternal historical elements and clinical features of the neonate are highly suggestive of EOS (Table 2). The challenge in diagnosing EOS is that many other noninfectious neonatal conditions that present in the immediate postnatal period (e.g., asphyxia, congenital heart and other anatomic anomalies, metabolic disorders, maternal medication exposure, and idiopathic “poor transition”) share similar symptoms. Thus, diagnosing EOS quickly and confidently on the basis of clinical findings alone is not always possible. Nevertheless, if a newborn presents with clinical or historical data strongly suggestive of EOS, a “septic workup” consisting of laboratory tests (blood

culture, complete blood cell count with differential, and C-reactive protein level) and initiation of antimicrobial therapy will immediately follow. If the newborn is asymptomatic or only mildly symptomatic but with a maternal history possibly suggestive of EOS, laboratory testing and close monitoring for the appearance of sepsis are important. Treatment should commence only if either symptoms or laboratory results highly suggest sepsis (Reference 10).

A pathogenic organism detected in the blood confirms the diagnosis of sepsis. However, the lack of a positive result does not necessarily rule out sepsis. A false-negative blood culture may occur, especially when the mother is treated with antibacterial agents during labor for chorioamnionitis, prolonged rupture of membranes, or GBS colonization. In addition, bacteremia may be transient in the early stages of infection and thereby missed on a single blood culture, particularly if the quantity of blood sampled for culture was inadequate (less than 1 mL). The sensitivity of blood culture in diagnosing EOS is 50% to 80% (References 10, 12). Abnormal laboratory results such as elevated C-reactive protein levels, elevated immature neutrophils, and low platelet counts on their own lack sufficient positive predictive value (i.e., probability that the neonate has EOS when the results are abnormal) to establish the diagnosis of sepsis (Table 2 and Table 4). However, in the absence of a positive culture, several abnormal laboratory values may tip the diagnostic balance toward EOS if clinical features are present and other common causes of the symptoms are excluded. Algorithms for the diagnosis and empiric treatment of EOS are available (References 10, 22, 34). One algorithm is presented in Figure 3.

### Meningitis and Pneumonia

Early-onset neonatal meningitis and bacterial pneumonia are focal infections that share the same clinical histories, symptoms, disease severity, and microbiologic etiology with EOS. Meningitis is a secondary infection caused by hematogenous delivery of the infecting organism(s) to the choroid plexus after primary bacteremia and sepsis. Pneumonia is a primary pulmonary focus of infection that can spread to the bloodstream and cause secondary bacteremia and sepsis.

Symptoms that suggest meningitis in term neonates include hyperthermia (e.g., axillary temperature greater than 37°C), high-pitched cry, apnea, hypotonia, hypertonia, irritability, convulsions, and a bulging fontanel. Because meningitis is a secondary infection that follows bacteremia, none of these symptoms need be present for meningitis to be considered if other symptoms or a maternal history suggestive of sepsis exists. In VLBW preterm neonates, fewer meningitis symptoms are present because of their immature immune, neuromuscular,

**Table 4.** Abnormal Laboratory Values Suggestive of Neonatal Sepsis or Meningitis (References 10, 11, 31–33)

Value	Suggestive	Normal Range
<b>Blood</b>		
WBC <sup>a</sup>	< 5	9–30 <sup>b</sup>
ANC <sup>a</sup>	< 1.75	10–20
I:T	> 0.2	0.05–0.25
Platelet count <sup>a</sup>	< 100	150–400
CRP (mg/dL)	> 1	≤ 1
<b>CSF</b>		
WBC (cells/mm <sup>3</sup> )	> 25	0–20
Protein (mg/dL)		
Term	> 100	40–80
Preterm	> 250	60–230
Glucose (mg/dL)	< 10	40–60

<sup>a</sup>10<sup>3</sup> cells/mm<sup>3</sup>.

<sup>b</sup>5–20 after first week of life.

ANC = absolute neutrophil count; CRP = C-reactive protein; CSF = cerebrospinal fluid; I:T = immature-to-total neutrophil ratio; WBC = white blood cell (count).

and respiratory systems. Confounding this, symptoms such as apnea, respiratory distress, and hypotonia are common features present in very preterm infants and may not be related to infection. Given these difficulties in differentiating sepsis from meningitis on the basis of symptoms alone, and considering that negative blood culture results occur in 15% to 40% of neonatal meningitis cases (References 21, 32, 35, 36), it is recommended that all neonates with signs of sepsis undergo a diagnostic lumbar puncture for collection and analysis of cerebrospinal fluid (CSF) as a routine part of their sepsis evaluation (References 21, 22, 31).

The most common pathogens causing neonatal meningitis are *E. coli*, GBS, *Staphylococcus aureus*, viridans *streptococci*, and *Candida* (References 15, 31, 32). Positive identification of a pathogen from cultured CSF is limited by the potential for false-negative results because of pre-CSF sampling antibiotic use and inadequate sample volume (Reference 31). If CSF cultures are negative or unavailable, consideration should be given to other CSF findings. Cerebrospinal fluid elevations in white blood cell (counts) and protein content with low glucose concentrations relative to serum concentrations are associated with bacterial meningitis in neonates (Table 4). However, normal CSF findings do not necessarily exclude meningitis (References 32, 33, 35). Therefore, some experts recommend obtaining

a CSF culture when a blood culture is performed and before antibiotics are initiated in all neonates suspected of having sepsis, regardless of the presence or degree of symptoms (References 11, 32). Such a recommendation is controversial because of the practical challenges associated with performing a lumbar puncture, such as technical expertise, parental consent, and preparation of an unstable patient, all of which can delay the initiation of antimicrobial therapy.

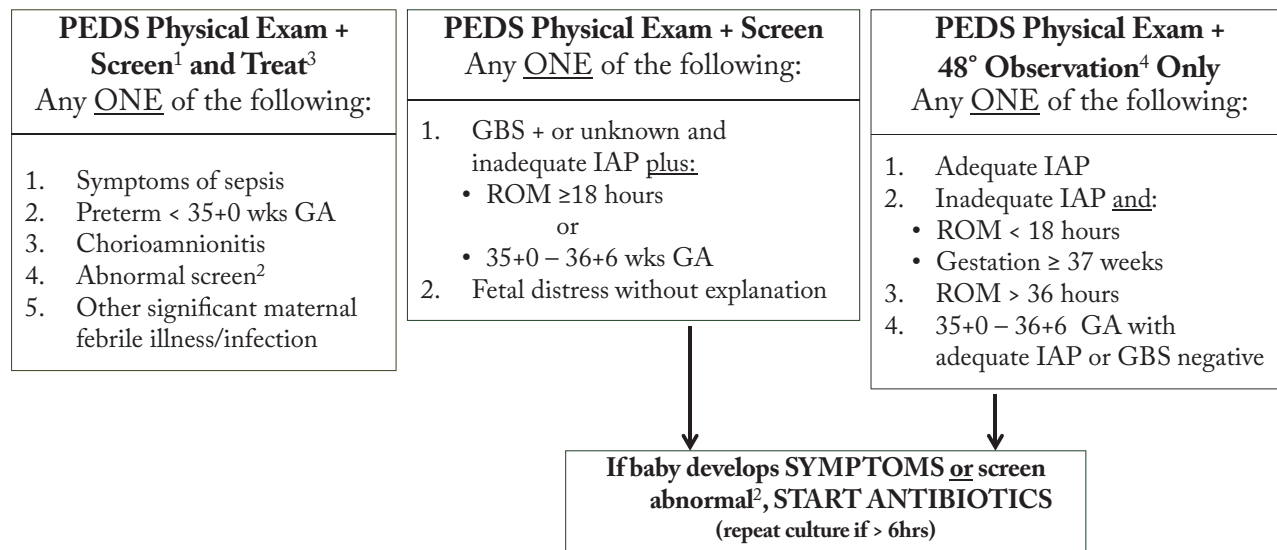

Early-onset neonatal bacterial pneumonia is acquired through aspiration of maternal flora or pathogens from an active intrauterine infection. The microbial etiology of early-onset pneumonia is therefore the same as that of EOS (see section on *Ureaplasma*, below). Respiratory distress dominates the clinical presentation, particularly in term neonates. Other signs of severe systemic illness may also be present and may initially be indistinguishable from, and considered part of, EOS. A chest radiograph, if available, may confirm the presence of early-onset bacterial pneumonia (Reference 37). If the neonate has been endotracheally intubated for respiratory failure shortly after birth, a positive tracheal aspirate culture can help distinguish infection from noninfectious respiratory disease (Reference 10). The remaining approach to management follows the same course as for EOS, with blood sampled for culture and cell count and initiation of empiric therapy.

### Late-Onset Sepsis

A characteristic unique to LOS is the gradual onset of clinical deterioration compared with EOS. Increased oxygen or ventilation requirement, increased apneic events, feeding intolerance, bloody stools, lethargy, and hypotension are symptoms associated with LOS (Reference 38). Meningitis is more prevalent in LOS than in EOS (Reference 21). The pathogens that can cause LOS are varied, consisting of nosocomial bacteria, CoNS, and *Candida* (Table 3). Knowledge of the institutional pathogen distribution and antimicrobial sensitivity is therefore prudent in selecting an appropriate empiric therapy for LOS.

The diagnostic tools available for LOS are similar to those available for EOS. A urine culture is of greater diagnostic value in LOS, compared with EOS, and thus should be in the LOS diagnostic workup. A urine culture can be considered positive on the basis of three scenarios: the growth of a pathogenic organism from a urine sample collected by suprapubic needle aspiration; an organism quantity of more than 10,000 colonies/mL when collected by sterile catheterization; or an organism quantity of more than 50,000 colonies/mL when obtained by bag collection (Reference 39). The bag collection method is least reliable because of potential contamination during collection. Any symptomatic neonate with a positive urine culture should be considered

## Does this newborn need antibiotics?

1. Screen=CBC + diff and blood culture (CRP not generally indicated for initial evaluation of asymptomatic newborn).
2. Abnormal screen = WBC ≥ 35,000 or < 9,000; ANC < 1500; platelet count < 150 (confirmed). Note: a specific I:T ratio is not an indication for therapy, but immature forms may be suggestive of sepsis and should be considered when making treatment decisions.
3. Treatment = ampicillin 100 mg/kg IV q12h PLUS gentamicin (see gestational age-dependent dosing in NICU formulary.)
4. Exception: Early discharge at 24-48 hrs if ≥ 37 wks, ready access to medical care, telephone, and reliable observer at home.

**Figure 3.** Early-onset sepsis diagnosis and treatment algorithm. (Adapted from the University of California, San Diego Infant Special Care Center Housestaff Manual, with permission)

ANC = absolute neutrophil count; bpm = beats per minute; CBC = complete blood cell count; CRP = C-reactive protein; GA = gestational age; GBS = group B Streptococcus; h/hr = hour(s); IAP = intrapartum antibiotic prophylaxis; I:T = immature-to-total neutrophil ratio; IV = intravenous(ly); NICU = neonatal intensive care unit; PEDS = Pediatrician; q = every; ROM = rupture of membranes; WBC = white blood cell (count)

to have septicemia necessitating treatment. Hematogenous infection of the kidney is more often the cause of a positive urine culture in an infected neonate compared with older infants and children, in whom the ascending route is more common (Reference 40).

Another distinction of LOS compared with EOS is the greater prevalence of central line-associated bacteremia (i.e., “line sepsis”) due to the high frequency of catheter use for parenteral nutrition. Coagulase-negative staphylococci and other gram-positive organisms that are part of the normal neonatal skin flora are common causes of central line-associated bloodstream infection (CLABSI) and LOS (Reference 24). To differentiate CoNS infection from colonization or contamination, the same organism must be present in at least two separate blood cultures collected within 48 hours (Reference 41). In practice, two blood cultures are usually sampled at the same time during the initial LOS diagnostic workup; one blood sample is taken from the central catheter and the other from a peripheral venipuncture.

## TREATMENT AND PREVENTION

Although confirmed EOS is rare, occurring in 0.1% of all neonates, the use of empiric antibiotics for presumed EOS remains high (Reference 15). In fact, 12–28 antibiotic courses are initiated for every one case of confirmed or strongly suspected EOS (References 42, 43). In a large multicenter data set of more than 250,000 neonatal hospitalizations, around 70% of neonates were exposed to empiric EOS therapy (Reference 44). More than 50% of VLBW neonates receive antibiotics for presumed LOS during their NICU stay (Reference 17). Antibacterials are the most common medications used in neonates (References 44–46). It is thus a routine experience for the neonatal/pediatric intensive care pharmacist to participate in the initiation of empiric antibacterial therapy.

The explanation for this dichotomy between the high rate of empiric neonatal sepsis treatment and the low rate of actual confirmed sepsis is 3-fold: (1) the imprecision and unreliability of the sepsis diagnostic tools available, (2) the overlapping symptomatology of sepsis and other common neonatal diseases, and (3) the fast

onset of clinical deterioration and higher rate of mortality and neurodevelopmental morbidity in neonates who develop sepsis compared with those who do not (References 9, 10, 28). Because of this diagnostic uncertainty, early aggressive treatment is warranted to minimize significant morbidity and mortality.

The choice of empiric therapy for EOS or LOS targets the most likely pathogens (Table 5, Table 6, and Table 7). No single regimen has been found superior (References 13, 47, 48).

### Early-Onset Sepsis

Intravenous ampicillin or penicillin plus an aminoglycoside (AMG) is the most common regimen for EOS (References 15, 47). This regimen provides coverage for

the two of the most common pathogens, GBS and *E. coli*, and for less common infecting bacteria such as *Listeria*, *Haemophilus*, and other streptococci. The combination is also synergistic against GBS and *Listeria* (Reference 59). In the United States, GBS cultured from neonates with EOS is universally sensitive to both ampicillin and penicillin (Reference 15). Ampicillin is more commonly used in the United States for empiric EOS because of its commercial availability in a dose form appropriate for neonates (e.g., 250-mg and 500-mg vials), which allows rapid therapy initiation. Intravenous amoxicillin instead of ampicillin is commonly used for EOS elsewhere in the world where it is available (Reference 60). Gentamicin is the most commonly used AMG in the United States for EOS, whereas tobramycin, netilmicin, and amikacin are widely used elsewhere (Reference 61).

**Table 5. Recommended Treatments for Severe Neonatal Infections (References 9–11, 20, 31, 49–56)**

Infection/Etiology	Treatment <sup>a</sup>	Duration
Empiric EOS	Ampicillin + AMG/cefotaxime <sup>b</sup>	7–10 days for presumed sepsis <sup>b</sup>
GBS, <i>Listeria</i>	Ampicillin/PCN + gentamicin	10 days for confirmed sepsis
<i>Escherichia coli</i> <sup>c</sup>	Cefotaxime, AMG, <sup>d</sup> meropenem <sup>e</sup>	14 days for GBS meningitis
<i>Enterococcus</i>	Ampicillin/vancomycin + gentamicin	21 days for <i>Listeria</i> or GNR meningitis
HSV	Acyclovir	21 days for disseminated or CNS 14 days if focus limited to SEM
<i>Ureaplasma</i> , <i>Chlamydia trachomatis</i>	Erythromycin, azithromycin	10–14 days of erythromycin 5 days of azithromycin
<i>Mycoplasma hominis</i>	Clindamycin	10 days
<i>Bacteroides fragilis</i>	Metronidazole, meropenem, chloramphenicol	Not well established; continue until clinical resolution
Tetanus	Metronidazole, PCN	10–14 days
Omphalitis	Clindamycin + gentamicin, pip-tazo, meropenem	10 days
Empiric LOS	Vancomycin + gentamicin or amikacin	Same durations as for EOS
<i>Pseudomonas</i>	Pip-tazo/cefotaxime + tobramycin, ceftazidime, meropenem	
CoNS, <i>Staphylococcus aureus</i>	Vancomycin, oxacillin	14 days <sup>f</sup>
<i>Candida</i>	Amphotericin B	21 days, may switch to fluconazole if sensitive
NEC	Vancomycin/ampicillin + gentamicin/cefotaxime ± metronidazole, meropenem	10 days or more depending on clinical response

<sup>a</sup>Commas separate alternatives; virgules separate alternatives within a combination regimen. Listed agents should be given intravenously. Some may be given intramuscularly if intravenous access is temporarily unavailable. See Table 5 and Table 6 for dosing recommendations.

<sup>b</sup>Controversial; see text.

<sup>c</sup>Or other enteric bacilli or *H. influenzae*.

<sup>d</sup>If meningitis ruled out.

<sup>e</sup>If ESBL or AMG/cefotaxime-resistant.

<sup>f</sup>5–7 days if central line removed.

AMG = aminoglycoside; CNS = central nervous system; CoNS = coagulase-negative staphylococci; EOS = early-onset sepsis; ESBL = extended-spectrum  $\beta$ -lactamase; GBS = Group B *Streptococcus*; GNR = gram-negative rod; HSV = herpes simplex virus; LOS = late-onset sepsis; NEC = necrotizing enterocolitis; PCN = penicillin; pip-tazo = piperacillin/tazobactam; SEM = skin, eye, and mouth.

**Table 6.** Treatment Dosing Recommendations for Therapeutically Monitored Antimicrobial Agents in Neonates and Young Infants (References 53, 57)

Antimicrobial (route)	Dose (mg/kg) and Frequency			Target Serum Concentrations	Comments
Aminoglycosides (IV/IM)	GA				
		≥ 37 wk	32–36 + 6 wk	< 32 wk	
Gentamicin-tobramycin	0–7 DOL	4 q24h	4 q36h	5 q48h	Peak 6–12 mg/L Trough < 2 mg/L Use 0–7 DOL dosing for ELBW neonates (< 1000 g) until 10–14 DOL. Infuse over 30 minutes.
	> 7 DOL	4 q18h	4 q24h	5 q36h	
Amikacin	0–7 DOL	15 q24	15 q36h	15 q48h	Peak 20–30 mg/L Trough < 5 mg/L
	> 7 DOL	15 q18h	15 q24h	15 q36h	
Vancomycin (IV)	SCr				Trough 5–15 mg/L Add 0.2 to SCr if GA ≤ 28 wk Infuse over 2 h
		< 0.7	15 q12h

DOL = days of life; ELBW = extremely low birth weight; h = hour(s); GA = gestational age; IM = intramuscular(ly); IV = intravenous(ly); PO = orally; q = every; SCr = serum creatinine; wk = week(s).

Around 80% of *E. coli* causing EOS in the United States are ampicillin-resistant, while only 4% are gentamicin-resistant (Reference 15). To ensure adequate *E. coli* coverage when meningitis is suspected, cefotaxime should be added to empiric ampicillin/penicillin with AMG therapy, given the potential for poor CSF penetration of AMG. Treatment of confirmed meningitis is discussed in the Meningitis chapter. Treatment duration varies depending on the organism(s) isolated. For EOS without meningitis, treatment duration is 10 days, regardless of the infecting pathogen (Reference 11).

Some centers use cefotaxime in place of gentamicin for empiric EOS treatment (References 15, 62). This practice is controversial because of the increased risk of candidiasis correlated with the use of third-generation cephalosporins in the NICU, the reported rapid emergence of cephalosporin resistance after the initiation of routine cephalosporin use, and the retrospectively identified independent association of cefotaxime use with higher rates of death before NICU discharge (References 62–64). Advocates contend that cefotaxime use avoids inadequate empiric treatment of *E. coli* meningitis,

particularly if regional ampicillin-resistant *E. coli* (or other GNR species) EOS prevalence is high. Cefotaxime use also avoids the need for therapeutic drug monitoring and the potential for gentamicin adverse effects such as ototoxicity and nephrotoxicity (References 65–67). Centers that use cefotaxime should follow infection control standards to prevent the spread of cephalosporin-resistant organisms and *Candida* and consider the routine surveillance of stool cultures to monitor rates of cephalosporin-resistant bacterial colonization.

When neonates with signs and symptoms strongly suggestive of EOS do not have a pathogenic organism cultured from blood, CSF, or a tracheal aspirate (if intubated), they are considered to have “culture-negative” or “clinical” sepsis. The recommended treatment of clinical sepsis is combination therapy with ampicillin or penicillin plus an AMG for 7–10 days (Reference 10). A 7-day course is only used if there is an initial and sustained clinical response to therapy. The optimal duration of antibiotics for presumed sepsis is not entirely known (Reference 68), and practices differ among centers. If there is no clinical improvement by the end of the first 48–72 hours

**Table 7. Treatment Dosing Recommendations for Systemic Antimicrobial Agents in Neonates and Young Infants (References 53, 57, 58)**

		Dose (mg/kg) and Frequency of Administration				
		Chronologic Age ≤ 28 days				Chronologic Age > 28 Days

<sup>a</sup>May use the longer dosing interval listed in extremely low-birth-weight (less than 1000 g) neonates up until 2 weeks of life.

<sup>b</sup>Loading dose 3 mg/kg.

<sup>c</sup>50 mg/kg/dose q8h for *Pseudomonas* infections.

<sup>d</sup>For meningitis, may double the dose; keep interval the same.

<sup>e</sup>Dosage for 0–14 d old.

<sup>f</sup>Dosage for ≥ 14 d old.

<sup>g</sup>Loading dose 15 mg/kg.

<sup>h</sup>Dose is 50,000 units/kg. If using for GBS meningitis: dose is 100,000 units/kg, and use the frequency in parenthesis if infant is > 2 kg. DOL = days of life; GBS = group B *Streptococcus*; h = hour(s); IM = intramuscular; IV = intravenous; LB = lipid based; pip-tazo = piperacillin/tazobactam; PO = orally; q = every.

of empiric therapy and the suggestion of bacterial infection remains high, an undetected pathogen that is not sensitive to empiric therapy may be causing disease. Potential bacterial suspects in this situation are staphylococci, Enterobacteriaceae, and anaerobes. Changing treatment to vancomycin plus either cefotaxime, piperacillin/tazobactam, or meropenem is acceptable. Blood should be recultured before the new regimen is initiated.

### HSV and *Ureaplasma*

Other pathogens to consider when the response to initial standard treatment of clinical EOS is lacking include HSV and *Ureaplasma*.

Disseminated neonatal HSV infection primarily involves the lung, liver, and brain, leading to pneumonitis, hepatitis, encephalitis, and pleocytosis. Presenting symptoms are similar to bacterial sepsis: temperature

instability, lethargy, poor feeding, convulsions, or respiratory compromise. Symptom onset can be early or late, but it is usually within the first 3 weeks of life. About one-third of HSV-infected neonates will not have a vesicular rash or conspicuous lesions in the eye or mouth, and there may be no history of known maternal HSV disease (Reference 49).

Diagnostic tests for neonatal HSV infection include the viral culture of blood, vesicular lesions (if present), and surface sites such as the conjunctiva, umbilicus, mouth, nasopharynx, and rectum. The CSF is also collected and analyzed by polymerase chain reaction (PCR) for the detection of HSV DNA; PCR is superior to culture for identifying HSV in CSF. Empiric treatment with intravenous acyclovir (Table 5 and Table 6) should be initiated after samples have been collected and should be continued until culture and PCR results are available. A positive culture or PCR result confirms the diagnosis of HSV infection and necessitates the continuance of intravenous acyclovir for 14–21 days (see Table 5). In neonates with central nervous system (CNS) infection, a repeat CSF collection for PCR analysis near the completion of the acyclovir course should be performed to document the absence of HSV. Without acyclovir treatment, the mortality rate for disseminated or CNS neonatal HSV infection is 50% to 85% by 12 months of age. With treatment, the mortality rate is 4% to 26% (References 49, 69, 70).

Potential complications of acyclovir include neutropenia and nephrotoxicity. Neutropenia occurs in 21% of acyclovir-treated infants, so the absolute neutrophil count (ANC) should be monitored two or three times/week. Acyclovir can be temporarily discontinued if the ANC falls below 500 cells/mm<sup>3</sup> and reinitiated when the ANC rises above this threshold (Reference 70). To minimize the risk of nephrotoxicity, appropriate hydration with intravenous fluids or enteral feedings should be used as clinical status allows, urine output should be strictly measured, acyclovir concentration for administration should be 7 mg/mL or less, and administration rate should not exceed 60 minutes. Care and maintenance of vascular catheter sites may be an ongoing challenge during the lengthy treatment course because acyclovir is incompatible with parenteral nutrition fluids and is a potent venous irritant. Regular monitoring for potential complications during an acyclovir course is recommended.

*Ureaplasma* spp. commonly colonize the female urogenital tract. These organisms can become pathogenic during pregnancy and cause maternal infections such as bacterial vaginosis, chorioamnionitis, and endometritis. Preterm labor and delivery is a potential outcome of maternal infection. Peripartum transmission from the vagina and cervix to the fetus can result in EOS, meningitis, and pneumonia in the neonate. *Ureaplasma* spp. lack a

cell wall and require urea for energy. They cannot be detected by Gram staining, nor can they be grown in standard bacterial culture media. They are also osmotically fragile; tissue or blood samples require special handling after collection to be reliable (Reference 50). Isolating *Ureaplasma* from blood, CSF, or the lower respiratory tract is a challenge and is thus not routinely part of the EOS diagnostic plan. No established standards exist for treating early-onset *Ureaplasma* infection. However, experts recommend treating with a macrolide antibiotic if *Ureaplasma* is identified in the blood, CSF, or respiratory secretions (tracheal aspirate) of a neonate with EOS/pneumonia. Empiric treatment may be initiated before culture results if the respiratory disease is severe and the patient requires increased supportive care. Treatment may also be initiated if preterm delivery, premature ruptured membranes, and/or chorioamnionitis were maternal complications and if the organism has been identified in tissue cultures sampled from the amniotic fluid, placenta, or umbilical cord. Little evidence is available to guide optimal therapy for severe neonatal *Ureaplasma* infection or to show that treatment improves outcomes. Erythromycin is the most commonly used antibiotic for *Ureaplasma* infection (Reference 71). Several case series of preterm neonates indicate that erythromycin therapy usually achieves microbiologic cure, but improvement in short- or long-term clinical pulmonary disease does not always occur. Azithromycin use for neonatal *Ureaplasma* infection has not been reported; however, intravenous azithromycin has been safely used in this population for other indications (References 72, 73). See Table 7 for dosing recommendations.

### Omphalitis

Omphalitis is an early-onset infection of the skin and soft tissues on and adjacent to the umbilical cord stump. Bacteria acquired during or after birth colonize the moist, necrotic stump and proliferate. Initial symptoms include local erythema, drainage, tenderness, periumbilical edema, and purulent discharge. If untreated, the infection can spread to the bloodstream by the umbilical vessels, causing sepsis and peritonitis, or it can extend to surrounding skin and subdermal tissues, causing abdominal wall cellulitis, lymphangitis, and necrotizing fasciitis. Initial symptoms suggestive of systemic spread are nonspecific, similar to those of EOS. Aseptic cord care after birth can prevent omphalitis. The incidence of omphalitis is believed to be lower in developed countries (1% to 2% vs. 6%) because of better cord care. Because omphalitis-related complications are so severe, prompt intervention with parenteral antibiotics upon identification of periumbilical erythema, cord edema, or purulent discharge is a standard of care. Broad-spectrum empiric therapy with clindamycin plus gentamicin, piperacillin/tazobactam, or meropenem will target

the likely pathogens: staphylococci, streptococci, enteric bacilli, *Pseudomonas*, and anaerobes (see Table 5). Mild disease, defined as cord erythema with no evidence of local symptoms, may be treated with the local application of alcohol, antibiotic ointment, and drying of the affected area (References 55, 56).

### Late-Onset Sepsis

Treatment of LOS follows general principles similar to those for EOS. Empiric therapy targets the most likely organisms, including CoNS and other staphylococci, Enterobacteriaceae, and *Candida*, on the basis of local patterns of pathogen prevalence and sensitivities. Examples of recommended empiric regimens and drug dosing are listed in Table 5, Table 6, and Table 7. Treatment is tailored on the basis of culture and sensitivity results.

### Neonatal Candidiasis

*Candida albicans* and *Candida parapsilosis* are responsible for causing 12% of LOS episodes and 20% of LOS-related deaths in VLBW neonates (Reference 17). The skin and gastrointestinal tract of neonates can become colonized with *Candida* spp., which can then opportunistically invade the bloodstream by gut translocation or through central venous catheters. Early exposure to cephalosporins and extreme prematurity (GA younger than 28 weeks) are known risk factors. Clinical presentation of late-onset fungal sepsis is generally the same as for bacterial LOS. Hyperglycemia and thrombocytopenia are also prevalent features. The kidney and urinary tract are among the most common sites of infection in neonatal disseminated candidiasis. Because of this potential for a renal focus of infection, conventional amphotericin B, which readily distributes to the kidney, is the treatment of choice for LOS from presumed or confirmed candidemia (References 74–76). Amphotericin B is not associated with nephrotoxicity in neonates at the same rates as in adults. Several case series and open-label prospective studies have examined amphotericin B efficacy and safety in neonates. Most report nephrotoxicity (elevated serum creatinine or oliguria) rates between 0% and 15% (References 77–82). A small prospective study comparing amphotericin B with fluconazole reported that only 1 of 11 neonates exposed to amphotericin B experienced mild renal impairment (Reference 83). One large study examined the nephrotoxic effects of amphotericin B in neonates during a 14-year period. Only 16% of 92 neonates showed a significant increase in serum creatinine during amphotericin B therapy. Most cases (94%) resolved despite the continuation of amphotericin B (Reference 84). In clinical practice, it is difficult to differentiate the cause of increased serum creatinine or decreased urine output. It may be related to amphotericin B or to the neonate's

underlying renal infection and/or hemodynamic instability from severe sepsis. Switching to lipid-based formulations of amphotericin B to avoid nephrotoxicity is not recommended because of the potential for reduced distribution to the presumed renal infection site. Lipid formulations have also not been shown to be less nephrotoxic in neonates compared with conventional amphotericin B (References 85, 86). A conservative approach in the face of renal dysfunction during amphotericin B therapy is to prolong the dosing interval to every 48 hours if the serum creatinine is greater than 1.5 mg/dL or if it is rising more than 0.3 mg/dL per day. Use of a lipid-based amphotericin B formulation is justified if *Candida* infection outside the kidney or urinary tract (e.g., cardiac, CNS) is present or if a non-*Candida* fungal pathogen is identified (Reference 52).

The biggest challenge for the pharmacist assisting in the care of a preterm neonate receiving amphotericin B is drug administration. Amphotericin B is a known venous irritant and should ideally be administered by a central catheter. It also requires a 2- to 4-hour infusion and is not compatible with parenteral nutrition. A sick premature neonate usually does not receive enteral feedings; hence, discontinuing parenteral nutrition intake for 2–4 hours during amphotericin B administration is challenging. To solve this nutritional dilemma, amphotericin B should be prepared in a concentration and volume of dextrose equal to what the parenteral nutrition would provide for the 2–4 hours when amphotericin B is infusing in its place. If the source of candidemia is the central venous catheter, it should be removed (Reference 27). Consequently, this will leave the sick preterm neonate with limited peripheral venous access for parenteral nutrition and amphotericin B. The pharmacist should prepare an amphotericin B dose in the same volume and dextrose concentration as the parenteral nutrition, being mindful of the maximal recommended amphotericin B concentration for peripheral administration of 0.1 mg/mL. If the neonate has more than one peripheral intravenous catheter available and can tolerate the 10 mL/kg that an amphotericin B dose represents ( $1 \text{ mg/kg} \times 0.1 \text{ mg/mL}$ ), then the least complicated approach is to prepare a 0.1-mg/mL concentration in D<sub>5</sub>W (dextrose 5%) for administration in a separate site from the parenteral nutrition.

Other agents used to treat *Candida* LOS are fluconazole, flucytosine, and the echinocandins (Table 6 and Table 7). Fluconazole is not recommended for the empiric therapy of LOS because some non-*albicans Candida* spp. are intrinsically resistant to or have high rates of resistance to fluconazole. If the isolated species is sensitive to fluconazole, it may be used in lieu of amphotericin B to complete the course of therapy. Fluconazole is compatible with parenteral nutrition and hence is much less complicated to administer than

amphotericin B. Oral flucytosine is commonly combined with amphotericin B when CNS infection is present. Caspofungin, micafungin, and anidulafungin all have pharmacokinetic and safety data to guide dosing and monitoring in neonates (References 87–90). These data are preliminary, and more research is needed to determine the optimal dose, better appreciate the potential adverse effects, and develop practical methods of dose preparation and administration for neonates. Clinical experience with the echinocandins in the NICU is also very limited, typically involving cases of persistent fungemia or focal fungal infection and given in combination with amphotericin B. Currently, the echinocandins should only be used under the direction of a pediatric infectious disease consultation for rare cases in which conventional therapy is inadequate.

### Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is an intestinal disease predominantly in very premature neonates older than 7 days. The pathophysiology of NEC is not entirely understood, but it is thought that immature preterm mucosal tissue in the intestinal lumen becomes injured during early postnatal life. Injury can be the result of hypoperfusion and hypoxemia secondary to the typical comorbidities associated with prematurity such as sepsis, low cardiac output, and the presence of umbilical catheters. Intestinal bacteria that colonize the neonate may invade the injured mucosa. The injured and inflamed intestinal portion then becomes symptomatic when challenged with enteral feeding initiation and advancement. The initial clinical presentation is often acute feeding intolerance, abdominal distention, and bloody stools. In severe cases, LOS and rapid clinical deterioration occur, sometimes requiring emergency surgical intervention. Diagnosis is confirmed with a radiographic examination of the abdomen, which reveals evidence of air in the intestinal lining, outside the intestinal lumen, or in the peritoneum if intestinal perforation has occurred (Reference 91). In the United States, 11% of all VLBW neonates will develop NEC during their hospitalization, with an estimated mortality rate of 15% to 30% (Reference 92). Compared with those without NEC matched for GA, survivors of NEC are at high risk of poor neurodevelopmental outcomes such as vision and hearing impairment, cerebral palsy, and cognitive and motor developmental abnormalities (Reference 93).

Antibiotics are a standard intervention for NEC. The intent of antibiotic therapy is to reduce the organism burden contributing to the intestinal disease and prevent translocation into the bloodstream. No single antibiotic regimen is considered superior. Standard LOS therapy that provides broad coverage for nosocomial pathogens and intestinal flora is appropriate for NEC (e.g., vancomycin plus an AMG or other gram-negative

coverage). Treatment should continue for 7–14 days. Adding anaerobic coverage by using clindamycin or metronidazole or by substituting AMG or cefotaxime with piperacillin/tazobactam or meropenem can also be considered, particularly when perforation is suspected or confirmed (References 54, 94).

### Intravenous Immune Globulin

Meta-analysis of seven prospective placebo or non-treatment-controlled studies of intravenous immune globulin use in neonates with clinical features of sepsis found a significant relative risk reduction of 55% in deaths in those neonates with positive blood or CSF cultures. However, the overall mortality risk reduction was not observed in all study subjects. Because providers do not know when starting treatment whether a neonate will develop proven sepsis, the routine use of intravenous immune globulin to prevent mortality in neonates with presumed sepsis is not recommended (Reference 95). In addition, a large international prospective study of intravenous immune globulin (500 mg/kg administered every 48 hours for two doses) in predominantly VLBW neonates with suspected or proven sepsis did not find a reduction in mortality, subsequent sepsis, or disability compared with placebo, even in the subset of patients with proven sepsis (Reference 96). The routine administration of intravenous immune globulin to prevent nosocomial infection in VLBW preterm neonates is also not recommended because of marginal reductions in infection rates and no reduction in other preterm morbidities or mortality (Reference 97). Experts consider a single dose of intravenous immune globulin 750 mg/kg reasonable in cases of severe sepsis (e.g., hypotension and marked clinical deterioration) when bacterial infection has been proved or is highly likely and when the ANC is less than 1000 cells/mm<sup>3</sup> (References 98, 99).

### Prevention

#### *Group B Streptococcus*

The most successful strategy for preventing EOS in the United States has been GBS intrapartum antibiotic prophylaxis (Figure 2). This strategy involves screening pregnant women for the presence of vaginal GBS colonization with a lower vaginal and rectal swab collected at 35–37 weeks' GA as part of routine outpatient prenatal care. The collection may also take place in the hospital before 35 weeks if the mother presents with problems that threaten preterm delivery. If the specimen is positive for GBS, the mother is provided prophylactic intravenous antibiotics during labor. Prophylaxis is

discontinued after delivery. Penicillin 5 million units followed by 2.5–3 million units every 4 hours is the regimen of choice for intrapartum antibiotic prophylaxis (Reference 22).

Preterm premature rupture of membranes (pPROM), defined as the spontaneous rupture of the amniotic sac before 37 weeks' (term) gestation and before the onset of labor, increases the risk of intrauterine infection and preterm birth. When pPROM occurs at younger than 34 weeks' gestation, administering systemic antibiotics to the mother can delay birth by more than 7 days and reduce prematurity-associated morbidity in the neonate. Ampicillin or penicillin plus erythromycin or azithromycin decreases the relative risk of confirmed EOS by 39% (Reference 100).

A promising maternal-targeted solution to preventing neonatal sepsis is the development of a GBS vaccine. Ongoing research since the 1990s has contributed to discovering the qualities of a vaccine necessary to elicit a mucosal immune response to the many GBS serotypes known to colonize the maternal genital tract. If ultimately successful, a GBS vaccine administered preconceptionally could prevent GBS-related EOS and LOS. Furthermore, because maternal GBS colonization and urinary tract infection are associated with preterm labor and membrane rupture, a GBS vaccine might prevent pPROM and preterm births and decrease maternal antibiotic use during labor and delivery (References 101, 102).

### ***Herpes Simplex Virus***

Cesarean section delivery decreases the incidence of neonatal HSV infection by 80%, compared with vaginal delivery in women with genital HSV lesions or prodromal symptoms that are present at the time of delivery. Oral acyclovir or valacyclovir prophylaxis beginning at 36 weeks' GA in mothers with recurrent genital herpes reduces the recurrence of active maternal HSV infection at delivery by 75% and reduces viral shedding by 90%. The recommended acyclovir dose is 400 mg three times/day or valacyclovir 500 mg twice daily until delivery (Reference 103).

### ***Gonococcal Ophthalmia Neonatorum***

Neonatal *Neisseria gonorrhoeae* and *Chlamydia trachomatis* ophthalmic infections are acquired during delivery from exposure to infected maternal cervical secretions. These organisms infrequently can also cause disseminated disease or sepsis (References 104, 105). A single application of erythromycin 0.5% eye ointment to both eyes of newborns within 1 hour of birth is an important intervention for preventing ophthalmic gonococcal infection. Iodine 2.5% solution and tetracycline 1%

ointment are also efficacious and used throughout the world. No ocular agent, including erythromycin ointment, is known to be effective at preventing newborn *C. trachomatis* ophthalmic infection (References 104, 106).

### ***Late-Onset Sepsis***

Interventions to prevent late-onset infections and sepsis in the NICU include systemic fluconazole, oral nystatin, vancomycin central catheter flush, and breast milk feedings. Fluconazole prophylaxis reduces *Candida* colonization and disseminated infection in at-risk preterm neonates (e.g., birth weight less than 1000 g, 27 weeks or less GA). The dose is 3–6 mg/kg intravenously two or three times/week begun in the first 3 days of life and is continued for 6 weeks or until intravenous access is no longer needed (peripheral or central) (Reference 107). Oral nystatin suspension 100,000 units (1 mL) given by mouth or feeding tube three times/day to VLBW neonates beginning from within the first 3 days and continued until 2 months of life is also effective at preventing invasive fungal infection. The relative reduction in infection rates is about 20% for both fluconazole and nystatin. However, better-quality data are available for fluconazole (References 108, 109). One center that compared fluconazole with nystatin prophylaxis found a higher incidence of mortality from NEC and spontaneous intestinal perforations in preterm neonates who received nystatin (Reference 110).

The early initiation of breast milk feedings instead of cow's milk-based formula reduces the risk of NEC and LOS in preterm neonates (References 111–113). Although breast milk is not a medication, it does have a unique antimicrobial effect. Breast milk contains large quantities of secretory immunoglobulin A (IgA) antibodies that block bacteria from adhering to mucosal membranes and entering tissues (Reference 114). Oligosaccharides in milk also prevent intestinal pathogenic bacteria adhesion and serve as food for desirable intestinal bacteria such as *Bifidobacterium* (Reference 115). Studies of synthetic "medicinal" oligosaccharide prebiotics and lyophilized powder probiotics such as *Bifidobacterium*, *Lactobacillus*, and *Saccharomyces* as milk additives are encouraging and represent a potential NEC prevention strategy in very preterm neonates (References 116, 117).

Dilute vancomycin 25-mcg/mL flushes administered twice daily through peripherally inserted central venous catheters or administered continuously in parenteral nutrition can prevent CoNS CLABSI in preterm neonates (References 118, 119). Use of the vancomycin flush has been associated with a 6-fold reduction in the incidence of CoNS sepsis compared with placebo (Reference 118). A meta-analysis of vancomycin continuous-infusion studies has identified a 14-fold reduction in CoNS sepsis compared with placebo (Reference

119). Neither of these interventions is recommended for routine use because there is no documented effect on length of stay or mortality. There may also be an increased risk of developing vancomycin-resistant organisms (Reference 120). Nonetheless, their selective use in nurseries with high rates (e.g., greater than 20% of all patients) of staphylococcal CLABSI is considered acceptable (Reference 121).

In addition to recommending appropriate sepsis prevention medications, the pharmacist caring for neonates should participate in multidisciplinary quality assurance activities that prevent sepsis. Examples include implementing medication administration methods that prevent CLABSI and promoting the judicious use of antimicrobials (References 94, 122, 123). Restricting routine gastric acid inhibitor therapy is also encouraged. Stomach acid is an important barrier to infection, and the use of these agents is associated with an increased risk of sepsis, pneumonia, urinary tract infections, and NEC in preterm neonates (References 124, 125).

## CONCLUSIONS

Sepsis is a significant source of neonatal mortality and long-term morbidity, particularly in VLBW infants. The pharmacist caring for neonates can contribute to improving care by recommending and promptly furnishing individualized appropriate therapy, by closely following the response to therapy, and by helping direct local prescribing practices on the basis of local epidemiology. Because antibiotics are the most common medications used in neonates, pharmacists with a strong working knowledge of sepsis treatment will be a vital asset to the medical team.

Research into the pharmacokinetics and safety of anti-infective agents continues to expand in the United States because of national efforts such as the Pediatric Exclusivity program, the Best Pharmaceuticals for Children Act, and the Pediatric Trials network (see Introduction to Pediatrics chapter). These advances give pharmacists more confidence when making sepsis treatment decisions and contribute to building a larger sepsis treatment armamentarium.

Unfortunately, more or better sepsis treatment choices may not be what neonates need most. Overtreatment of nonseptic neonates remains an unavoidable outcome of a diagnostic dilemma; sepsis is difficult to diagnose because signs and symptoms are nonspecific, and underdiagnosis can lead to disastrous consequences. Any neonate acting abnormally will therefore be treated with anti-infective agents pending the evaluation of maternal history and the results of neonatal physical examination and laboratory testing, all of which suffer from a considerable degree of unreliability and ambiguity. Improvements in the

precision of diagnostic tests and sepsis symptom identification, together with treatment improvements, are needed to advance the rational use of antiseptic medications in neonatal care (References 126–128).

# CHAPTER 35

## MENINGITIS IN INFANTS AND CHILDREN

Erin J. McDade, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. Describe the epidemiology and pathophysiology of meningitis.
2. Identify the most common pathogens that cause bacterial and viral meningitis by age group.
3. Describe the signs and symptoms of meningitis in the pediatric population and compare them with those of the adult population.
4. Compare and contrast the diagnostic criteria between bacterial and viral meningitis.
5. Identify appropriate empiric treatment for bacterial meningitis based on the clinical characteristics of a pediatric patient.
6. Develop plan for monitoring pharmacologic therapy for clinical efficacy and potential adverse drug reactions.

### ABBREVIATIONS IN THIS CHAPTER

BBB	Blood-brain barrier
CFU	Colony-forming units
CNS	Central nervous system
CSF	Cerebrospinal fluid
CT	Computed tomography
Hib	<i>Haemophilus influenzae</i> type b
HSV	Herpes simplex virus
IDSA	Infectious Diseases Society of America
LP	Lumbar puncture
PCR	Polymerase chain reaction
PCV7	7-valent pneumococcal conjugated vaccine
WBC	White blood cell

### INTRODUCTION

Meningitis is defined as an inflammation of the meninges and, when suspected, is considered a medical emergency. Meningitis can be caused by a variety of pathogens, including bacteria, viruses, fungi, and parasites. This chapter will focus on bacterial meningitis with a brief overview of viral meningitis. Bacterial meningitis, when untreated, is associated with a mortality rate approaching 100% (Reference 1). With appropriate treatment, the mortality rate decreases to 20% to 30% in neonates and 1% in infants and children (Reference 2). Before vaccinations were used against common bacterial meningitis

pathogens such as *Streptococcus pneumoniae* (pneumococcus) and *Haemophilus influenzae*, bacterial meningitis occurred in almost 6000 infants and children every year, and 70% of these cases were caused by *H. influenzae* (Reference 3). The introduction of the *H. influenzae* type b (Hib) and 7-valent pneumococcal conjugate (PCV7) vaccines has reduced the incidence of disease caused by these pathogens. In 2000, 13 years after the introduction of the Hib conjugate vaccine, the incidence of meningitis caused by Hib decreased by 99% (Reference 4). Similarly, in 2010, 10 years after the introduction of PCV7, the incidence of invasive pneumococcal disease caused by the seven serotypes contained in the vaccine also decreased by 99% (Reference 5). Because of the emergence of pneumococcal serotypes not covered by the PCV7, *S. pneumoniae* continues to be one of the most prevalent meningitis pathogens. Thus, the FDA approved a 13-valent pneumococcal conjugate vaccine (PCV13) in early 2010 that now covers serotypes 1, 3, 5, 6A, 7F, and 19A in addition to those previously covered by PCV7. It is unclear how the introduction of PCV13 will affect the incidence of pneumococcal meningitis.

Despite reductions in mortality, morbidity associated with bacterial meningitis remains high. In neonates, the risk of neurologic sequelae and disabilities after bacterial meningitis is as high as 56%. Up to 25% of childhood meningitis survivors are at risk of developing major disabilities (References 6, 7). Common meningitis-induced neurologic impairments include behavior and adjustment disorders, hearing or visual loss, intellectual impairment, motor abnormalities, and seizures (Reference 7). Risk factors associated with poor outcomes include young age, delay in presentation, presence of seizures for more than 72 hours, coma, need for inotropes, leukopenia, and pneumococcal etiology (References 6, 8, 9). Fortunately, for meningitis caused by some bacteria, the timely addition of dexamethasone to antibiotic treatment has resulted in a decreased incidence of certain neurologic impairments.

Aseptic meningitis occurs in the absence of bacterial isolation from the cerebrospinal fluid (CSF). Viruses are the most common cause of aseptic meningitis. Viruses can also cause encephalitis, with inflammation that extends beyond the meninges and involves brain parenchyma, often referred to as viral meningoencephalitis. Viral meningitis and meningoencephalitis account for more central nervous system (CNS) infections in the United States than all other pathogens combined

(Reference 10). Despite recent advances in molecular diagnostics, a thorough understanding of viral CNS infections is lacking, which leads to delayed diagnosis and underreporting (Reference 10).

## ETIOLOGY

Although many pathogens have the potential to cause meningitis, few are responsible for most cases. The most common community-acquired bacterial pathogens depend on the age of the patient; see Table 1 for the most common pathogens based on age group and other predisposing factors.

Bacterial meningitis acquired early in the neonatal period is usually the result of colonization from vaginal delivery. Late-onset neonatal bacterial meningitis and meningitis in all other pediatric age groups are more likely to be caused by a community-acquired pathogen (Reference 12). *Streptococcus agalactiae*, otherwise known as group B *Streptococcus*, is a gram-positive organism commonly found in the vaginal canal and, because of vertical transmission from mother to child, is a common pathogen in neonatal early-onset sepsis and meningitis (see Neonatal Sepsis chapter). *Escherichia coli*, an enteric gram-negative bacillus, is the second leading

cause of bacterial meningitis in neonates (Reference 12). Most *E. coli* isolates responsible for meningitis in this age group possess the K1 capsular antigen, which is associated with higher morbidity and mortality rates than other *E. coli* isolates (Reference 13). *Listeria monocytogenes* is a gram-positive bacillus that can be acquired by the mother, most commonly through the consumption of contaminated food, and transmitted vertically to the fetus. *L. monocytogenes*, though not the most common cause of bacterial meningitis in neonates, has the potential to cause more morbidity and mortality than other common pathogens. Because of these risks, empiric coverage of *L. monocytogenes* should always be considered in infants younger than 1 month (Reference 14). Other gram-negative enteric organisms, such as *Klebsiella* spp., can also cause meningitis during the neonatal period.

Bacterial meningitis in patients aged 1–23 months is caused by several different pathogens. The most commonly reported causes in this age group are *S. pneumoniae* and *Neisseria meningitidis*, also known as meningococcal meningitis. *S. agalactiae*, *H. influenzae*, and *E. coli* are also potential pathogens in this age group. As discussed previously, the incidence of *H. influenzae* meningitis decreases dramatically after the introduction of the Hib conjugate vaccine. In fact, the mean age of recorded

**Table 1.** Common Pathogens by Age Group and Recommended Empiric Therapy for Bacterial Meningitis

Predisposing Factor	Bacteria	Empiric Therapy
<b>Age</b>		
< 1 month	<i>Streptococcus agalactiae</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i> , <i>Klebsiella</i> spp.	Ampicillin plus cefotaxime, or ampicillin plus an aminoglycoside
1–23 months	<i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>S. agalactiae</i> , <i>Haemophilus influenzae</i> , <i>E. coli</i>	Vancomycin plus a third-generation cephalosporin
2–18 years	<i>N. meningitidis</i> , <i>S. pneumoniae</i>	Vancomycin plus a third-generation cephalosporin
<b>Head Trauma<sup>a</sup></b>		
Basilar skull fracture	<i>S. pneumoniae</i> , <i>H. influenzae</i> , group A $\beta$ -hemolytic streptococci	Vancomycin plus a third-generation cephalosporin
Penetrating trauma	<i>Staphylococcus aureus</i> , coagulase-negative staphylococci (especially <i>Staphylococcus epidermidis</i> ), aerobic gram-negative bacilli (including <i>Pseudomonas aeruginosa</i> )	Vancomycin plus cefepime, vancomycin plus ceftazidime, or vancomycin plus meropenem
<b>Postneurosurgery<sup>a</sup></b>	Aerobic gram-negative bacilli (including <i>P. aeruginosa</i> ), <i>S. aureus</i> , coagulase-negative staphylococci (especially <i>S. epidermidis</i> )	Vancomycin plus cefepime, vancomycin plus ceftazidime, or vancomycin plus meropenem
<b>CSF shunt<sup>a</sup></b>	Coagulase-negative staphylococci (especially <i>S. epidermidis</i> ), aerobic gram-negative bacilli (including <i>P. aeruginosa</i> ), <i>S. aureus</i> , <i>Propionibacterium acnes</i>	Vancomycin plus cefepime, vancomycin plus ceftazidime, or vancomycin plus meropenem

CSF = cerebrospinal fluid.

<sup>a</sup>Empiric treatment of pathogens associated with these predisposing factors should be considered in combination with empiric treatment of pathogens based upon age.

Adapted from Tunkel AR, Hartman BJ, Kaplan SL, Kaufman BA, Roos KL, Scheld WM, et al. Practice guidelines for the management of bacterial meningitis. Clin Infect Dis 2004;39:1267–84, by permission of Oxford University Press (Reference 11).

*H. influenzae* meningitis increased from 15 months to 25 years of age (Reference 15). Meanwhile, *S. pneumoniae* serotypes not found in PCV7 have increased by 275% and are now the leading cause of meningitis in the 1- to 23-month age group (Reference 16). There are many different strains of *N. meningitidis*, a gram-negative diplococci, but the most common in the United States are serotypes B, C, and Y. Serotype B, which is not covered by the currently licensed meningococcal vaccine, is the most common in infants younger than 1 year (References 17, 18).

*N. meningitidis* is the most common bacterial pathogen reported in patients between 2 and 18 years of age (Reference 15). The most common meningococcal serotypes in children 11 years and older are C, Y, and W-135 (References 17, 18). The quadrivalent meningococcal vaccine licensed for use in the United States that includes serotypes A, C, Y, and W-135 is recommended for all children between 11 and 12 years of age followed by a booster at 16 years of age. In addition, routine meningococcal vaccination is recommended for those 2 years and older with specific disease states/medical conditions that result in reduced immune response (see Pediatric Vaccines chapter) (Reference 19). *S. pneumoniae* is the second leading cause of meningitis in this age group, and similar to younger children, the most common serotypes found in this age group that now cause meningitis are not found in PCV7.

As discussed previously, viral meningitis and meningoencephalitis account for more cases of meningitis than all other pathogens combined. The most common viral pathogen isolated is the enterovirus, which accounts for more than one-half of all cases each year (Reference 20). More than 50 serotypes of enterovirus have been associated with meningitis (Reference 20). In addition, respiratory viruses such as influenzae and adenoviruses, arboviruses such as West Nile virus, and herpes simplex viruses (HSVs) can cause viral meningitis (References 20, 21).

## ANATOMY AND PHYSIOLOGY OF THE CNS

### Meninges and Cerebrospinal Fluid

The CSF suspends the brain within the protective layers of the meninges. The meninges are composed of three layers: the pia mater, arachnoid mater, and dura mater (Reference 23) (Figure 1). Eighty-five percent of the CSF is produced by the choroid plexuses, which are located in the lateral third and fourth ventricles. Cerebrospinal fluid is secreted from the choroid plexus and flows outward into the subarachnoid space. Cerebrospinal fluid then circulates around the brain and the spinal cord by bulk flow; complete exchange of CSF occurs every 3–4 hours (Reference 23). Cerebrospinal fluid is normally clear, and in infants, children, and adults, it contains less than 50 mg/dL of protein (less than 170 mg/dL in neonates) (References 24, 25). A CSF glucose concentration of 50% to 55% of the peripheral serum concentration (75% to 80% in neonates) is a normal finding in the CSF of infants and children without CNS disease. In addition, in children it is normal for CSF to contain less than 5 white blood cells (WBCs) per cubic millimeter (less than 20 WBCs in neonates) (References 26, 27). These values change in the presence of infection with bacteria or viruses as shown in Table 2.

### Blood-Brain Barrier

The interface between the brain and the bloodstream, although commonly referred to as the blood-brain barrier (BBB), consists of two components: the BBB and the blood-CSF barrier. For this chapter, the combination of the BBB and blood-CSF barrier will be referred to as the BBB. The BBB is a functional barrier composed of brain microvascular

endothelial cells that regulate the passage of molecules to and from the brain and protect the brain from microbes and toxins (Reference 29). Tight junctions, the main functional component of the BBB, exist between the brain microvascular endothelial cells and restrict the passage of virtually all molecules. Because of the makeup of the BBB, molecules that are small and lipophilic are more likely to cross the BBB and enter the brain. The presence of transport proteins in the endothelial cells allow the transfer of essential nutrients and molecules to the brain that might not otherwise pass through the tight junctions (Reference 30). During bacterial meningitis, bacteria cause the release of proinflammatory cytokines and toxic compounds, resulting in pleocytosis, increased WBCs in the CSF, and increased permeability of the BBB (Reference 29).

## PATHOGENESIS

Most cases of meningitis occur spontaneously. Although the exact mechanism of CNS invasion is unknown, many cases begin with nasopharyngeal colonization (Reference 31). After mucosal colonization of the nasopharynx, bacteria must overcome the host defense mechanisms to invade the bloodstream and penetrate the CNS, thereby eliciting meningitis and neuronal damage (Figure 2) (Reference 29).

Bacterial colonization of the nasopharyngeal mucosa and systemic invasion are more likely when the bacteria possess fimbriae or a polysaccharide capsule. Fimbriae are organelles found on the surface of many bacterial cells that enhance the adhesion to host cells (Reference 31). *Neisseria meningitidis* is one species known

to possess fimbriae. It has been found that 80% of the *N. meningitidis* isolates in the nasopharyngeal mucosa and CSF of patients with meningitis are fimbriated (Reference 32). By inhibiting neutrophil phagocytosis and resisting complement-mediated bactericidal activity, bacterial polysaccharide capsules promote systemic invasion; *H. influenzae*, *S. pneumoniae*, *N. meningitidis*, and *S. agalactiae*, the most common meningeal pathogens, are examples of encapsulated bacteria. Before the routine use of the Hib vaccine, all strains of encapsulated *H. influenzae* accounted for only 5% of nasopharyngeal isolates; however, more than 95% of meningeal and systemic infections were caused by type b strains (References 31, 33).

The mechanism of meningeal invasion has not been well elucidated; one theory is that a high concentration of bacteria in the bloodstream for a sustained period (at least 6 hours in animal models) increases the likelihood of bacterial penetration into the CNS (Reference 34). Other studies evaluating *E. coli*, Hib, and *S. pneumoniae* in neonates and children show an increased likelihood of developing meningitis with high bacterial blood counts (greater than 100–1000 colony-forming units [CFU]/mL) (References 35–37). The site at which bacteria cross the BBB is also debated. Studies of infant rats and primates have shown that the choroid plexus, the site of the blood-CSF barrier, is the entry site because of its high blood flow rate compared with other areas, although other evidence points toward the dural venous sinus system as the point of entry (Reference 31). To further support the choroid plexus theory, studies have shown that meningeal pathogen receptors are present on choroid plexus cells, facilitating the

passage of pathogens across the blood-CSF barrier and into the subarachnoid space (Reference 31). Another hypothesis is that bacteria gain access to the CNS in association with monocytes migrating along normal pathways (Reference 38).

Once in the CNS, host defense mechanisms are usually unable to prohibit bacterial survival and replication, resulting in concentrations as high as  $10^7$  CFU/mL (Reference 39). The presence of bacteria in the CNS signals the release of proinflammatory cytokines and reactive oxygen species, which promote the migration of WBCs across the BBB. In turn, inflammation weakens the tight junctions of the BBB, allowing easier entry

of bacteria and other substances from the bloodstream into the CNS (Reference 29). Bacterial replication, cytokine production, and inflammation continue until appropriate antibiotic therapy is administered. The cycle of inflammation that ensues increases the risk of neuronal damage, increased intracranial pressure, decreased cerebral vascular perfusion, thrombus formation, and hydrocephalus. Not only do replicating bacteria in the CNS lead to inflammation and neuronal damage, but the by-products of bacterial lysis caused by antibiotic therapy also result in subarachnoid inflammation, further increasing the risk of neurologic sequelae (References 40, 41).

## RISK FACTORS

As with patients having many other infectious diseases, immunocompromised patients are at increased risk of developing meningitis. In addition, the incidence and severity of meningitis are increased in young children, with the highest incidence occurring in the first year of life (References 42, 43). The incidence remains high until 2 years of age and then drops off dramatically (Reference 44). Other risk factors include asplenia or splenosis, sickle cell disease and other hemoglobinopathies, terminal complement deficiencies, and recent exposure to someone with meningococcal or *H. influenzae*

meningitis. Any situation in which there is a direct route for bacteria to enter the CSF (e.g., surgical procedures, penetrating head trauma, neurosurgical procedures, presence of CSF leak, presence of a CSF shunt, cochlear implants) increases the risk of bacterial meningitis. When meningitis occurs under these circumstances, the most common bacteria found are from the environment (*Staphylococcus* spp. and gram-negative organisms such as *Pseudomonas* spp.) (References 44–46). The focus of this chapter is community-acquired meningitis in the nonsurgical, nontrauma patient; therefore, information regarding the treatment of these organisms is limited to Table 1 and Table 3.

**Table 3.** Recommendations for Specific Therapy Based on Isolated Pathogen and Susceptibility

Microorganism, Susceptibility	Standard Therapy	Alternative Therapies
<i>Streptococcus agalactiae</i>	Penicillin G or ampicillin	Third-generation cephalosporin <sup>a</sup>
<i>Escherichia coli</i> and <i>Klebsiella</i> spp.	Third-generation cephalosporin	Aztreonam, fluoroquinolone, meropenem, trimethoprim/sulfamethoxazole, <sup>b</sup> ampicillin
<i>Listeria monocytogenes</i>	Penicillin G or ampicillin	Meropenem
<i>Streptococcus pneumoniae</i> Penicillin MIC		
< 0.1 mcg/mL	Penicillin G or ampicillin	Third-generation cephalosporin <sup>a</sup>
0.1–1 mcg/mL <sup>c</sup>	Third-generation cephalosporin <sup>a</sup>	Cefepime, meropenem
≥ 2 mcg/mL	Vancomycin plus third-generation cephalosporin <sup>a</sup>	Fluoroquinolone <sup>d</sup>
Cefotaxime/ceftriaxone MIC ≥ 1 mcg/mL	Vancomycin plus third-generation cephalosporin <sup>a</sup>	Fluoroquinolone <sup>d</sup>
<i>Haemophilus influenzae</i>		
β-Lactamase negative	Ampicillin	Third-generation cephalosporin, <sup>a</sup> cefepime, fluoroquinolone
β-Lactamase positive	Third-generation cephalosporin <sup>a</sup>	Cefepime, fluoroquinolone
<i>Neisseria meningitidis</i> Penicillin MIC		
< 0.1 mcg/mL	Penicillin G or ampicillin	Third-generation cephalosporin <sup>a</sup>
0.1–1 mcg/mL	Third-generation cephalosporin <sup>a</sup>	Fluoroquinolone, meropenem
<i>Staphylococcus aureus</i>		
Methicillin susceptible	Nafcillin or oxacillin	Vancomycin, meropenem
Methicillin resistant	Vancomycin	Trimethoprim/sulfamethoxazole, <sup>b</sup> linezolid
<i>Staphylococcus epidermidis</i>	Vancomycin	Linezolid
<i>Pseudomonas aeruginosa</i>	Cefepime or ceftazidime	Aztreonam, ciprofloxacin, meropenem

<sup>a</sup>Cefotaxime or ceftriaxone (avoid the use of ceftriaxone in the first 28 days of life).

<sup>b</sup>Avoid the use of trimethoprim/sulfamethoxazole in the first 28 days of life.

<sup>c</sup>Cefotaxime/ceftriaxone-susceptible isolates.

<sup>d</sup>Guidelines recommend gatifloxacin or moxifloxacin, but there are no dosing recommendations for use in pediatric patients.

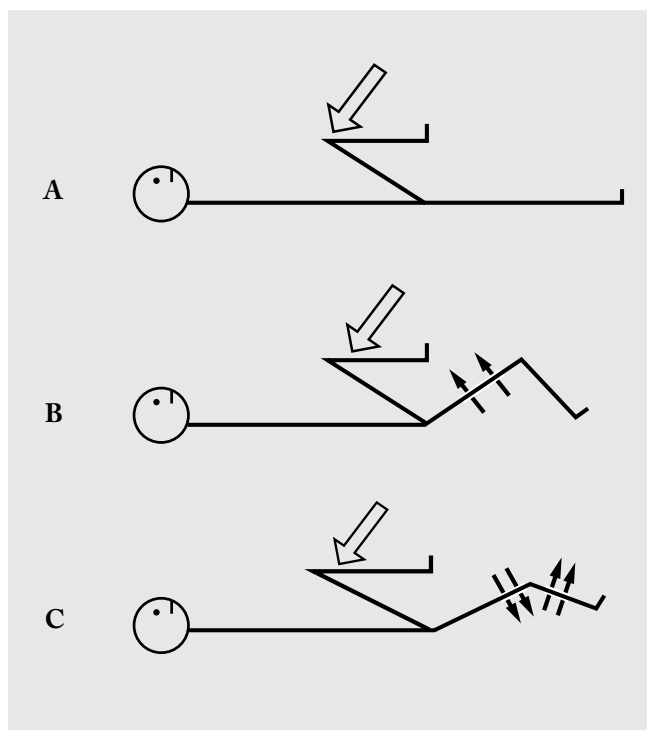

MIC = minimum inhibitory concentration.

## CLINICAL PRESENTATION AND DIAGNOSIS

### Signs and Symptoms

The signs and symptoms of meningitis in the pediatric population, unlike the adult population, are generally nonspecific and can lead to misdiagnosis, especially in young children. Infants and young children often present with the following signs and symptoms: fever, poor feeding, vomiting, lethargy, apnea, irritability, and seizures (more commonly seen in pediatric patients than in adults). In addition, a bulging fontanel can often be seen in neonates and young infants. A study of 110 pediatric patients with bacterial meningitis found that the most common presenting symptoms were irritability and impaired consciousness in patients 1–5 months and 6–11 months of age, respectively. In children 12 months or older, vomiting and nuchal rigidity (neck stiffness) were the most commonly seen signs and symptoms of meningitis (Reference 47). This supports the premise that older children and adolescents are more likely to present with classic meningeal signs and symptoms of

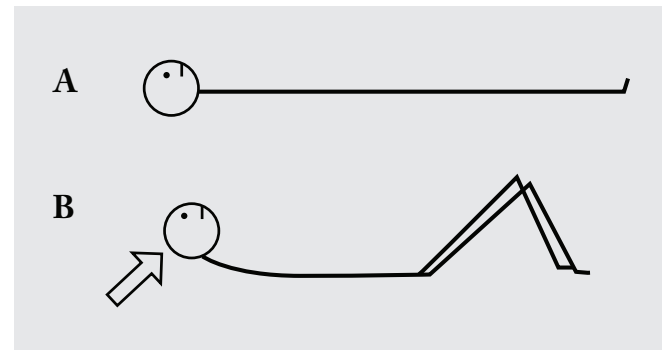

**Figure 3.** Brudzinski's leg sign.

(A) Examiner passively flexes patient's leg (large arrow). (B) The identical contralateral sign: contralateral leg begins to flex (small arrows). (C) The reciprocal contralateral sign: the same leg that exhibited the active flexion begins to extend spontaneously—a reflex resembling a little kick (double arrows).

Verghese A, Gallemore G. Kernig's and Brudzinski's signs revisited. *Rev Infect Dis* 1987;9:187–92, by permission of Oxford University Press (Reference 49).

nuchal rigidity headache and photophobia than are infants and young children. In addition, compared with infants and children younger than 18 months, older children and adolescents are more likely to present with a positive Kernig's and/or Brudzinski's sign (Figure 3, Figure 4, and Figure 5) (References 28, 48).

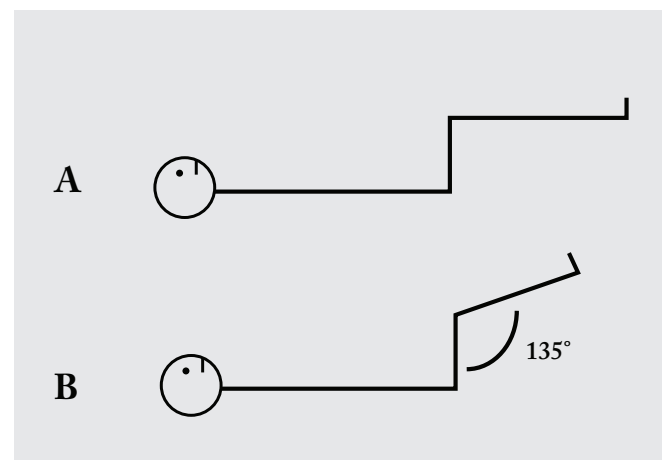

A systematic review reported that a history of bulging fontanel, nuchal rigidity, seizures (if patient is out of the age range for febrile seizures), and poor feeding were associated with an increased likelihood of meningitis. According to the same review, the presence of the following findings on physical examination was

**Figure 4.** Brudzinski's neck sign.

Flexion of the neck (A) by the examiner produces hip and knee flexion (B).

Verghese A, Gallemore G. Kernig's and Brudzinski's signs revisited. *Rev Infect Dis* 1987;9:187–92, by permission of Oxford University Press (Reference 49).

**Figure 5.** Kernig's sign.

Flexion of the knees to 90 degrees (A), the examiner attempts to extend the knees. Once the patient's knee angle reaches about 135 degrees (B), the examiner cannot extend any further because of contracture or extensor spasm.

Adapted from Verghese A, Gallemore G. Kernig's and Brudzinski's signs revisited. *Rev Infect Dis* 1987;9:187–92, by permission of Oxford University Press (Reference 49).

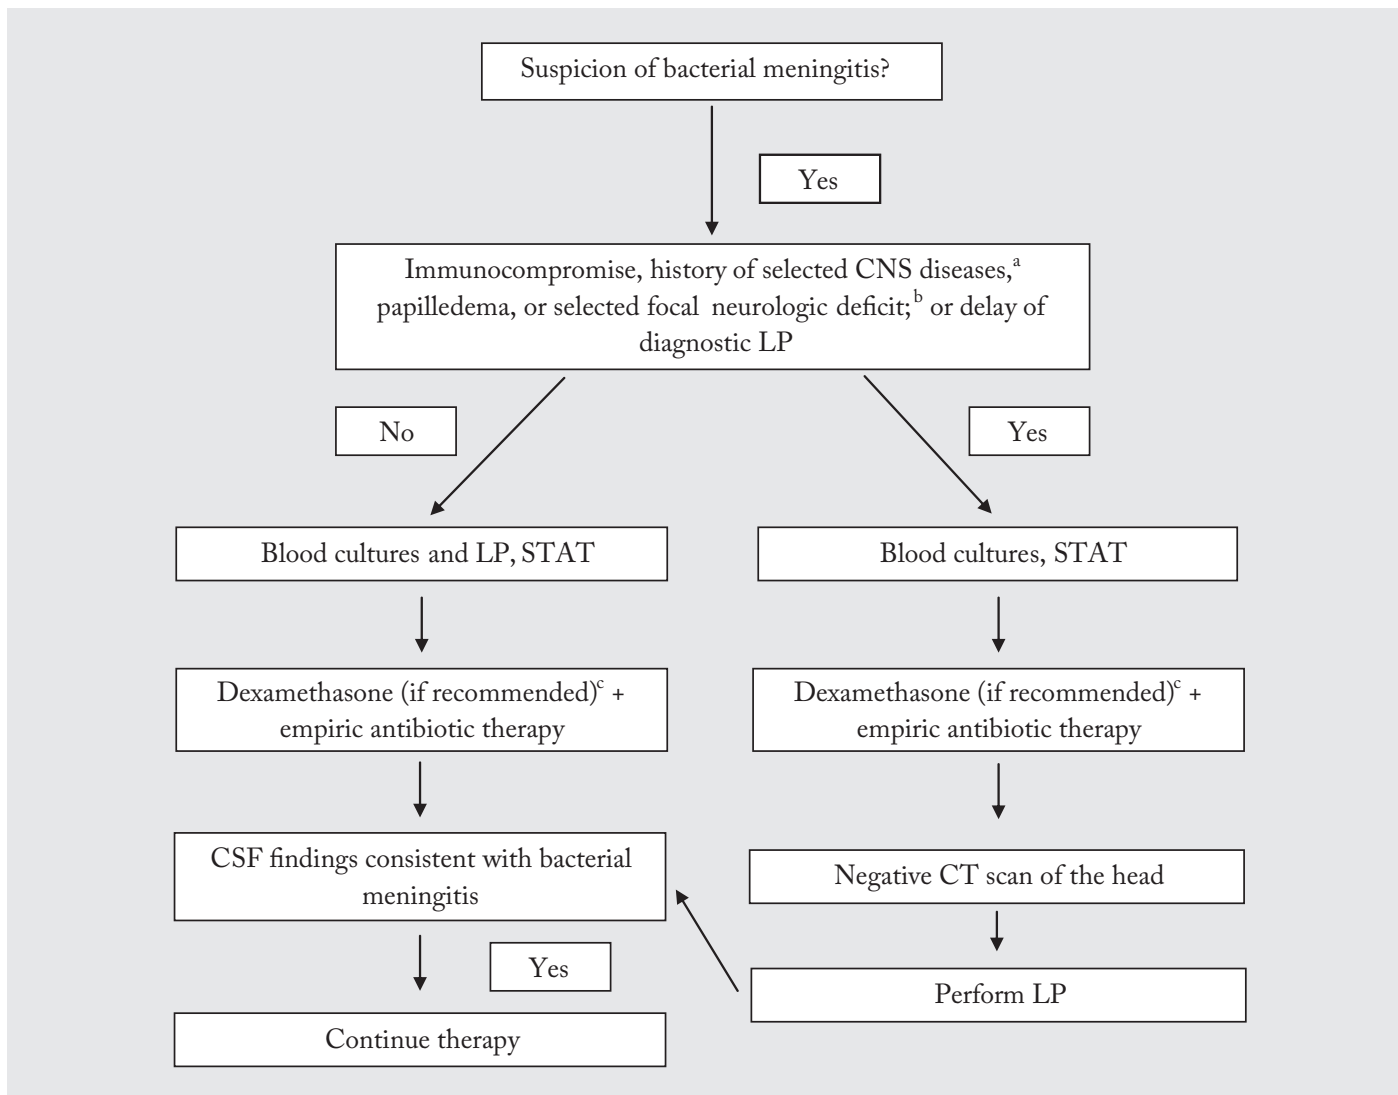

also associated with increased likelihood of meningitis: jaundice, bulging fontanel, toxic appearance, positive Kernig's and/or positive Brudzinski's sign, and increased tone (Reference 50).

### Diagnosis

Although most diagnostic signs and symptoms of meningitis can be debated, it is well known that many are nonspecific and that diagnosis can be easily missed, resulting in greater morbidity and mortality. A definitive diagnosis of meningitis can only be made through an examination of the CSF; therefore, in most cases, a

lumbar puncture (LP) is required. After the removal of CSF by LP, it is normal to have mild, transient lowering of the CSF pressure (Reference 11). In some patients with certain intracranial lesions, this decrease in CSF pressure could precipitate brain herniation. Given that the risk of herniation is restricted to certain patient populations and the time required for neuroimaging can delay treatment with antibiotics, computed tomography (CT) scans should not be performed routinely (Reference 51). The Infectious Diseases Society of America (IDSA) recommends that only infants and children with certain signs and symptoms receive a head CT scan before an LP (Figure 6) (Reference 11).

**Figure 6.** Decision tree for diagnosis and treatment of suspected meningitis.

<sup>a</sup>Includes diseases associated with CSF shunts, hydrocephalus, or trauma; diseases occurring after neurosurgery; or space-occupying lesions.

<sup>b</sup>Palsy of cranial nerves VI or VII is not an indication to delay LP.

<sup>c</sup>See text for adjunctive dexamethasone recommendations.

CNS = central nervous system; CSF = cerebrospinal fluid; CT = computed tomography; LP = lumbar puncture.

Adapted from Tunkel AR, Hartman BJ, Kaplan SL, Kaufman BA, Roos KL, Scheld WM, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis* 2004;39:1267–84, by permission of Oxford University Press (Reference 11).

Once an LP has been performed, CSF should be sent to the laboratory for cell counts (WBC and RBC), glucose and protein content, and Gram stain and culture. In addition, measuring the opening CSF pressure during LP may provide diagnostic information. Table 2 summarizes the CSF findings in patients with bacterial and viral meningitis. While CSF RBC count is not used for direct diagnosis of meningitis, it is routinely used to determine occurrence of a traumatic LP or presence of subarachnoid or intracerebral hemorrhage. If RBCs are present in the CSF, the WBC count could be falsely elevated because of WBCs introduced from the bloodstream. Performing a Gram stain on the CSF allows an accurate identification of the causative organism in most community-acquired bacterial meningitis cases with a specificity of 97% (Reference 52). The accuracy by which a Gram stain detects a bacterial pathogen is directly related to the concentration of bacteria in the CSF: the higher the concentration, the greater the chance of pathogen detection (Reference 53). In addition, it is exceedingly important to note whether the patient received antibiotic therapy before LP. Sterilization of the CSF can occur after one dose of intravenous antibiotic therapy. The speed at which the CSF will become sterile depends on the bacterial pathogen present and the antibiotic used (Reference 54).

Other laboratory tests that may help determine the presence of bacterial meningitis include latex agglutination, limulus lysate assay, and polymerase chain reaction (PCR). Latex agglutination is a rapid test that uses either a serum containing bacterial antibodies or commercially available antisera that are directed against the capsular polysaccharides of meningeal pathogens (Reference 11). A rapid turnaround time, simple technique, and low cost are advantages to the use of latex agglutination. The sensitivity of the test depends on the meningeal pathogen that is present and the specific latex agglutination test. Depending on the assay used, average sensitivities range from 82% to 94% for Hib, 81% to 100% for *S. Pneumoniae*, 73% to 100% for *Streptococcus* group B, and 55% to 74% for *N. meningitidis* (Reference 27). Although this test may be useful to determine the pathogen present, it does not appear to alter the decision to administer antimicrobial therapy. Therefore, the IDSA does not recommend the routine use of latex agglutination to rapidly determine bacterial etiology. The guidelines recommend the use of this modality in patients who have been pretreated with antibiotic therapy and whose CSF Gram stain and culture results are negative (Reference 11).

The limulus lysate assay, which is prepared from an amebocyte of the horseshoe crab, is designed as a test to determine the presence of gram-negative meningitis. The test works by giving a positive result in the presence of endotoxin from gram-negative bacteria. The sensitivity of this test is controversial, with some evidence to support that it is not sensitive enough to serve as a screening tool

in the diagnosis of neonates with gram-negative meningitis (Reference 55). Therefore, the IDSA does not recommend the routine use of the limulus lysate assay for patients with meningitis (Reference 11).

Polymerase chain reaction is a primer-mediated technique for the enzymatic amplification of specific DNA sequences. It can be used to detect the presence of many pathogens, including the most common causes of bacterial meningitis (*N. meningitidis*, *S. pneumoniae*, Hib, *S. agalactiae*, and *L. monocytogenes*). The sensitivity and specificity of PCR vary depending on the test, but when a broad range of bacterial primers are used, the sensitivity is 100% with a specificity of 98%, a positive predictive value of 98%, and a negative predictive value of 100% (Reference 56). The IDSA guidelines suggest PCR is useful for excluding the diagnosis of bacterial meningitis and that it potentially plays an influential role in the decision to initiate or discontinue antibiotic therapy (Reference 11).

Clinicians are often faced with the diagnostic dilemma of differentiating between bacterial and viral meningitis, especially when CSF Gram stain and culture yield negative results. Several tests have been shown to be somewhat helpful in differentiating bacterial from viral meningitis, including CSF lactate concentration, serum C-reactive protein concentration, and serum procalcitonin. Although these tests have not yet replaced standard measures for the diagnosis of bacterial versus viral meningitis, high CSF lactate concentrations, high serum C-reactive protein, and serum procalcitonin greater than 2 ng/mL have been found to be indicators of bacterial rather than viral meningitis (References 57–59). In addition, the presence of a CSF glucose concentration of less than 34 mg/dL, a ratio of CSF to serum glucose of less than 0.23, a CSF protein concentration of greater than 220 mg/dL, a CSF leukocyte count of more than 2000 leukocytes/mm<sup>3</sup>, or a CSF neutrophil count of greater than 1180 neutrophils/mm<sup>3</sup> is an individual predictor of bacterial, rather than viral, meningitis with 99% or higher certainty (References 60, 61).

The diagnosis of viral meningitis, in most clinical settings, involves the exclusion of bacterial meningitis. In addition to CSF cell counts, glucose and protein concentrations, and viral culture, PCR has become an important diagnostic tool to determine the cause of meningitis. Commercial PCR kits are available for the detection of various HSVs as well as enteroviruses (References 62–64).

## TREATMENT

Empiric therapy for the treatment of community-acquired bacterial meningitis depends on the age of the patient and should cover all commonly encountered organisms for that age group (Table 1). Once cultures and sensitivities are reported, the antimicrobial therapy

should be narrowed for treatment of the specific isolated organism (Table 3). For maximum penetration into the CSF, antibiotics should be administered intravenously; recommended antimicrobial doses are summarized in Table 4. The duration of antibiotic therapy depends on the offending pathogen. The IDSA recommends a 7-day treatment course for meningitis caused by *N. meningitidis* and *H. influenzae*, a 10- to 14-day course for *S. pneumoniae* meningitis, a 14- to 21-day course for *S. agalactiae* meningitis, 21 days for *E. coli* (and other aerobic gram-negative bacilli), and 21 days or more for *L. monocytogenes* meningitis (Reference 11). In addition, guidelines recommend that neonates with gram-negative meningitis be treated for 2 weeks after the first sterile CSF culture or for 3 weeks or more, whichever is longer (Reference 11). The remainder of this section focuses on the treatment of specific community-acquired bacteria, adjunctive treatment, and supportive care.

### *S. agalactiae* (Group B Streptococci)

*S. agalactiae* is susceptible to various antibiotics, but with a goal of achieving adequate CNS penetration with a narrow-spectrum agent, treatment with penicillin, ampicillin, or a cephalosporin is recommended. Ampicillin is typically the drug of choice for empiric coverage of *S. agalactiae*. Once *S. agalactiae* has been identified and clinical and microbiologic response has been documented, penicillin or ampicillin alone can be used. To minimize the potential development of antibiotic resistance, penicillin should be used, if possible, because of its narrow spectrum of activity (References 12, 67). Although higher-than-normal doses of antibiotics are routinely used in the treatment of meningitis because it is a sequestered infection site, use of these high doses is even more important with *S. agalactiae* meningitis in neonates. Neonates often present with a higher CSF bacterial load than older age groups, and *S. agalactiae* has a minimum bactericidal concentration that is 10-fold higher than other *Streptococcus* spp., warranting more aggressive doses of antibiotics than in infants and children (Reference 64).

### *E. coli* and *Klebsiella* spp.

Although the combination of ampicillin and an aminoglycoside is adequate for most empiric treatments of *E. coli* and *Klebsiella* infections in neonates, emerging ampicillin resistance, coupled with the relatively poor CSF penetration of aminoglycosides, warrants the use of a different agent. The most commonly used antibiotic in this setting is cefotaxime, a third-generation cephalosporin. Although second- and third-generation cephalosporins have similar spectra of activity against common meningeal pathogens, the use of third-generation cephalosporins for the treatment of meningitis

has been shown to result in better outcomes (Reference 68). For several reasons, cefotaxime is preferred to other intravenous third-generation cephalosporins such as ceftazidime and ceftriaxone. Cefotaxime provides unnecessarily broad gram-negative coverage for community-acquired meningitis, including *Pseudomonas aeruginosa*, and less gram-positive activity than cefotaxime. Unlike cefotaxime, ceftriaxone is up to 95% protein bound and has the ability to displace bilirubin from albumin-binding sites. In neonates, increased free bilirubin increases the risk of kernicterus, a neurologically devastating condition in which bilirubin deposits in the basal ganglia of the brain; therefore, cefotaxime is preferred in this population. Although cefotaxime has a broader spectrum of activity than aminoglycosides, which may lead to an increased incidence of antibiotic resistance, it safely reaches much higher CSF concentrations than aminoglycosides. Cefotaxime may decrease the risk of prolonged infection and treatment failure, so it should be considered for empiric coverage of suspected neonatal meningitis caused by *E. coli* and *Klebsiella* spp. (Reference 12).

### *L. monocytogenes*

As discussed previously, *L. monocytogenes* is a potentially devastating meningeal pathogen in neonates. The mainstay of treatment for *L. monocytogenes* is the combination of ampicillin and gentamicin. Although ampicillin is typically the drug of choice for treatment, the combination of ampicillin and an aminoglycoside is typically used initially because of improved survival observed in animal models (References 14, 69). Gentamicin is the preferred aminoglycoside because tobramycin and amikacin are typically reserved for resistant organisms.

### *S. pneumoniae*

*S. pneumoniae* is the most common and second most common pathogen in patients 1–23 months and 2–18 years of age, respectively. Historically *S. pneumoniae* was best treated by penicillin. In the 1960s, the first case of penicillin-resistant *S. pneumoniae* was documented, and since then, the emergence of resistant pneumococcus has increased around the world. More recently, pneumococcal isolates resistant to third-generation cephalosporins have become more common (References 15, 70). In 1998, data published from the Active Bacterial Core Surveillance program in the United States showed that as many as 35% of invasive *S. pneumoniae* isolates were resistant to penicillin, and 14% of isolates were resistant to cefotaxime (Reference 71). For this reason, vancomycin should always be given with a third-generation cephalosporin, either ceftriaxone or cefotaxime, for empiric treatment of suspected meningitis in patients 1 month and older for adequate coverage of *S. pneumoniae*

**Table 4. Antimicrobial Dosing for Meningitis (References 11, 24, 45, 65, 66)**

Antimicrobial Agent	CSF Penetration <sup>a</sup>	Dose (mg/kg/dose), dosing interval (hours)			Maximum Single Dose (unless stated otherwise)	Comments
		Neonates, age in days (> 2000 g)		Infants and Children		
		0–7	8–28			
Amikacin	-	10 mg/kg, every 12	10 mg/kg, every 8	10 mg/kg, every 8	N/A <sup>b,c</sup>	Goal peak: 30–40 mcg/mL Goal trough: < 10 mcg/mL
Ampicillin	+	100 mg/kg, every 8	75 mg/kg, every 6	75 mg/kg, every 6	2000 mg	
Aztreonam	+	30 mg/kg, every 8	30 mg/kg, every 6	30 mg/kg, every 6	2000 mg	
Cefepime	+	50 mg/kg, every 12	50 mg/kg, every 12	50 mg/kg, every 8	2000 mg	
Cefotaxime	+	50 mg/kg, every 8–12	50 mg/kg, every 6–8	75 mg/kg, every 6	2000 mg	
Ceftazidime	+	50 mg/kg, every 8–12	50 mg/kg, every 8	50 mg/kg, every 8	2000 mg	
Ceftriaxone	+	—	—	50 mg/kg, every 12	2000 mg	Not for neonates. <sup>d</sup> Avoid use with calcium-containing IV fluids. <sup>e</sup>
Chloramphenicol	++	—	—	25 mg/kg, every 6	4000 mg/day	Not routinely used because of adverse effects.
Ciprofloxacin	+	—	—	10–15 mg/kg, every 12	800 mg/day	Not first line in pediatrics <sup>f</sup>
Gentamicin	-	2.5 mg/kg, every 12	2.5 mg/kg, every 8	2.5 mg/kg, every 8	N/A <sup>b,c</sup>	Goal peak: 8–10 mcg/mL Goal trough: < 2 mcg/mL
Meropenem	+	20 mg/kg, every 12	20 mg/kg, every 8	40 mg/kg, every 8	2000 mg	
Nafcillin	+	25 mg/kg, every 8	25–35 mg/kg, every 6	50 mg/kg, every 6	12 g/day	
Oxacillin	+	50 mg/kg, every 8	50 mg/kg, every 6	50 mg/kg, every 6	12 g/day	
Penicillin G	+	50,000 units/kg, every 8	50,000 units/kg, every 6	66,000 units/kg, every 4	24 million units/day	
Rifampin	++	—	10 mg/kg, every 12	10 mg/kg, every 12	600 mg	
Tobramycin	-	2.5 mg/kg, every 12	2.5 mg/kg, every 8	2.5 mg/kg TMP, every 8	N/A <sup>b,c</sup>	Goal peak: 8–10 mcg/mL Goal trough: < 2 mcg/mL
Trimethoprim/sulfamethoxazole	++	—	—	5 mg/kg TMP, every 6–8	N/A <sup>b</sup>	Not for use in neonates <sup>d</sup>
Vancomycin	+	15 mg/kg, every 8–12	15 mg/kg, every 6–8	15 mg/kg, every 6	N/A <sup>b,c</sup>	Goal trough: 15–20 mcg/mL <sup>g</sup>

<sup>a</sup>++: Therapeutic levels in the CSF with or without inflammation of the meninges; +: therapeutic levels in the CSF with inflammation of the meninges; -nontherapeutic levels in the CSF without inflammation and minimal penetration with inflammation.

<sup>b</sup>No true maximum dose.

<sup>c</sup>Monitor serum concentrations, doses should be adjusted to achieve appropriate serum concentrations.

<sup>d</sup>Highly protein bound; risk of bilirubin displacement and development of kernicterus.

<sup>e</sup>Because of risk of precipitation.

<sup>f</sup>Reference 66.

<sup>g</sup>Reference 11.

CSF = cerebrospinal fluid; IV = intravenous; N/A = not applicable; TMP = trimethoprim.

Adapted from Tunkel AR, Hartman BJ, Kaplan SL, Kaufman BA, Roos KL, Scheld WM, et al. Practice guidelines for the management of bacterial meningitis. Clin Infect Dis 2004;39:1267–84, by permission of Oxford University Press (Reference 11).

(Reference 11). Of note, the use of ceftriaxone in patients older than 1 month is safe because the risk of kernicterus is greatly decreased after this time. As is true with all other isolated pathogens, if *S. pneumoniae* is isolated, the antibiotic therapy should be tailored to the narrowest agent on the basis of susceptibility.

### *H. influenzae*

Despite the routine use of the Hib conjugate vaccine in the United States, *H. influenzae* remains a potential and important cause of meningitis in infants 1–23 months of age. In the 1970s,  $\beta$ -lactamase-producing *H. influenzae* resulted in penicillin treatment failures. In some areas of the United States, the incidence of  $\beta$ -lactamase-positive *H. influenzae* is now approaching 50% (Reference 70). To overcome this resistance and reduce the risk of treatment failures, a third-generation cephalosporin, either cefotaxime or ceftriaxone, is recommended for empiric treatment of patients 1–23 months of age who are at risk of *H. influenzae* meningitis (Reference 11). If *H. influenzae* is isolated from the CSF and the  $\beta$ -lactamase enzyme is not present, antibiotic therapy should be narrowed on the basis of susceptibilities.

### *N. meningitidis*

Penicillin is the treatment of choice for *N. meningitidis*, the most common meningeal pathogen isolated in patients older than 2 years. Although penicillin-resistant strains of *N. meningitidis* are rare, a third-generation cephalosporin, either ceftriaxone or cefotaxime, should be used empirically until susceptibilities are reported. If a penicillin-susceptible strain of *N. meningitidis* is isolated, therapy should be changed to penicillin for the duration of treatment. Although *N. meningitidis* is a highly pathogenic organism, it is easily treated with appropriate antibiotic therapy. In one study, after the single dose of a third-generation cephalosporin, all CSF cultures were negative after just 2 hours, much less time than was seen for other pathogens (Reference 54). The treatment duration required for meningococcal meningitis is 7 days, much shorter than for other pathogens. In fact, some evidence, although limited, supports even shorter durations with no increased incidence of relapse (Reference 72).

### Viral Pathogens

Therapy for viral meningitis pathogens is limited; therefore, supportive care is typically the mainstay of treatment. Unfortunately, no antiviral treatment is available for enterovirus, the most common viral pathogen isolated in viral meningitis cases. If HSV is suspected, especially in neonates, parenteral acyclovir should be initiated and continued for 14–21 days until HSV infection is ruled out, at which point acyclovir can be discontinued.

Acyclovir dosing in neonates, infants, and children younger than 12 years with suspected HSV meningitis or encephalitis is 20 mg/kg/dose intravenously administered every 8 hours. Of note, some experts recommend 15 mg/kg/dose every 8 hours for children older than 2 months to younger than 12 years. For children 12 years and older, a dose of 10 mg/kg intravenously administered every 8 hours is recommended (Reference 73). Acyclovir has the potential to cause nephrotoxicity; therefore, pharmacists should ensure patients receive adequate hydration as well as proper monitoring of urine output and renal function, especially when acyclovir is combined with other nephrotoxic agents. There are no effective therapies for the other potential viral causes of meningitis, such as respiratory viruses or arboviruses.

### Supportive Care

The maintenance of normal temperature and blood pressure, adequate cerebral perfusion pressure, and management of increased intracranial pressure is paramount in preventing the most life-threatening complications of bacterial meningitis. Strategies used to reduce intracranial pressure include bed head elevation of 30 degrees, avoidance of frequent vigorous procedures, mannitol or hypertonic saline administration, and, potentially, administration of high-dose barbiturates (Reference 45). In addition, patients who become obtunded and unable to protect their airway often require intubation and mechanical ventilation.

### Adjunctive Treatment with Dexamethasone

As discussed previously, bacterial meningitis remains an important and significant cause of morbidity and mortality in children. The neurologic sequelae associated with this disease are mainly a result of the inflammatory processes from bacterial proliferation and bacterial lysis in the CSF. For this reason, dexamethasone, a corticosteroid with potent anti-inflammatory effects, has been studied in patients with bacterial meningitis to decrease the incidence of morbidity and mortality. It has been shown that dexamethasone, when used in the appropriate pediatric patient, can improve morbidity but does not seem to affect mortality (References 11, 74, 75).

Dexamethasone use in neonatal meningitis is not well studied; therefore, it is not recommended for treatment of bacterial meningitis in this population. According to a recent meta-analysis, in children older than 1 month with bacterial meningitis mainly caused by *H. influenzae*, administration of dexamethasone decreased the risk of hearing loss (Reference 74). Because of the potential for increased inflammation as a result of bacterial lysis after antibiotic therapy, dexamethasone should be administered before the first dose of

antibiotic therapy to be most effective. The latest IDSA treatment guidelines for meningitis recommend the use of dexamethasone, at a dose of 0.15 mg/kg every 6 hours for 2–4 days, in infants and children with *H. influenzae* meningitis as long as it is initiated before the administration of antibiotic therapy (Reference 11).

The use of adjunctive dexamethasone treatment for pneumococcal meningitis is controversial. Given the lack of supporting evidence, the IDSA guidelines state that dexamethasone therapy should be considered in patients with pneumococcal meningitis and that the potential risks and benefits should be weighed before initiating treatment (References 11, 76). More recently, it was found that in high-income countries, dexamethasone treatment has a protective effect against the development of hearing loss in non-*H. influenzae* meningitis in children (Reference 74). There is no evidence supporting the use of adjunctive dexamethasone in meningococcal or gram-negative meningitis.

### Adjunctive Treatment with Rifampin

Rifampin is an agent commonly used synergistically in combination with other antibiotics for the treatment of *Staphylococcus* spp. Although rifampin may be an attractive agent for the treatment of CNS infections because of its excellent BBB penetration, resistance to rifampin develops quickly when it is used alone. Therefore, rifampin should always be used in combination with another

agent when treating bacterial meningitis. On the basis of its activity against *Staphylococcus* spp., it is recommended that rifampin be considered in addition to vancomycin in patients with CNS shunt infections, particularly if the shunt is not going to be removed (Reference 11). Although data are limited, some experts recommend the addition of rifampin to either cefotaxime or ceftriaxone for the treatment of *S. pneumoniae* meningitis in the following circumstances: the patient's condition continues to deteriorate after 24–48 hours of therapy, a repeat CSF culture shows continued growth or does not show a significant reduction in the number of organisms growing, or the *S. pneumoniae* isolate has a cefotaxime/ceftriaxone MIC greater than 2 mcg/mL (References 11, 77).

### Monitoring Treatment

Patients should be monitored for improvement in signs and symptoms of meningitis. For patients who respond appropriately to treatment, repeat LP is not routinely recommended. For patients in whom symptoms do not improve after 48 hours of therapy, repeat LP should be considered (Reference 11). This is especially true for patients with pneumococcal meningitis that is resistant to penicillin or cephalosporins, neonates with meningitis caused by gram-negative bacteria, or those who have received adjunctive dexamethasone therapy. Patients should also be monitored for adverse effects of antibiotic/antiviral treatment (Table 5).

**Table 5.** Common Adverse Effects of Therapy (Reference 65)

Agent	Adverse Effects
Acyclovir	Rash, nausea, phlebitis, nephrotoxicity, elevated liver function tests
Aminoglycosides (amikacin, gentamicin, tobramycin)	Nephrotoxicity, ototoxicity
Aztreonam	Neutropenia, elevated liver function tests, pain at injection site, elevated serum creatinine
Cephalosporins (ceftriaxone, cefotaxime, ceftazidime, cefepime)	Hypersensitivity reactions, nausea, vomiting, diarrhea, pain at injection site, biliary sludging (ceftriaxone)
Chloramphenicol	Gray baby syndrome, reversible bone marrow suppression, aplastic anemia
Ciprofloxacin	Neurologic events (dizziness, nervousness), rash, photosensitivity, nausea, vomiting, tendon rupture
Meropenem	Hypersensitivity reactions, headache, rash, nausea, vomiting, diarrhea, phlebitis, seizures (rare)
Penicillins (ampicillin, nafcillin, oxacillin, penicillin G)	Hypersensitivity reactions, seizures (with high concentrations), bone marrow suppression, elevated liver function tests, interstitial nephritis (rare)
Trimethoprim/sulfamethoxazole	Nausea, vomiting, rash, jaundice/kernicterus in neonates, blood dyscrasias (rare), hepatotoxicity (rare)
Vancomycin	Red man syndrome, nephrotoxicity, hypotension, fever, neutropenia

**Table 6.** Chemoprophylaxis Agents and Dosing (References 78, 79)

Meningeal Pathogen	Rifampin <sup>a</sup>	Ceftriaxone	Ciprofloxacin <sup>a,b</sup>
<i>Haemophilus influenzae</i> type b	< 1 month old: 10 mg/kg orally every day for 4 days	Not recommended	Not recommended
	≥ 1 month old: 20 mg/kg (maximum 600 mg) orally every day for 4 days		
<i>Neisseria meningitidis</i>	< 1 month old: 5 mg/kg orally every 12 hours for 2 days	< 15 years old: 125 mg intramuscularly once	≥ 1 month old: 20 mg/kg (maximum 500 mg) orally once
	≥ 1 month old: 10 mg/kg (maximum 600 mg) orally every 12 hours for 2 days	≥ 15 years old: 250 mg intramuscularly once	

<sup>a</sup>Not recommended for use in pregnant women.

<sup>b</sup>Use only if fluoroquinolone-resistant strains of *N. meningitidis* have not been identified in the community.

### Chemoprophylaxis

Chemoprophylaxis for *H. influenzae* should be provided for specific household contacts. Household contact is defined as people residing with the index patient or nonresidents who spent 4 or more hours with the index patient for at least 5 of the last 7 days preceding the day of hospital admission. Any household with at least one child who is younger than 4 years and unimmunized or incompletely immunized, or any household with a person who is immunosuppressed (regardless of immunization status), should also receive chemoprophylaxis. Chemoprophylaxis is also recommended for nursery school and day care center contacts when two or more *H. influenzae* cases have occurred in the past 60 days (Reference 78).

Chemoprophylaxis is recommended in the following situations if a documented case of meningococcal meningitis occurs: household contact (as previously defined), especially children younger than 2 years; day care or preschool contact at any time during the previous 7 days from the onset of illness; anyone who has had direct exposure to the index patient's secretions through kissing, sharing toothbrushes, or eating utensils; and markers of close social contact at any time during the previous 7 days leading up to illness. In addition, people who have frequently slept in the same dwelling as the index patient during the 7 days preceding the illness or any passenger seated directly next to the index case during airline flights lasting more than 8 hours during the 7 days before illness should receive chemoprophylaxis for meningococcal disease. Only health care providers who have provided mouth-to-mouth resuscitation or had unprotected contact during endotracheal intubation at any time within 7 days before the onset of illness should receive chemoprophylaxis. Otherwise, routine chemoprophylaxis for health care providers is not recommended (Reference 79). See Table 6 for a list of recommended chemoprophylaxis agents and dosage.

### Vaccination

Vaccination is the most effective way to prevent bacterial meningitis in infants and children (Reference 80). Refer to the Pediatric Vaccines chapter for further information on specific vaccinations.

### CONCLUSIONS

Bacterial meningitis is a medical emergency requiring prompt diagnosis and treatment. The exact pathophysiology of the disease has yet to be elucidated, but evidence supports the theory of nasopharyngeal colonization leading to bacteremia and eventual penetration of the meninges. Without a true understanding of the development of the disease, regardless of improvements in diagnostic testing, accurate diagnosis of bacterial meningitis remains a challenge. Nevertheless, the timely use of appropriate antibiotic therapy and dexamethasone has resulted in improved outcomes through the years, but morbidity and mortality in young infants and children remain high. The most effective means of reducing morbidity and mortality from the disease is prevention of the disease through the development and implementation of effective conjugate vaccines.

# CHAPTER 36

## ACUTE OTITIS MEDIA AND UPPER RESPIRATORY TRACT INFECTIONS

Jennifer Le, Pharm.D., MAS, FCCP, BCPS (AQ-ID)

### LEARNING OBJECTIVES

1. Compare and contrast the etiologic pathogens causing upper respiratory tract infections (URTIs), including acute otitis media (AOM), rhinosinusitis, and pharyngitis.
2. Explain recent trends in antimicrobial resistance among bacterial respiratory tract pathogens.
3. Counsel parents and caregivers on the importance of the judicious use of antibiotics and symptomatic medications, including antipyretics, decongestants, and antihistamine, by pediatric age groups.
4. Discuss scenarios when you would or would not recommend the use of a cephalosporin in a child with a penicillin allergy.
5. Formulate a therapeutic plan for a given case study of a patient with a URTI, including AOM, rhinosinusitis, and pharyngitis.

### LIST OF ABBREVIATIONS

ABRS	Acute bacterial rhinosinusitis
AOM	Acute otitis media
CMV	Cytomegalovirus
DRSP	Drug-resistant <i>Streptococcus pneumoniae</i>
EBV	Epstein-Barr virus
GAS	<i>Streptococcus pyogenes</i> or group A $\beta$ -hemolytic <i>Streptococcus</i>
HSV	Herpes simplex virus
RADT	Rapid antigen detection test
TMP/SMX	Trimethoprim/sulfamethoxazole
URTI	Upper respiratory tract infection

### INTRODUCTION

Acute otitis media (AOM) and upper respiratory tract infections (URTIs), including rhinosinusitis and pharyngitis, are common infections affecting different pediatric groups. Although AOM and rhinosinusitis peak in infants and young children, pharyngitis occurs more frequently in children older than 5 years. Both viruses and bacteria may cause these infections; therefore,

antibiotic therapy should be carefully selected for those with true infection of bacterial origin or those at risk of serious complications. The most common bacterial etiologies for AOM and rhinosinusitis are *Streptococcus pneumoniae*, *H. influenzae*, and *M. catarrhalis*. *Streptococcus pyogenes* is the most common bacterial cause of pharyngitis. Some infections may be self-limiting and resolve without treatment. As such, watchful waiting to delay or minimize the use of antibiotics is a prudent strategy for these infections, particularly AOM, without adversely influencing the clinical course. However, because pharyngitis caused by *S. pyogenes* can progress to potentially fatal complications, antibiotic treatment should ensue after confirmed diagnosis.

### ACUTE OTITIS MEDIA

Acute otitis media is an infection of the middle ear characterized by middle ear effusion, inflammation, and acute onset of symptoms. It is the most common diagnosis leading to antibiotic prescription in children (References 1, 2). Because the incidence of AOM peaks in infants and young children between 6 months and 2 years of age, 80%–90% of children will have at least one episode by 2–3 years of age (References 3–5). Complications of AOM may occur that consist of temporary hearing impairment, which may delay speech, language, and cognitive abilities; perforation of the tympanic membrane; and intracranial suppurative complications such as meningitis and brain abscess (Reference 6). Temporary hearing loss, caused by the presence of fluid in the middle ear, is the most common complication. In contrast, intracranial complications seldom occur.

The immature immune systems and the function of the eustachian tube predispose young children to AOM. In particular, the angle of the opening of the eustachian tube is decreased in young children. This allows nasopharyngeal bacteria to ascend to the middle ear cavity and prevents adequate drainage of middle ear fluid, both resulting in infection. The anatomic features of the eustachian tubes, together with other risk factors, are associated with the development of otitis media (Box 1) (References 3, 7). Around 37% of children with recent viral URTIs, particularly caused by rhinovirus and adenovirus, will subsequently develop AOM, showing that a viral URTI is an important risk

### Box 1. Risk factors associated with otitis media.

- Young age, especially < 2 years
- Day care attendance
- Recent viral upper respiratory illness
- Nasopharyngeal colonization with middle ear bacterial pathogens
- Tobacco smoke exposure
- Bottle-feeding
- Pacifier use
- Sick sibling(s) in household
- Native American, Eskimo, and Australian ethnicities
- Allergies to foods or airborne particles
- Familial predisposition
- Immunodeficiency
- Cleft palate or other craniofacial abnormalities
- Male sex
- Low socioeconomic status

factor for AOM (Reference 5). In addition, exposure to tobacco smoke, allergies to food or airborne particles, and attendance in day care should be evaluated in every child with AOM. If modifiable, exposure to these risk factors should be minimized.

Although viruses, including respiratory syncytial virus, rhinoviruses, influenza, and adenoviruses, cause 20% of AOM cases, the most common etiologies in the United States are bacterial and include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* (References 8, 9). Bacteria that infrequently cause AOM are atypical pathogens, group A *Streptococcus*, and gram-negative organisms including *Pseudomonas aeruginosa* (References 7, 10). Mixed infections caused by both bacterial and viral respiratory tract pathogens can occur in up to two-thirds of cases (Reference 11).

Widespread immunization with the heptavalent pneumococcal conjugate vaccine, which covers 60%–70% of the pneumococcal serotypes isolated in AOM, has contributed to the changing epidemiology of bacterial AOM. Certain *S. pneumoniae* serotypes not contained in this vaccine, like serotypes 6C and 19A, have become more prevalent in the United States and worldwide (References 12–17). In addition, penicillin-resistant pneumococcal strains significantly increased from 4% to 13% between 2000 and 2008 (Reference 13). Furthermore, nontypeable *H. influenzae* strains have now become the predominant pathogen causing AOM (References 13, 14). Introduced in the United States in 2010, the 13-valent pneumococcal vaccine provides coverage against all the serotypes available in the 7-valent vaccine, with additional coverage against 19A and potentially 6C through cross-protection (Reference 12).

This new pneumococcal vaccine, together with vaccines for *M. catarrhalis* that are under development, will continue to change the microbiology of AOM (Reference 18).

Antimicrobial resistance among the common bacterial respiratory tract pathogens has become a major public health concern during the past decades. In the 1960s, *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* were susceptible to penicillin. However, today, all of these bacteria have developed resistance to penicillin. In fact, a significant proportion of *H. influenzae* (30%–50%) and *M. catarrhalis* (more than 90%) isolates cultured from the effusions of children with otitis media in the United States produce  $\beta$ -lactamases (Reference 19). As such,  $\beta$ -lactamase/inhibitor combinations (e.g., amoxicillin with clavulanate), cephalosporins (specifically, ceftriaxone, cefixime, and cefdinir), and fluoroquinolones retain excellent activity against these pathogens. The prevalence of resistance to trimethoprim/sulfamethoxazole (TMP/SMX) among the *H. influenzae* isolates obtained worldwide was 17% between 1998 and 2000 (Reference 20).

Alteration of the penicillin-binding proteins, a resistance mechanism acquired by pneumococci, renders the organism resistant to penicillins, cephalosporins, and other  $\beta$ -lactam antibiotics. In the United States, the prevalence of penicillin-nonsusceptible (including resistant and intermediately susceptible) strains of *S. pneumoniae* reached 42% in 2009 (Reference 21). *S. pneumoniae*, now termed *drug-resistant S. pneumoniae* (DRSP), has developed resistance beyond just penicillin. Resistance or reduced susceptibility has developed to other antibiotics, namely cephalosporins, macrolides (including clarithromycin and azithromycin), tetracyclines, and TMP/SMX (References 20–22). Cross-resistance between erythromycin and clindamycin, which is mediated by the *ermB* ribosomal methylation mechanism (MLS<sub>B</sub>-phenotype) that inhibits binding of the antibiotic to the target site, was observed in 32% of *S. pneumoniae* isolates in the United States (References 20, 23). Resistance to fluoroquinolones has been reported, partly because of their extensive use for community-acquired respiratory tract infections, but the incidence remains low (References 24, 25). With respect to age, the prevalence of DRSP appears to be higher in children than in adults and, in fact, peaks in patients younger than 2 years (Reference 26).

### CLINICAL PRESENTATION AND DIAGNOSIS

Middle ear effusions with acute onset of symptoms—including fever, rhinorrhea, irritability, otalgia (or ear pain), tugging or rubbing of the ear, and other non-specific symptoms—are presenting attributes of AOM

(Reference 10). In contrast to AOM, otitis media with effusion refers to uninfected middle ear effusion (i.e., presence of fluid in the middle ear cavity) without acute onset of symptoms, and it can precede or follow AOM.

On otoscopic examination for AOM, the tympanic membrane typically appears erythematous, cloudy, white, or pale yellow. The presence of middle ear effusion is evident by changes in the tympanic membrane including bulging or fullness into the external auditory canal, impaired or absent mobility, and otorrhea (References 10, 27). A bulging tympanic membrane is most characteristic of acute inflammation and therefore AOM (Reference 27). Acute perforation with purulent otorrhea is diagnostic for AOM once otitis externa has been excluded.

The diagnosis of AOM is primarily based on clinical presentation with otoscopic examination, and it should follow stringent criteria to ensure diagnostic accuracy and judicious use of antibiotics. Two significant challenges in diagnosing AOM are establishing the presence of middle ear effusion and distinguishing it from otitis media with effusion (Reference 10). Consequently, some uncertainty exists when diagnosing AOM centered on clinical signs and symptoms. To determine the actual etiology, aspiration of the middle ear fluid (also called tympanocentesis) for culture can be performed. However, this is reserved for special cases, including children who are toxic appearing or unresponsive to several courses of empiric antibiotic therapy.

## TREATMENT

The therapeutic goals for AOM include alleviating symptoms (excluding middle ear effusion), preventing recurrence, using antibiotics judiciously, ensuring patient adherence, and preventing adverse drug reactions. In many cases, the presenting symptoms of AOM usually resolve within 2–3 days after onset. However, middle ear effusion can persist for weeks to months in up to 70% of children (Reference 28). Middle ear effusion has been associated with temporary hearing loss; however, of note, prolonged middle ear effusion alone is not AOM and does not require the use of antibiotics. If antibiotics are used, medication nonadherence, likely because of poor taste, is an issue that should be considered when treating a pediatric patient. Several methods are suggested to improve adherence to prescribed therapies (Box 2).

### Nonpharmacologic Therapy

Mild cases of AOM are self-limiting. Even when left untreated, clinical symptoms improve in the first 24 hours and without any major adverse sequelae in most of these cases (Reference 10). As such, initial observation has been widely accepted by the medical community to

promote judicious antibiotic use. Initial observation allows a delay in antibiotic therapy, if even necessary, for up to 48–72 hours in some children with AOM (Reference 10). The American Academy of Pediatrics endorses initial observation based on certainty of diagnosis, age, and severity of illness. A certain diagnosis of AOM requires meeting all three criteria: rapid onset of symptoms, middle ear effusion, and middle ear inflammation. For age, initial observation is warranted in children 2 years and older with uncertain diagnosis and in those 6 months to 2 years with uncertain diagnosis and presenting with nonsevere infection (defined as mild otalgia or temperature not exceeding 102.2°F [39°C] in the previous 24 hours) (Reference 10). Appropriate follow-up mechanisms should be in place to monitor children if initial observation is employed (Reference 29).

One primary concern with initial observation is its effect on the clinical course of infection. Mild infections in most children will resolve spontaneously without the need for antibiotic therapy. However, children with AOM who do not improve must subsequently receive antibiotic treatment, with a potential delay of up to 3 days. Compared with those receiving immediate therapy, children with non-severe AOM who received delayed antibiotic therapy experienced more pain initially and took longer to recover from symptoms (References 30, 31). However, these symptoms resolved, regardless of antibiotic use, within 7–10 days. Although symptomatic control was achieved faster than with delayed therapy, immediate antibiotic treatment resulted in more drug-related adverse events and nasopharyngeal carriage of multidrug-resistant *S. pneumoniae* on day 12 (Reference 31). Clinic and emergency department visits, days of missed work or school, and parent satisfaction were unaffected by delayed antibiotic therapy (References 30, 31). Furthermore, delayed therapy is not associated with an increase in mastoiditis in children older than 2 years (Reference 32). In children with severe AOM admitted to the emergency department, reduction in antibiotic prescribing for AOM because of the initial observation strategy was not associated with any adverse outcomes (Reference 33).

### Pharmacologic Therapy

Antibiotic treatment should be initiated immediately in children with severe disease (i.e., bulging tympanic membrane with apparent pus, severe otalgia, or temperature of 102.2°F [39°C] or greater). In addition, a child younger than 6 months is usually at increased risk of a more serious infection and therefore should always be initiated on antibiotic therapy, even if the diagnosis is uncertain (Reference 10). Most clinical symptoms, except for middle ear effusion, resolve within 48–72 hours after antibiotic initiation. Of note, persistent middle ear effusion is not indicative of treatment failure.

## Box 2. Medication adherence and counseling tips.

### Tips to improve adherence to oral medications in children

- Use flavoring services offered by pharmacies, or mix with small amounts of juice or milk to improve palatability.
- Use oral syringes to easily extract the medication dose. Quickly push the plunger in so that the liquid squirts on the inner cheek. Blowing on the child's face can facilitate swallowing.
- Use oral suspensions for a child younger than 2 years. Chewable tablets may be tolerated by some 2-year-old children. Most children will be unable to swallow tablets or capsules until they are 8 years old.
- Acetaminophen suppositories should be considered for an uncooperative child.

### Important counseling points for parents and caregivers

- Antibiotics do NOT cure viral infections (like the cold or flu), nor do they relieve fever or pain.
- Mild cases of acute otitis media will resolve without antibiotic use.
- Observation for 48–72 hours is an acceptable alternative to antibiotic treatment in older children with mild symptoms of acute otitis media. If the child does not improve within 48–72 hours, follow up with the pediatrician.
- When an antibiotic is prescribed, provide dosing instructions and emphasize the importance of completing the full course of antibiotic to successfully treat the infection and prevent the development of antibiotic resistance. Instruct on the common adverse effects of the prescribed antibiotic (as noted in Table 1).
- Ensure that the duration of antibiotic therapy is 10 days for any child younger than 2 years.
- Relieve anxiety about a febrile child. Explain that fever is a natural body response to infection and that it will not harm the child.
- When recommending acetaminophen or ibuprofen for fever or ear pain, provide clear instructions on the following points:
  - Ensure that parents understand how much to give, expressed in both milligrams and milliliters. Infant formulations are more concentrated and thus require less volume per dose.
  - Optimize the dose for fever control. In general, ibuprofen 10 mg/kg is about equal to acetaminophen 15 mg/kg (Reference 49). Acetaminophen can be administered as often as every 4 hours (not to exceed five doses in 24 hours) and ibuprofen as often as every 6 hours.
  - Discourage methods of alternating acetaminophen and ibuprofen unless clear verbal and written instructions are provided.
- Encourage routine childhood vaccinations using the schedule recommended by the Centers for Disease Control and Prevention. Be prepared to recommend local clinics and pharmacies that provide immunizations. Identify and recommend the annual flu vaccine for all people at high risk of complications from influenza infection.

### Resources for additional information

- “Get Smart: Know When Antibiotics Work” by checking the Web site of Centers for Disease Control and Prevention ([www.cdc.gov/getsmart/](http://www.cdc.gov/getsmart/)).
- Check the official Web site of the American Academy of Pediatrics.

Antibiotic therapy is generally empiric and usually involves the use of oral agents. High-dose amoxicillin, defined as 80–90 mg/kg/day, is the first-line treatment, with a reported response rate of greater than 80% (Table 1) (Reference 10). High-dose amoxicillin achieves elevated drug concentrations in the middle ear to consequently provide activity against intermediately susceptible and many resistant *S. pneumoniae* (Reference 34). The most common adverse effects are gastrointestinal tract-related, including nausea and diarrhea. The incidence of adverse effects associated with high-dose amoxicillin is comparable to that of standard-dose amoxicillin (Reference 35). Compared with twice-daily dosing, however, three times/day-dosing of high-dose amoxicillin is associated with a significantly higher incidence of diarrhea (Reference 36).

Adding clavulanic acid to high-dose amoxicillin or changing to ceftriaxone (intramuscular injection) can be considered if the patient does not respond to high-dose amoxicillin (References 10, 37). Other candidates for these antibiotics include children with antibiotic exposure within the previous 30 days and children in whom *H. influenzae* or *M. catarrhalis* infection is suspected. The addition of clavulanic acid, or substitution with a cephalosporin, enhances activity against  $\beta$ -lactamase-producing *H. influenzae* and *M. catarrhalis*. Oral cephalosporins including cefuroxime axetil, cefdinir, and cefpodoxime are other treatment options.

The standard duration of antibiotic therapy, particularly for children who are younger than 2 years or have severe disease, is 10 days (Reference 29). However, a shorter course of 5–7 days is an option for children with mild disease, particularly those 6 years and older

**Table 1. Antibiotic Treatment Options for Upper Respiratory Tract Infections in Children<sup>a</sup>**

Infection Type	Common Causative Bacterial Pathogens	Recommended Therapy	Alternative Therapy	Common Adverse Effects
Acute otitis media	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , and <i>Moraxella catarrhalis</i>	High-dose amoxicillin 80–90 mg/kg/day divided in two or three doses <sup>b</sup>	High-dose amoxicillin 80–90 mg/kg/day with clavulanate 6.4 mg/kg/day divided in two doses <sup>b</sup>  Ceftriaxone 50 mg/kg/day intramuscularly once daily for 1–3 days <sup>c</sup>  Azithromycin 10 mg/kg/day once daily for 3 days (maximum 500 mg/day); or 15 mg/kg on day 1, followed by 5 mg/kg/day as a single dose for 4 days; or 30 mg/kg as one dose on a single day (maximum 1,500 mg) <sup>d</sup>	Diarrhea and allergic reactions (including Stevens-Johnson syndrome)  Pain at injection site, allergic reactions, diarrhea, and gallbladder sludging  Diarrhea, abdominal pain, nausea, and vomiting
Acute bacterial rhinosinusitis	<i>S. pneumoniae</i> , <i>H. influenzae</i> , and <i>M. catarrhalis</i> (less common anaerobic bacteria, <i>Streptococcus</i> spp. and <i>Staphylococcus aureus</i> )	Amoxicillin-clavulanate 45 mg/kg/day, divided in two doses <sup>b,h</sup>	Clarithromycin 15 mg/kg/day divided in two doses <sup>d,e</sup>  Clindamycin 30–40 mg/kg/day divided in three doses <sup>d,f</sup>  Levofloxacin 6 months to 5 years old: 20 mg/kg/day divided in two doses; > 5 years old: 10 mg/kg/day once daily (maximum 500 mg/day) <sup>f</sup>	Diarrhea, abdominal pain, nausea, vomiting, and drug interactions  Diarrhea and pseudomembranous colitis  Musculoskeletal disorders (arthralgia, arthritis, tendinopathy, and gait abnormality); vomiting and diarrhea
		Amoxicillin-clavulanate 90 mg/kg/day, divided in two doses <sup>b,h</sup>  Ampicillin-sulbactam 200–400 mg/kg/day intravenously divided every 6 hours  Ceftriaxone 50 mg/kg/day intravenously or intramuscularly once or twice daily <sup>i</sup>  Cefotaxime 100–200 mg/kg/day intravenously or intramuscularly divided every 6–8 hours <sup>i</sup>  Clindamycin 30–40 mg/kg/day in three divided doses plus cefixime 8 mg/kg/day in two divided doses, or cefpodoxime 10 mg/kg/day in two divided doses <sup>i</sup>  Levofloxacin 10–20 mg/kg/day every 12–24 hours <sup>d</sup> (intravenous route recommended for hospitalized patients)	Diarrhea and allergic reactions (including Stevens-Johnson syndrome)  Rash and diarrhea  Pain at injection site, allergic reactions, diarrhea, and gallbladder sludging  Rash and diarrhea  Diarrhea and pseudomembranous colitis (clindamycin); rash and diarrhea (cephalosporins)  Tendonopathy, arthritis, or arthralgia of weight-bearing joints	

Acute pharyngitis	<i>Streptococcus pyogenes</i> (or group A $\beta$ -hemolytic <i>Streptococcus</i> )	Oral penicillin V (phenoxymethyl penicillin) $\leq 27$ kg: 250 mg (400,000 units) two or three times/day for 10 days; > 27 kg: 250 mg (400,000 units) four times/day, or 500 mg (800,000 units) two times/day	Intramuscular benzathine penicillin <sup>k</sup> $\leq 27$ kg: 600,000 units as a single dose > 27 kg: 1,200,000 units as a single dose	Allergic reactions (including anaphylaxis), pain at injection site (if applicable), serum sickness-like reactions, and diarrhea
			Amoxicillin 50 mg/kg/day orally as a single dose (maximum 1,000 mg) or in two divided doses $\geq 12$ years: 775-mg extended-release tablet once daily with meals; 875 mg twice daily, or 500 mg three times/day	Diarrhea and allergic reactions (including Stevens-Johnson syndrome)
			Ampicillin 50–100 mg/kg/day in three or four divided doses	Diarrhea and allergic reactions (including Stevens-Johnson syndrome)
			Cephalexin 40 mg/kg/day in two divided doses (maximum 1,000 mg/day) <sup>l</sup>	Rash and diarrhea
			Cefadroxil 30 mg/kg once daily (maximum 1,000 mg) <sup>l</sup>	Rash and diarrhea
			Azithromycin 12 mg/kg once daily for 5 days (maximum 500 mg/day); 500 mg on day 1, followed by 250 mg/day on days 2–5 <sup>dm</sup>	Diarrhea, abdominal pain, nausea, and vomiting
			Clindamycin 20 mg/kg/day in three divided doses (maximum 900 mg/day) <sup>df</sup>	Diarrhea and pseudomembranous colitis

<sup>a</sup>All antibiotic dosing regimens are based on normal renal and hepatic functions. All antibiotics are available in oral formulations except for ceftriaxone, cefotaxime, and penicillin G benzathine.

<sup>b</sup>To minimize diarrhea, the maximal recommended daily dose of amoxicillin is 3–4 g, and twice-daily administration is preferred for high-dose amoxicillin with clavulanic acid.

<sup>c</sup>Ceftriaxone may be useful for nonadherent patients, and its duration varies from 1 to 3 days. Ceftriaxone provides sufficient antibiotic concentrations in the middle ear for activity against penicillin-nonsusceptible *S. pneumoniae*. Oral cephalosporins, including cefuroxime axetil 30 mg/kg/day, cefdinir 14 mg/kg/day, and cefpodoxime 10 mg/kg/day, can be alternatively used but may not achieve adequate concentrations.

<sup>d</sup>Safe alternatives for severe or type I hypersensitivity reactions to penicillin or cephalosporins.

<sup>e</sup>Together with reduced activity against *H. influenzae* among macrolides, resistance limits their clinical utility. Clarithromycin has many significant drug interactions.

<sup>f</sup>Although clindamycin is active against drug-resistant *S. pneumoniae*, 22 to 31% of strains are resistant (Reference 21, 71).

<sup>g</sup>Since not approved for acute otitis media, it should be reserved for persistently recurrent otitis media.

<sup>h</sup>High-dose amoxicillin with clavulanate should be reserved for children with antibiotic exposure within the past 30 to 90 days, recent hospitalization, severe symptoms, < 2 years of age, day-care attendance, or residing in regions with penicillin-nonsusceptible *S. pneumoniae*  $\geq 10\%$ .

<sup>i</sup>For children with vomiting that precludes the use of oral antibiotics. Conversion to an oral antibiotic should be instituted within 24 hours or on resolution of vomiting (whichever is earlier).

<sup>j</sup>Although viruses and other bacteria may cause acute pharyngitis, antimicrobial treatment is indicated for group A *Streptococcus* (GAS). To successfully eradicate GAS, oral antibiotics should be administered for 10 days (unless otherwise indicated).

<sup>k</sup>Indicated for those who cannot complete or tolerate a 10-day course of oral therapy, or those at increased risk of acute rheumatic fever. The formulation of benzathine penicillin G 900,000 units (562.5 mg) with procaine penicillin G 300,000 units (187.5 mg) is recommended for children weighing 27 kg or less. The efficacy of this combination for adolescents weighing more than 27 kg and adults has not been shown. The sites for intramuscular administration are the mid-lateral aspect of the thigh for infants and small children and the upper, outer quadrant of the buttock for adolescents and adults.

<sup>l</sup>Other oral cephalosporins are acceptable alternatives, including cefprozil, cefaclor, cefuroxime, cefdinir, cefpodoxime, cefixime, and cefibuten. Therapy duration is 5 days for cefpodoxime and cefdinir and 10 days for all other cephalosporins.

<sup>m</sup>Use should be based on local resistance patterns. Erythromycin or clarithromycin for 10 days is an alternative. However, erythromycin is associated with a high incidence of gastrointestinal adverse effects.

(References 10, 37). The only exceptions are ceftriaxone for 1–3 days and azithromycin for 3–5 days, depending on the severity of disease and persistence of symptoms.

The high prevalence of resistance to TMP/SMX and erythromycin by DRSP hinders the utility of these antibiotics (Reference 34). At least 80% of DRSP are resistant to TMP/SMX and 50% to erythromycin (Reference 38). In addition, TMP/SMX has limited activity against group A *Streptococcus* that can cause AOM associated with perforation of tympanic membranes. Pediazole (contains sulfisoxazole and erythromycin) may be considered in geographic regions with a low prevalence of DRSP and is a safe alternative in children with a history of hypersensitivity reactions to penicillin. Nonetheless, these agents are not recommended in children whose high-dose amoxicillin therapy has failed.

### Judicious Antibiotic Use

The use of antibiotics comes with risks, which must be carefully considered and recognized by both health care professionals and parents (Table 1). In addition to its contribution to the increasing prevalence of antimicrobial resistance, antibiotic use can lead to adverse drug reactions. In fact, antibiotics were categorized as the No. 1 cause of adverse drug reactions in hospitalized children (Reference 39). Among specific antibiotics, penicillins and cephalosporins most often contributed to the adverse events. Specifically, children with AOM treated with antibiotics have more adverse effects than those untreated (Reference 37).

Although hospitals have implemented antimicrobial stewardship programs to optimize antimicrobial use, these efforts in the outpatient and community settings can be improved (Reference 40). Not all infections require antibiotics, an important concept embraced and promoted by the Centers for Disease Control and Prevention through its Get Smart campaign. Specifically for AOM, initial observation should be considered in certain cases to increase efforts toward judicious antibiotic use. If antibiotics are prescribed, proper drug, dose, and duration should be reviewed for age appropriateness. In addition to antibiotic therapy, recommendations for over-the-counter medications to control symptoms, like ear pain and fever, may be necessary. When recommending these products, providers must give clear instructions on dosing and ensure that parents and caregivers understand that the various nonprescription drug formulations are not interchangeable (Box 2).

### Penicillin Allergy

The use of amoxicillin or cephalosporins may present a dilemma in a child with penicillin allergy. The risk

of cross-reactivity to cephalosporins is increased in children with a history of penicillin allergy and between different cephalosporins, particularly first-generation cephalosporins (References 41, 42). Based on a review of seven studies, the cross-reactivity to cephalosporins in patients with positive penicillin skin tests is 4.4%, not 10%–15% as previously suggested by retrospective studies that lacked routine skin testing (Reference 43). Furthermore, cross-sensitivity is insignificant with second- and third-generation cephalosporins in children with penicillin allergy (Reference 42). A prospective study of children reported 30% cross-reactivity to cephalosporins among those with penicillin allergy (Reference 41). These data suggest that most children with a history of mild reactions to penicillin will tolerate cephalosporins.

Although most children with mild penicillin allergy will tolerate cephalosporins, the safety of administering cephalosporins remains uncertain. Assessing the timing (including first-dose response) and nature of the penicillin allergy to determine the presence of potentially life-threatening type I, immunoglobulin E (IgE)-mediated hypersensitivity reaction is critical in making the clinical decision of whether to expose a child to a cephalosporin (Reference 44). If a child has a non-life-threatening or mild reaction to penicillin (including morbilliform rashes commonly reported with amoxicillin), then a cephalosporin (e.g., cefdinir, cefpodoxime, cefuroxime, or ceftriaxone) may be considered because serious reactions to cephalosporins are rare (References 10, 45). In contrast, if the child develops an IgE-mediated hypersensitivity reaction (i.e., urticaria or anaphylaxis) that is considered life threatening, both amoxicillin and cephalosporins should be avoided.

In evaluating an antibiotic allergy, obtaining an accurate medical history is essential to distinguish true hypersensitivity reactions from other, less severe adverse reactions (Reference 44). A non- $\beta$ -lactam antibiotic should be selected in children with IgE-mediated hypersensitivity reactions or perhaps when the nature of the reaction or history of penicillin allergy is uncertain. Treatment options include macrolides (specifically, azithromycin and clarithromycin) and clindamycin. Clarithromycin and azithromycin possess activity against *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and atypical respiratory pathogens. A recent study showed similar effectiveness, but with fewer adverse effects and improved adherence, between a single 60-mg/kg dose of azithromycin and a 10-day course of high-dose amoxicillin with clavulanate in children with AOM (Reference 46).

Although they are not  $\beta$ -lactam antibiotics, the high prevalence of resistance to Pediazole (which contains erythromycin and sulfisoxazole) and the risk of cartilage toxicity associated with fluoroquinolones (particularly levofloxacin) limit their utility for routine use in children with AOM. However, levofloxacin may play a role in children with persistent and recurrent AOM even though it is not an approved indication. Tympanocentesis should be performed first to determine the causal pathogen; subsequently, tympanostomy tube placement or therapy with levofloxacin, especially for susceptible isolates, can be considered (Reference 47).

### Adjunctive Therapy

A child with AOM may present with fever. Hence, it is important to instruct parents on the appropriate use of antipyretic medications (Box 2). A fever is defined as an elevation in body temperature exceeding 100°F by mouth (100.4°F rectally) and is mediated by an increase in the hypothalamic heat regulatory set point regulated by prostaglandins. Acetaminophen 10–15 mg/kg given every 4–6 hours can be administered orally to children of all ages and is considered the agent of choice for infants younger than 6 months. Alternatively, ibuprofen 5–10 mg/kg administered orally every 6–8 hours can be used for children older than 6 months.

According to a meta-analysis, ibuprofen may be more effective than acetaminophen as an antipyretic, particularly in sustaining this effect (Reference 48). However, this speculation was based on studies with small sample sizes and assessing the effect of a single dose. Although it can be administered in infants younger than 6 months, acetaminophen does not have an anti-inflammatory effect, which is present in ibuprofen.

Several methods exist for alternating antipyretics (e.g., interchanging acetaminophen and ibuprofen every 2–3 hours, or acetaminophen every 4 hours within ibuprofen every 6 hours). These methods contain inherent flaws, including surpassing the five-dose daily allowance of acetaminophen, inappropriately shortening the frequency of ibuprofen at every 4 hours, and administering both medications at two same time points within a 24-hour period (Reference 49). Together with the lack of evidence for efficacy, the primary concern for alternating antipyretics is potential dosing errors. Dosing errors can lead to intoxication or hepatotoxicity from acetaminophen or nonoliguric renal dysfunction from ibuprofen. Providing a thorough education to parents and caregivers on the appropriate use of antipyretics is imperative for preventing dosing errors and is a critical role that health care professionals can assume (Box 2).

A child with AOM usually presents with ear pain. Assessment and treatment of pain should be provided for all patients with AOM (Reference 10). For mild to moderate pain, acetaminophen and ibuprofen

are equally effective. Codeine may be required for the management of moderate to severe pain. Otic products, including aqueous lidocaine (lignocaine) and herbal extract Otikon, require additional studies to ascertain their effectiveness for pain relief in children. In the presence of heavy middle ear effusion, draining this fluid may relieve the pain caused by the fluid pressure.

Antihistamines and decongestants for symptomatic relief of AOM have not been well studied. In fact, their use has been associated with increased medication adverse effects (Reference 50). Furthermore, over-the-counter cough and cold medications should not be given to infants and children younger than 2 years because of the risk of life-threatening adverse effects (Reference 51).

### PREVENTION THROUGH IMMUNIZATION

The two vaccines that have shown effectiveness in preventing AOM are the influenza and pneumococcal vaccines. The influenza vaccine may reduce the occurrence of AOM by 50%, particularly in young children attending day care (Reference 52). The injectable influenza formulations are indicated for infants at least 6 months old, and the intranasal spray is recommended for children older than 2 years. For any child aged 6 months to 9 years who receives the vaccine for the first time, two doses are recommended to enhance immunity (Reference 53).

The 7-valent pneumococcal conjugate vaccine, introduced in the United States in 2000, provides only a modest decrease in the occurrence of AOM, compared with the flu vaccine (Reference 54). However, it may reduce the need for tympanostomy tube placement and nasal carriage of penicillin-nonsusceptible strains (in conjunction with restriction in antibiotic use) in children with AOM (References 54, 55). One study suggested that standard-dose, rather than high-dose, amoxicillin is effective for children with mild cases of AOM who received at least three doses of the pneumococcal conjugate vaccine (Reference 56). Replacing the 7-valent vaccine, the 13-valent pneumococcal conjugate is now recommended for routine immunization in infants. Its effects on the incidence and epidemiology of AOM will remain uncertain until its use becomes widespread.

### PREVENTION OF RECURRENCE

Recurrence, defined as three or more documented episodes within 6 months or four or more episodes within 12 months, can occur in some children, particularly those who first experienced AOM younger than 6 months of age and those with immune deficiencies (e.g., IgG deficiency) or craniofacial abnormalities (e.g., cleft palates) (Reference 57). In addition to first

providing parent education and immunization, antibiotic prophylaxis and surgery—including myringotomy and placement of tympanostomy tubes—are important interventions in children with recurrent AOM.

Antibiotic prophylaxis has been shown to reduce the occurrence of AOM by 20%, where five children need to be treated to prevent one child from experiencing AOM (Reference 58). With this modest benefit, antibiotic prophylaxis should be considered only in selected children with well-documented recurrences of AOM. Children most likely to benefit from prophylactic therapy include those younger than 2 years, day care attendants who cannot modify this risk factor, infants who experienced their first episode of AOM before 6 months of age, and those with developmental or language delays.

When indicated, prophylactic therapy should be initiated in the fall or winter and should continue consistently through the winter season for a maximum of 6 months (Reference 59). Amoxicillin 40 mg/kg once daily is the first-line agent for prophylaxis. Alternatively, sulfisoxazole 50 mg/kg once daily can be used, particularly in a child with a penicillin allergy. In children with breakthrough AOM while receiving antibiotic prophylaxis, a different agent is necessary, like high-dose amoxicillin/clavulanate or ceftriaxone.

Although antibiotic prophylaxis reduces episodes of AOM, this protection wanes once prophylaxis is discontinued (References 58, 60). In addition, prolonged antibiotic use may select for infections caused by resistant nasopharyngeal bacteria (Reference 61). Because of these concerns for waning effectiveness and selection for resistant bacteria, surgical intervention should be considered in children with recurrent AOM.

Myringotomy with tympanostomy tube placement helps drain the copious middle ear fluid that is evident in patients with chronic otitis media. Although it is the treatment of choice for chronic otitis media, tube placement decreases infection rates only modestly in patients with recurrent AOM, especially in the first 6 months after surgery (References 62, 63).

## SUMMARY

The treatment modality for AOM does not necessitate the use of antibiotics in all cases. In fact, because AOM is self-limiting, initial observation is warranted for mild cases, and antibiotic therapy should be reserved for those with severe disease or young infants. Although antibiotic therapy improves patient response within 3 days, adverse drug effects may occur. Thus, more studies are needed to ascertain the characteristics of children who will most benefit from antibiotic therapy. Parent or caregiver education on the proper use

of antibiotics, if warranted, and other medications for symptomatic relief, including their adverse effects, is critical to ensure optimal management of AOM.

## RHINOSINUSITIS

Sinusitis, an inflammatory process that involves the mucous membranes of both the nose and paranasal sinuses, is more properly termed *rhinosinusitis*. Rhinosinusitis is classified as acute (sudden onset of symptoms with a duration of less than 30 days), subacute (duration of 30 days or more and less than 90 days), or chronic (duration greater than 90 days). Viruses (including the human rhinovirus, influenza A and B viruses, parainfluenza virus, respiratory syncytial virus, adenovirus, and enterovirus) are responsible for most acute cases of rhinosinusitis (also called the “common cold”); most cases are self-limiting and resolve without treatment within 5–10 days after symptom onset.

Acute bacterial rhinosinusitis (ABRS) is a secondary infection that occurs in 8% of children with viral URTI and peaks in the second year of life (Reference 64). In addition to inhibiting macrophage and lymphocyte function, viruses induce inflammatory changes to block the sinus ostia, impair mucous drainage, and cause poor aeration, leading to increased susceptibility to secondary bacterial infection. Day care attendance and allergic rhinitis may also predispose children to ABRS (References 65–67). Because ABRS requires appropriate management to facilitate recovery and prevent orbital and intracranial complications, the following sections will focus strictly on the etiology and management of ABRS, excluding viral rhinosinusitis.

By early childhood, most children are colonized by at least one of three respiratory tract pathogens, including *S. pneumoniae*, *H. influenzae* (nontypeable), and *M. catarrhalis*. These respiratory tract bacteria are the most common causes of ABRS (References 68–70). The prevalence of *H. influenzae* increased and *S. pneumoniae* decreased after routine pneumococcal vaccination in children in the United States (Reference 71). As such, the production of  $\beta$ -lactamases that are common in *H. influenzae* limits the clinical utility of amoxicillin alone compared with amoxicillin plus clavulanate. Similar to AOM, anaerobic bacteria, *Staphylococcus aureus*, and *S. pyogenes* can also cause ABRS, although less commonly. The clinical significance of atypical pathogens, including *Chlamydia pneumoniae* and *Mycoplasma pneumoniae*, in the pathogenesis of ABRS remains unclear.

Inflammation of the paranasal sinuses exceeding 90 days is considered chronic rhinosinusitis and should be distinguished from ABRS. In contrast to ABRS, the pathogenesis of chronic rhinosinusitis is believed to be multifactorial, with potential causes including microorganisms (bacteria, fungi), inflammatory agents (e.g.,

allergens, pollutants, smoke), asthma, cystic fibrosis, gastroesophageal reflux, immunodeficiency, and nasal polyposis (References 66, 68, 70). These factors may appear concurrently to cause persistent inflammation of the nose and paranasal sinuses.

## CLINICAL PRESENTATION AND DIAGNOSIS

Evidence of respiratory symptoms, including nasal discharge and congestion, with or without daytime cough are the clinical features of ABRS. The nasal discharge may be watery, serous, or purulent. Of importance, purulent nasal secretions and a change in the color of nasal discharge are not specific indicators of ABRS. Purulent discharge can also occur in patients with viral rhinosinusitis. When cough is present, it may be wet or dry, occur during the day, and possibly worsen at night. Fever, sore throat, headache, and malodorous breath may occur together with these cardinal respiratory symptoms (Reference 72). The fever usually subsides within 48 hours when the nasal symptoms become more evident.

A diagnostic challenge of ABRS is that no single sign or symptom clinically distinguishes it from viral rhinosinusitis. Although the clinical presentations of ABRS and viral URTIs are similar, the distinctive characteristics of ABRS are the persistence, severity, and progression (or worsening) of symptoms (Reference 73). Respiratory symptoms in children with ABRS persist without improvement beyond 10 days, unlike viral URTIs, in which symptoms usually abate within 5–10 days (References 70, 71). In addition, a slight improvement that precedes the considerable worsening of symptoms on the sixth or seventh day of illness, known as “double sickening,” suggests ABRS (Reference 73). Another indicator of ABRS is the presence of a high fever (defined as a temperature of 102.2°F [39°C] or higher) with purulent nasal discharge, or facial pain for 3 or more consecutive days (Reference 71).

Diagnosis of ABRS is generally based on clinical presentation noted as persistent, worsening, or severe symptoms that extend beyond 10 days. Although no single sign or symptom is highly sensitive or specific, the presumptive diagnosis of ABRS based on the overall constellation of clinical findings is generally sufficient for treatment. Viral or allergic etiologies that may present similarly to ABRS should be excluded. Sinus aspiration with positive microbiologic culture results definitively confirms a diagnosis of ABRS. However, because this procedure is invasive and requires a skilled specialist, it is not routinely performed.

The use of imaging studies (radiography, computerized tomography [CT], or magnetic resonance imaging) is unnecessary to confirm the diagnosis because abnormal findings indicate the presence of inflammation without providing the cause (i.e., virus, bacteria,

or allergy). Radiologic examination is recommended only in children with suspected orbital or intracranial complications associated with ABRS, or in those with persistent or recurrent infection who are unresponsive to therapy (References 70, 71). A sinus CT scan is the imaging study of choice because it is more sensitive and specific than plain radiographs (Reference 71).

In children with inadequate treatment, complications of ABRS may occur and can range in severity from mild, such as periorbital cellulitis, to serious, including orbital cellulitis, osteomyelitis of the frontal bone, meningitis, and epidural or brain abscess (References 69, 70, 74). Immediate aggressive medical therapy, which may include surgery, is necessary, especially if abnormal vision, altered mental status, and periorbital edema are presenting symptoms (Reference 75).

## TREATMENT

Symptomatic relief, prevention of complications, and minimization of adverse drug effects are the primary goals of antibiotic therapy in children with ABRS. Although the effectiveness of antibiotic therapy in preventing complications remains uncertain, it appears to improve clinical cure rates (References 71, 76).

### Pharmacologic Therapy

Antibiotic treatment of ABRS should target the common etiologic culprits, particularly *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*, and account for resistance patterns among these pathogens (as described in the previous section on AOM). Overuse of antibiotics has contributed to the emergence and increasing prevalence of resistance in the United States. To address resistance, the most recent guidelines for the treatment of acute rhinosinusitis focus on the judicious use of antibiotics (Reference 70).

Because of its safety, palatability, and low cost, amoxicillin with clavulanate is recommended by the Infectious Diseases Society of America as first-line therapy in children (Table 1). Dosing of the amoxicillin component should depend on the potential for drug-resistant pneumococci (e.g., recent antibiotic exposure, day care attendance) and severity of illness. High-dose amoxicillin with clavulanate is recommended for children with severe symptoms (including a temperature of 102.2°F [39°C] or greater with concurrent purulent nasal discharge for at least 3–4 consecutive days), with recent hospitalization or antibiotic exposure, who are younger than 2 years, who attend day care, or who reside in regions with penicillin-nonsusceptible *S. pneumoniae* at 10% or greater (References 70, 71). When high-dose amoxicillin is used with clavulanate, the recommended dose of clavulanate is 6.4 mg/kg/day to limit the occurrence of diarrhea (Reference 76).

When *H. influenzae* or *M. catarrhalis* is highly suspected, the use of amoxicillin alone is ineffective because most isolates produce  $\beta$ -lactamases. Treatment options consist of amoxicillin with clavulanate or cephalosporins. Third-generation cephalosporins (specifically, cefixime and cefpodoxime), in addition to clindamycin, are alternatives to amoxicillin with clavulanate. Otherwise, a single dose of ceftriaxone can be administered either intravenously or intramuscularly when oral therapy is not possible. Although treatment most often occurs in the outpatient setting, seriously ill children with ABRS should be hospitalized for intravenous antibiotics, including ampicillin-sulbactam, cefotaxime, ceftriaxone, or levofloxacin.

Concern for musculoskeletal adverse effects associated with levofloxacin limits its use to children with immediate type I hypersensitivity to  $\beta$ -lactam antibiotics. Except for those with a history of true type I hypersensitivity to  $\beta$ -lactams, children with other types of reactions to a specific  $\beta$ -lactam antibiotic may tolerate another  $\beta$ -lactam. Macrolides, doxycycline, and TMP/SMX are not routinely used in children because of concern about treatment failures, based on susceptibility patterns. Doxycycline is also contraindicated in children 8 years and younger because of the risk of permanent teeth discoloration.

Telithromycin, the first agent in a class of antibiotics called the ketolides, was developed to address macrolide-resistant *S. pneumoniae* (Reference 59). In the presence of the *ermB* gene (and, for telithromycin, the *ermB* and *mefA* genes), ketolides remain active against macrolide-resistant pathogens (Reference 60). Although similar to the macrolides, telithromycin binds more tightly to the 50S ribosomal subunit to enhance activity against respiratory pathogens (Reference 61). Although telithromycin is approved by the U.S. Food and Drug Administration for the treatment of ABRS, it is not indicated for pediatric use. The most common adverse effects reported have been gastrointestinal tract related, including nausea and diarrhea. Furthermore, telithromycin has been associated with life-threatening and fatal hepatic failure. Telithromycin is also contraindicated in patients with myasthenia gravis because of reports of fatal respiratory failure.

Patients generally respond to appropriate treatment within 48–72 hours (Reference 76). The recommended therapy duration for ABRS is 10–14 days, or at least 7 days after clinical improvement begins (References 70, 71). Antibiotic therapy in children with ABRS who are unresponsive 72 hours after treatment initiation should be changed to high-dose amoxicillin with clavulanate or other second-line alternatives, including intravenous formulations, if deemed necessary. If orbital or intracranial complications are suspected, or the use of intravenous antibiotics is contemplated, the diagnosis

of ABRS should be confirmed with sinus imaging. In addition, sinus aspiration with subsequent cultures can help identify the causative pathogen and thereby tailor therapy appropriately under these circumstances.

### Adjunctive Therapy

Symptomatic relief is one of the goals in the treatment of ABRS. Intranasal budesonide provides a modest reduction in nasal discharge and cough (Reference 77). Similarly, the combination of an antihistamine and decongestant offers minimal symptomatic relief (Reference 78). As such, these adjunctive therapies are not recommended for routine use in children (References 70, 71, 79). However, saline nasal drops, spray, or irrigation helps dissolve secretions and prevent crust formation (Reference 80). Because it possesses minimal risk, saline topical therapy may be used in children for symptomatic relief of nasal symptoms.

### SUMMARY

Appropriate management of ABRS requires an understanding of its distinctive pathogenesis and clinical features. In contrast to the common cold and chronic rhinosinusitis, ABRS does not originate from viral or allergic etiologies. In addition, the symptoms of ABRS persist without improvement beyond 10 days and usually completely resolve by 30 days. Even though it is a secondary infection caused by respiratory tract bacterial pathogens, ABRS treatment with antibiotics should be judicious to limit the development of resistance.

### PHARYNGITIS

Pharyngitis, characterized by inflammation of the mucous membranes and structures of the throat, encompasses tonsillitis, tonsillopharyngitis, and nasopharyngitis. It occurs frequently in children and therefore accounts for many annual clinic visits (Reference 81). Although sore throat accompanies pharyngitis, objective findings of erythema, exudates, or ulceration are required for diagnosis. Many etiologic agents or factors have been implicated for pharyngitis, including infectious vehicles, aphthous stomatitis, Behçet syndrome, and Kawasaki disease (Reference 82). Nonetheless, viruses, followed by bacteria, are the most common infectious causes of pharyngitis in children and adolescents. Viral pharyngitis predominates in the summer and fall seasons, whereas bacterial pharyngitis occurs in the late autumn, winter, and spring in temperate climates (Reference 83).

Certain viruses, including the Epstein-Barr virus (EBV), cytomegalovirus (CMV), adenoviruses, herpes simplex virus (HSV), influenza viruses, and enterovirus directly insult the pharynx to elicit inflammation

(Reference 84). Other viruses, including rhinoviruses, coronaviruses, respiratory syncytial virus, and parainfluenza viruses, cause nasopharyngitis. In these cases, the sore throat is not the result of direct pharyngeal insult, but rather, the result of irritation related to mouth breathing or cough caused by rhinorrhea.

Among bacterial pathogens, *S. pyogenes* (group A  $\beta$ -hemolytic *Streptococcus* [GAS]) accounts for up to 37% of all pharyngitis cases in children and adolescents (References 85, 86). As such, it is the most common bacterial cause of pharyngitis, particularly in children older than 5 years (References 86, 87). Penicillin resistance has not been a significant issue for GAS; however, erythromycin resistance has been reported in school-aged children (References 88, 89). Other bacterial culprits of pharyngitis are non-group A *Streptococcus*, *M. pneumoniae*, *Neisseria gonorrhoeae* (particularly in adolescents who engage in oral-genital sex), *Arcanobacterium haemolyticum*, and *Corynebacterium diphtheriae* (Reference 82).

The following sections will accentuate the clinical presentation and therapeutic management of bacterial—particularly streptococcal—pharyngitis. However, distinctive clinical features of viral and bacterial pharyngitis will also be presented because differentiation between the two etiologies is critical to justify the initiation of antibiotic therapy.

## CLINICAL PRESENTATION AND DIAGNOSIS

Evidence of erythema, edema, or exudates of the pharynx on physical examination is mandatory for diagnosing acute pharyngitis caused by either viruses or bacteria. Pharyngitis caused by GAS often occurs in school-aged children and adolescents. Rapid onset of symptoms including sore throat, fever, tonsillar exudates, cervical adenopathy, headache, abdominal pain, nausea, and/or vomiting are clinical characteristics of GAS pharyngitis (References 83, 90, 91). An inflamed uvula may also be present. The inception of symptoms is abrupt, and they usually resolve without antibiotic treatment within 3–5 days. In fact, sore throat persisting for greater than 7 days suggests other causes of pharyngitis. Nonetheless, antibiotic treatment is indicated for clinical cases of GAS pharyngitis to minimize progression to serious complications.

Although uncommon, GAS pharyngitis may occur in infants and children younger than 3 years, particularly as outbreaks in child care settings. The clinical presentation in this age group is generally nonspecific and subtle and includes fever, irritability, and anorexia. However, the finding of close contacts (e.g., siblings and day care attendants) with recent GAS infection strongly suggests GAS pharyngitis.

The common features of viral pharyngitis are concurrent conjunctivitis, cough, coryza, diarrhea, anterior stomatitis, ulcerative lesions, and rash (References 57, 81, 83, 92). Certain viruses exhibit unique clinical attributes. For example, infectious mononucleosis caused by EBV and CMV that commonly occurs in adolescents manifests as prolonged exudative pharyngitis, cervical lymphadenopathy, hepatitis, and rash that develops when treated with ampicillin or amoxicillin. Pharyngoconjunctival fever is highly indicative of adenovirus, and herpangina with small vesicles appearing in the posterior pharynx is indicative of coxsackie A viruses (a type of enterovirus). Pharyngitis caused by HSV generally presents with ulcerative lesions of the mouth and lips in young children and adolescents. Finally, the seasonality of infection, in addition to fever, cough, and myalgias, is typical of influenza infection.

Although clinical signs and symptoms may provide evidence for GAS etiology, diagnosis should be validated by throat culture and/or rapid antigen detection test (RADT), ideally before therapy is begun (References 93, 94). In the absence of indicators for viral URTI, candidates likely to have GAS pharyngitis consist of those in recent contact with an individual infected by GAS (including a history of acute rheumatic fever or poststreptococcal glomerulonephritis) or those residing in a region with a high prevalence of GAS (Reference 95). In addition, age ranging from 5 to 15 years, winter months, enlarged anterior cervical lymph nodes (greater than 1 cm), and temperature between 101°F and 103°F are predictive factors for positive GAS throat cultures and scarlatiniform rash (References 85, 92). Laboratory confirmation should be performed in children who present with acute onset of sore throat with pharyngeal exudates or pain on swallowing and who possess or exhibit these predisposing factors.

The throat culture for diagnostic workup is the gold standard and is more cost-effective than RADT (References 90, 96). Neither test can differentiate between infection and carrier state; however, throat cultures are highly sensitive and specific in identifying GAS as well as other bacteria. The throat culture should thus be used in primary testing to confirm the presence of GAS. Even if RADT is employed initially, negative RADT, with its limited sensitivity, should always be confirmed with throat cultures in children and adolescents (References 81, 92). Situations in which RADT may be beneficial are when throat culture results are unavailable for more than 48 hours (i.e., RADT results are available in minutes) and when testing is performed in children who are highly likely to have positive throat cultures. Because RADT is very specific (95%–98%), a positive test is adequate for antibiotic initiation. Serologic testing for antistreptococcal antibody titers can validate true streptococcal infection (References 81,

95). However, positive titers occur 2–3 weeks after infection; hence, they are not valuable during the diagnostic process for acute GAS pharyngitis.

Complications caused by GAS pharyngitis consist of acute rheumatic fever, acute glomerulonephritis, streptococcal toxic shock syndrome, and scarlet fever. Some of these sequelae are serious and potentially life threatening (Reference 83). Other complications, particularly those of a purulent nature, include otitis media, sinusitis, peritonsillar and retropharyngeal abscesses, necrotizing fasciitis, and bacteremia.

## TREATMENT

Antibiotic treatment is indicated for symptomatic GAS pharyngitis because it can progress to serious complications. In particular, antibiotic therapy eradicates certain GAS strains that can elicit an immune response, subsequently leading to acute rheumatic fever (Reference 90). Viral pharyngitis, in contrast, can self-resolve with or without adjunctive remedies for symptomatic relief. Laboratory confirmation of GAS as the etiologic agent during diagnostic workup is essential to appropriately managing the infected patient as well as ensuring judicious antimicrobial use (i.e., avoiding antibiotics in patients with viral infections).

Preventing the subsequent development of acute rheumatic fever is the primary goal for antibiotic treatment. Symptomatic recovery, eradication of GAS from the pharynx, prevention of suppurative and nonsuppurative complications, and prevention of transmission are other therapeutic goals. Symptom resolution generally occurs within 3–4 days but can occur as soon as 2 days with appropriate antibiotic therapy. To expedite clinical recovery, antibiotics should be initiated promptly within the first 2 days of infection, if possible (Reference 97). However, prevention of rheumatic fever requires antibiotic initiation within 9 days after illness onset (Reference 98). Eradication of GAS from the upper respiratory tract is an indicator of successful prevention of rheumatic fever. Prevention of glomerulonephritis through antibiotic use remains unclear (Reference 97). Although the risk of transmitting GAS pharyngitis peaks during acute infection, communicability decreases markedly after 24 hours of appropriate antibiotic therapy (References 83, 99).

### Pharmacologic Therapy

Penicillin, available in oral and injectable formulations, is the treatment of choice for GAS pharyngitis because it is effective, safe, and relatively inexpensive (Table 1) (References 81, 83, 90). Injectable benzathine penicillin G is beneficial for children at enhanced risk of rheumatic fever, including those who live in crowded conditions or have a history of rheumatic heart disease.

In addition, benzathine penicillin G is a prudent choice for children who are nonadherent to oral penicillin, which is a major contributing factor to treatment failure. Because one dose provides bactericidal levels for about 2 weeks, benzathine penicillin G is administered as a single intramuscular dose for the treatment of GAS pharyngitis (Reference 100). Benzathine penicillin G should be warmed to room temperature before intramuscular injection to minimize pain. The combination product containing benzathine penicillin G and procaine penicillin G can be considered to minimize discomfort (Reference 83).

Predominantly for young children, amoxicillin is a reasonable oral alternative to penicillin because of its enhanced palatability and activity against GAS. Other oral antibiotics are reserved for patients with penicillin allergies (Table 1). With their enhanced microbiologic and clinical cure rates in children, cephalosporins are excellent substitutes for those with mild penicillin allergies (References 101–103). However, first-generation cephalosporins are preferred because of their cost-effectiveness and because of concerns about antibiotic resistance with second- and third-generation cephalosporins (Reference 101).

Cephalosporins should be avoided in children with life-threatening immediate or type I hypersensitivity to  $\beta$ -lactams. Oral clindamycin and macrolides, including azithromycin, are appropriate options in these patients, but their selection for use should be based on local susceptibility patterns (Table 1). Because of their reported high resistance rates and failure to eradicate GAS, sulfonamides and tetracyclines should not be used for treating pharyngitis (Reference 83).

Empiric antibiotic initiation while waiting for confirmatory laboratory results remains controversial. The decision to initiate antibiotics empirically should be based on patient circumstances, although prevention of rheumatic fever allows antibiotic initiation as late as the ninth day of illness, when laboratory results should be available (References 94, 98). Antibiotics should be discontinued in the absence of positive throat cultures or RADT, except in patients with acute rheumatic fever who may initially have negative throat cultures. The duration of oral penicillin or amoxicillin therapy to achieve pharyngeal GAS eradication and thereby prevent acute rheumatic fever is 10 full days, even in the presence of clinical resolution. Shorter courses of oral therapy, with efficacy similar to a 10-day course of penicillin, are available for cefpodoxime, cefdinir, cefixime, cefadroxil, and azithromycin.

A posttreatment throat culture to confirm cure is recommended for patients and their domestic contacts, even if asymptomatic, who developed pharyngitis during an outbreak of acute rheumatic fever or poststreptococcal glomerulonephritis; have a history or are at high

risk of rheumatic fever; or have several family members in whom GAS infection has occurred (References 83, 104). More importantly, under these circumstances, asymptomatic household contacts with positive laboratory results should be treated with a standard course of antibiotic therapy.

Complications, including acute rheumatic fever, are unlikely to occur from pharyngitis caused by bacteria other than GAS; therefore, antimicrobial therapy is unnecessary in many of these situations, except for rare cases of acute pharyngitis caused by *C. diphtheria*, *N. gonorrhoeae*, and *A. haemolyticum*. In addition, antibiotics (usually for 5 days) may improve clinical response to non-group A streptococcal pharyngitis; hence, antibiotics may be considered in this situation (Reference 90). Pharmacologic and nonpharmacologic therapies for other causes of acute pharyngitis may be warranted, including activity restriction for EBV mononucleosis to prevent splenic rupture, acyclovir for HSV, and other antiviral agents for influenza.

### Recurrent Infection and Pharyngeal Carriage

Recurrence of acute pharyngitis may occur in some children, particularly in those who are nonadherent to prescribed antibiotics, those who are streptococcal pharyngeal carriers with concurrent viral infection, those acquiring a new infection from GAS-infected close contacts, or those with a history of rheumatic fever. Streptococcal carriage occurs in 20% of asymptomatic school-aged children and may persist for months in the pharynx. Carriers can be identified by positive GAS laboratory tests between episodes of acute pharyngitis when carriers are asymptomatic or by serologic response to GAS extracellular antistreptolysin O antigen (even though titers are generally low) (Reference 83). Transmission of GAS to close contacts and development of suppurative complications are low in GAS carriers. However, eradication of GAS presents a therapeutic challenge (References 105, 106). Nonetheless, antibiotic therapy is indicated for GAS pharyngeal carriers only under special circumstances, including an outbreak of acute rheumatic fever, a case of poststreptococcal glomerulonephritis, or a family history of acute rheumatic fever (Reference 83).

A repeated course of antibiotics, using any of the therapeutic options other than the one prescribed initially, is indicated for those with a second incident of laboratory-confirmed pharyngitis. Intramuscular benzathine penicillin G is a practical selection for those with medication adherence issues. In addition, clindamycin and amoxicillin/clavulanate are effective for recurrent GAS pharyngitis, given their high eradication and clinical cure rates (Reference 107). These are reasonable options for patients with several recurrent episodes, which are likely caused by non-streptococci (i.e., viral) in GAS

pharyngeal carriers. A combination of rifampin for the last 4 days of treatment with penicillin is an alternative for chronic streptococcal carriage (References 57, 83, 92). Tonsillectomy is not recommended if the goal of therapy is solely reduction in the episodes of GAS pharyngitis (Reference 92).

### Adjunctive Therapy

Nonprescription remedies for sore throat, including lozenges and mouthwashes, provide few benefits (Reference 83). Similarly, antihistamines and decongestants offer minimal symptomatic relief. With their potential risks of adverse drug effects, these adjunctive therapies are not recommended for routine use in children and adolescents with URTIs. Acetaminophen or ibuprofen can be advantageous for its analgesic and antipyretic effects and thus can be considered an adjunct to antibiotic therapy (Reference 92).

### Prevention

Secondary prevention of recurrent rheumatic fever using prophylactic antibiotics is recommended for individuals with a documented history of acute rheumatic fever or rheumatic heart disease (Reference 83). Penicillin, including penicillin G benzathine administered every 3–4 weeks, is recommended for secondary prophylaxis. Otherwise, sulfadiazine, sulfisoxazole, or macrolides can be substituted for patients with anaphylactic reactions to penicillin. Leukopenia associated with sulfonamides may occur after 2 weeks of prophylaxis and should be monitored.

Chemoprophylaxis should be initiated at the time of diagnosis and continued indefinitely for children with rheumatic heart disease. For individuals with rheumatic fever, antibiotic prophylaxis should be continued for at least 5 years, or until these individuals are 21 years old (whichever is longer). Although not well studied under controlled environments, tonsillectomy may be considered for patients with six or more GAS infections per year—or five or more episodes each year in 2 consecutive years (Reference 108).

### CONCLUSIONS

Acute pharyngitis can be caused by viruses or bacteria. Discerning the clinical manifestations for each form of acute pharyngitis is imperative in identifying pediatric patients with GAS pharyngitis, an infection that can progress to serious complications including acute rheumatic fever. Patients with GAS pharyngitis are usually between 5 and 15 years of age; and acutely present with exudative sore throat, fever, and cervical lymphadenitis. Diagnosis should be confirmed with laboratory testing before initiating antibiotic therapy to ensure the appropriate use of these therapies.

# CHAPTER 37

## LOWER RESPIRATORY TRACT INFECTIONS

Kristin C. Klein, Pharm.D., FPPAG

### LEARNING OBJECTIVES

1. List the goals of therapy for the treatment of bronchiolitis, pertussis, acute bronchitis, influenza, and community-acquired pneumonia.
2. Describe the role of palivizumab in the prevention of bronchiolitis.
3. Describe when postexposure prophylaxis would be beneficial for a child exposed to pertussis.
4. Describe situations in which the use of antivirals might be beneficial for the treatment of influenza in pediatric patients.
5. Formulate an appropriate antibiotic regimen for a pediatric patient with pertussis, community-acquired pneumonia, lung abscess, empyema, or necrotizing pneumonia on the basis of age, infecting organism, and severity of illness.

### ABBREVIATIONS IN THIS CHAPTER

AAP	American Academy of Pediatrics
CA-MRSA	Community-associated methicillin-resistant <i>Staphylococcus aureus</i>
CAP	Community-acquired pneumonia
CDC	Centers for Disease Control and Prevention
CYP	Cytochrome P450
LRTI	Lower respiratory tract infection
MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
OTC	Over-the-counter
PCR	Polymerase chain reaction
PICU	Pediatric intensive care unit
PRSP	Penicillin-resistant <i>Streptococcus pneumoniae</i>
RSV	Respiratory syncytial virus
WHO	World Health Organization

### INTRODUCTION

Lower respiratory tract infections (LRTIs) are a significant cause of morbidity and mortality in pediatric patients. Between 2006 and 2008, 25% of all hospitalizations in American children younger than 5 years were caused by an LRTI (Reference 1). This chapter will discuss the management of LRTIs commonly observed in pediatric patients.

### BRONCHIOLITIS

Bronchiolitis is the most common LRTI in infants younger than 12 months and is usually the result of a viral infection (Reference 2). Bronchiolitis is characterized by inflammation of the bronchioles and is often associated with wheezing (Reference 3). In addition to inflammation, bronchiolitis is associated with airway edema, epithelial lining necrosis, mucous production, and bronchospasm (Reference 4). Infection occurs after exposure to infected respiratory droplets. The incubation period is generally 2–8 days, but it may last up to 4 weeks in young infants (Reference 5).

### Epidemiology

In the United States, bronchiolitis usually occurs during winter months (November through April). Many viruses have been implicated as causing bronchiolitis, but respiratory syncytial virus (RSV) has been most closely associated and is the causative organism in 80% to 100% of cases occurring during the winter months (References 4, 5).

It is estimated that more than 2 million children younger than 5 years require medical intervention each year in the United States because of bronchiolitis from RSV and that 3% of children are hospitalized for bronchiolitis during the first year of life (References 4, 6). Bronchiolitis is a significant cause of hospitalization, with an estimated annual cost to the health care system of \$500 million (References 7, 8). By 2 years of age, almost 100% of children will contract RSV (Reference 9). Infection with RSV does not confer lifelong immunity. Reinfection with RSV can occur throughout a person's lifetime (Reference 3). An estimated 200–500 children die of RSV bronchiolitis annually in the United States, and about 80% of these deaths occur in infants younger than 12 months (Reference 10). In one study, an overall

mortality rate of 0.9% caused by RSV infection was reported, but the mortality rate for infants admitted to the pediatric intensive care unit (PICU) with RSV was significantly higher (4.4%) (Reference 11). All the infants who died had underlying medical conditions, such as chronic lung disease, cardiac abnormalities, chromosomal abnormalities, or immunodeficiency. None of the deaths occurred in previously healthy children.

Children who develop RSV bronchiolitis are also at higher risk of recurrent wheezing episodes throughout childhood and adolescence (References 12, 13). The link between wheezing and RSV bronchiolitis is not fully understood. It is theorized that children who are predisposed to developing asthma are more likely to have severe RSV disease. Alternatively, severe RSV infections may cause lung damage, making a child more susceptible to developing asthma later in life. In one study, children who developed RSV bronchiolitis before 1 year of age were followed until 18 years of age to determine whether recurrent wheezing or asthma persisted into early adulthood (Reference 12). Recurrent wheezing or asthma occurred in 39% of the RSV-infected group compared with 9% of the control group at 18 years of age, showing that this effect persists at least through late adolescence (Reference 12).

### Etiology

In addition to RSV, viruses associated with bronchiolitis include rhinovirus, human metapneumovirus, human bocavirus, influenza A and B, adenovirus, and parainfluenza viruses (References 14, 15). Children at highest risk of developing severe RSV bronchiolitis include those with prematurity (especially younger than 35 weeks' gestation), chronic lung disease, bronchopulmonary dysplasia, or congenital heart disease (References 16, 17). Additional risk factors associated with contracting RSV include birth within 6 months of the RSV season, product of multiple births, attendance at day care, school-aged siblings, exposure to cigarette smoke, neuromuscular disease, and low socioeconomic status (References 5, 17).

### Clinical Presentation

For most children, bronchiolitis initially presents with cold-like symptoms, such as low-grade fever, rhinorrhea, and cough (References 3, 17). Tachypnea, wheezing, retractions, and nasal flaring may also be present later in the disease course (References 3, 17). Bronchiolitis is generally a self-limited condition. Most children with bronchiolitis experience complete resolution of their symptoms within 8–15 days without needing medical intervention (Reference 17). Those who experience more severe disease might present with the additional symptoms of hypoxia, cyanosis, apnea, and

respiratory distress (References 3, 17). Infants with more severe disease will likely require hospitalization, may require mechanical ventilation, and, in extreme cases, may require extracorporeal membrane oxygenation until the lung injury has improved.

### Diagnosis

The American Academy of Pediatrics (AAP) recommends diagnosing bronchiolitis based on clinical presentation, a thorough history and physical examination, and investigation of known risk factors in a child presenting with probable bronchiolitis (Reference 3). Diagnosis of RSV bronchiolitis should also consider the time of year and the respiratory viruses circulating in the community. For example, RSV likely would not be considered the cause of a child's presenting with bronchiolitis during the summer months unless the virus was circulating through the local community. Infants presenting with probable bronchiolitis should be evaluated for risk factors for severe disease (e.g., history of premature birth, younger than 12 weeks, chronic lung disease, congenital heart defect, immunodeficiency) to help determine whether hospitalization is warranted. Other nonspecific indicators of infection, such as white blood cell count, are not clinically useful in diagnosing bronchiolitis. As with other viral infections, these values are likely to be within normal limits or only slightly elevated.

Viral cultures and antigen testing of nasopharyngeal swabs and chest radiography are of limited benefit in diagnosing bronchiolitis because their results do not help predict the severity of illness. The polymerase chain reaction (PCR) tests for many of the viruses that commonly cause bronchiolitis are now available commercially, which may allow faster, more reliable identification of these viruses.

### Prevention

Palivizumab is a humanized monoclonal antibody specific for RSV. It is labeled for prevention of LRTIs from RSV in high-risk pediatric populations (Reference 18). Palivizumab is currently the only product licensed for the prevention of RSV infection in the United States.

Palivizumab is administered at a dose of 15 mg/kg intramuscularly every month during the RSV season. The RSV season generally occurs from late October or early November to late March or early April; however, prophylaxis should not be initiated until the local RSV season has begun. The season officially starts when the average RSV positivity rate is 10% or greater in the community for 2 consecutive weeks (Reference 19). The season ends when the community's positivity rate drops below 10% (Reference 19). Prophylaxis should continue until a child has received the maximum number

of doses recommended, even if the community positivity rate drops below 10%. Palivizumab is generally well tolerated. The most common adverse effects include fever and injection site reactions, such as pain, redness, or swelling (Reference 20).

The AAP recently updated its recommendations regarding the use of palivizumab for prevention of severe RSV infections. The AAP recommends palivizumab prophylaxis be considered for the following pediatric populations: infants born at younger than 32 weeks' gestation; infants and children younger than 24 months with chronic lung disease who required medical management of their chronic lung disease within 6 months of the start of RSV season; infants and children younger than 24 months with a "hemodynamically significant" congenital heart defect; and infants born between 32 weeks' and 34 weeks 6 days' gestation with additional risk factors (Reference 21). Infants born at younger than 29 weeks' gestation may benefit from palivizumab prophylaxis during RSV season through the first 12 months of age. Those born between 29 and 32 weeks' gestation may benefit from prophylaxis during RSV season through the first 6 months of life. Refer to Table 1 for more information regarding the use of palivizumab for prophylaxis of RSV bronchiolitis.

Palivizumab serum concentrations remain above the concentration necessary to suppress viral replication for greater than 30 days after several doses, resulting in sustained RSV protection well beyond administration of a fifth dose of palivizumab (References 20, 21). This

led the AAP to recommend a limit to the number of doses of palivizumab that at-risk infants should receive. For infants born between 32 weeks and 34 weeks 6 days who qualify for palivizumab administration, the AAP recommends monthly palivizumab for three doses or until 3 months of age, whichever comes first (Reference 21). All other high-risk infants and children may receive a maximum of five doses of palivizumab during the RSV season (Reference 21).

The updated AAP maximum dose limitation has generated a fair amount of controversy. If palivizumab administration begins in October, then the last dose of palivizumab a child is eligible to receive would occur in February, potentially 4–6 weeks before the end of the RSV season. Most insurance companies cover only the cost of palivizumab doses that meet the AAP criteria for administration. As a result, if the recommended number of doses of palivizumab is exceeded, then either the child's caregivers will be financially responsible for the costs associated with the additional doses or the health care facility will be required to cover the cost. The average wholesale price for a 100-mg vial of palivizumab is around \$2,200, which can result in a substantial financial loss to a health care facility if the facility initiates early prophylaxis (Reference 22).

## Treatment

The goals of therapy for bronchiolitis are to maintain oxygenation, maintain adequate hydration, and reduce fever. The treatment of bronchiolitis is primarily supportive. Supplemental oxygen and intravenous fluids may be necessary to limit symptoms and avoid dehydration. Both nonpharmacologic and pharmacologic therapies for bronchiolitis will be discussed in this chapter.

### Nonpharmacologic Therapy

Healthy children generally exhibit oxygen saturations above 95% (Reference 3). Children with bronchiolitis may exhibit a decrease in oxygen saturations because of airway edema, excessive mucous production, and bronchospasm. For this reason, the AAP recommends children with signs or symptoms consistent with bronchiolitis receive supplemental oxygen once their O<sub>2</sub> saturations decrease below 90% (Reference 3).

Chest physiotherapy, the process of using percussion or vibration to clear the airways, has been used in other pulmonary diseases, like cystic fibrosis. A study evaluating the use of chest physiotherapy compared with nasal suctioning in infants with bronchiolitis found no significant differences in recovery time between the two groups (Reference 23). Other studies have also failed to show a significant improvement in children

**Table 1.** Indications for Palivizumab Prophylaxis (Reference 21)

Indication	Maximum Number of Doses
Premature infants < 32 weeks' gestation	5
Premature infants 32 weeks' to 34 weeks 6 days' gestation <sup>a</sup>	3
Infants < 24 months with chronic lung disease <sup>b</sup>	5
Infants < 24 months with certain congenital heart diseases <sup>c</sup>	5

<sup>a</sup>Indicated if the child is younger than 3 months at the start of the RSV season or if the child has the additional risk factor of attending day care or living in a home with other children younger than 5 years.

<sup>b</sup>Indicated if the child requires oxygen or pharmacologic treatment of lung disease within 6 months of RSV season.

<sup>c</sup>Indicated if the child has a "hemodynamically significant" cardiac lesion (e.g., cyanotic heart disease, moderate or severe pulmonary hypertension, receiving therapy for congestive heart failure).

RSV = respiratory syncytial virus.

with bronchiolitis treated with chest physiotherapy. As a result, the AAP does not recommend the routine use of physiotherapy as a treatment option for infants with bronchiolitis (Reference 3).

Heliox therapy, a blend of helium and oxygen, is an intervention that was recently evaluated for bronchiolitis. In a recent review, heliox was associated with an improvement in respiratory scores, but it was not associated with significant improvements in the need for intubation and mechanical ventilation or in the length of PICU stay (Reference 24). Heliox is unlikely to benefit infants with bronchiolitis.

### *Pharmacologic Therapy*

Both  $\alpha$ -adrenergic (e.g., racemic epinephrine) and  $\beta$ -adrenergic (e.g., albuterol) bronchodilators have been used in the management of bronchiolitis. A 2010 Cochrane review evaluated 28 studies to determine the effectiveness of bronchodilators for outcomes such as oxygen saturation, clinical improvement, and length of hospital stay (Reference 25). For children who received bronchodilators as outpatients, there was no significant reduction in hospitalization rates (Reference 25). For children who received bronchodilators as inpatients, there was no significant reduction in length of hospital stay (Reference 25). Bronchodilators also failed to show a significant improvement in oxygen saturation (Reference 25). However, children who received bronchodilators did exhibit a small, although nonsignificant, improvement in clinical scores (Reference 25). The AAP does not recommend the routine use of bronchodilators for children with bronchiolitis (Reference 3). The AAP does, however, acknowledge that some children may exhibit clinical improvement after receipt of bronchodilators, so a trial of bronchodilators may be attempted (Reference 3). However, children receiving bronchodilators should be closely monitored, and therapy should be discontinued if no improvement is observed.

Corticosteroids such as dexamethasone and methylprednisolone have been theorized to reduce inflammation associated with bronchiolitis. A 2010 Cochrane review evaluated the use of both inhaled and systemic corticosteroids for bronchiolitis for reduction in hospitalization and length of hospital stay (Reference 26). Similar to other pharmacologic interventions discussed previously, corticosteroids did not show a significant reduction in hospitalizations, nor did they show a significant decrease in length of hospital stay (Reference 26). The AAP does not recommend the routine use of corticosteroids in children with bronchiolitis, although children with asthma who develop bronchiolitis may benefit from corticosteroids (Reference 3).

The use of nebulized hypertonic saline (3% to 12%) was identified as a treatment modality for clearing mucous plugs in individuals with cystic fibrosis in the

mid-2000s. In recent years, its use has been studied in bronchiolitis. A Cochrane review found that children who received 3% hypertonic saline had significantly shorter lengths of hospital stay (mean of 1.16 fewer hospital days,  $p < 0.00001$ ) and significantly lower clinical severity scores during the first 3 days of therapy (lower scores indicate less severe response to disease) (Reference 27). The authors concluded that the use of nebulized hypertonic saline 3% may be beneficial in reducing length of hospital stay and severity scores for infants with bronchiolitis. A major criticism of this review is that bronchodilators were used in conjunction with hypertonic saline for many of the studies that were included, making it difficult to differentiate the effects of the two agents used (Reference 28).

Ribavirin is a nucleoside analog with activity against RSV. Inhaled ribavirin has been used for decades as the primary treatment of RSV bronchiolitis; however, its use has decreased dramatically during the past 10–15 years. Many published clinical trials have shown that inhaled ribavirin does not improve clinical outcomes, such as time on the ventilator, length of stay in the intensive care unit, or hospital length of stay (References 29–31). Inhaled ribavirin requires administration by a special nebulizer (SPAG-2 [small-particle aerosol generator]) for a minimum of 12–18 hours (Reference 32). It has teratogenic potential in animal models and is a pregnancy risk category X (Reference 32). As a result, women of childbearing age, including female nurses and the mothers of infected children, should be counseled regarding the teratogenic potential, and pregnant women should not be allowed in a recipient's room during administration. Although oral ribavirin is contraindicated in male partners of pregnant women, the risk of teratogenicity after exposure of the male partner to inhaled ribavirin is unknown. Inhaled ribavirin has been associated with bronchospasm, hypotension, bradycardia, and hemolytic anemia (Reference 32). The use of inhaled ribavirin may also cause considerable anxiety to the child because of isolation from other children or a pregnant mother and feelings of claustrophobia if the child is placed in a tented crib to receive the aerosol. Aerosolized ribavirin may also stick to contact lenses (Reference 32), so contact lens wearers should avoid entering the room of a child receiving ribavirin. If a contact lens wearer must enter the room of a child receiving ribavirin, he or she should wear protective goggles. Because of ribavirin's adverse effects, administration difficulties, and unproven benefit, the AAP does not recommend routine ribavirin administration to infants and children with bronchiolitis (Reference 3).

Antibiotics have been used in children with bronchiolitis; however, their use does not result in significant clinical improvement (Reference 33). Bronchiolitis is primarily the result of a viral infection. As such, antibiotics should be reserved for children with a concomitant bacterial infection (Reference 3).

Leukotriene antagonists have been used in asthma for more than a decade, and recently, the leukotriene antagonist montelukast was evaluated for use in bronchiolitis. One study showed significantly shorter hospital lengths of stay in infants and children 24 months and younger who were hospitalized for bronchiolitis and received montelukast compared with placebo (Reference 34). Another study showed a significant decrease in wheezing 12 months after the use of montelukast in infants and children 6–24 months of age who received montelukast for 3 months after hospitalization for bronchiolitis (Reference 35). These two studies included less than 250 pediatric subjects. As such, more studies regarding the utility of leukotriene antagonists for bronchiolitis are warranted.

## CONCLUSIONS

Many pharmacologic and nonpharmacologic therapies have not shown efficacy in relieving symptoms or improving clinical outcomes in children with bronchiolitis. The AAP has not revised its recommendations regarding the medical management of children with bronchiolitis since 2006, so newer therapies such as nebulized hypertonic saline and leukotriene antagonists are not presently recommended but may be of benefit. Because smoking exposure is a modifiable risk factor for bronchiolitis, parents and caregivers should be counseled to quit smoking. If that is not possible, they should be counseled not to smoke in the home, car, or other locations where their children are present. Families should also be counseled regarding proper hand hygiene, including washing hands before and after contact with a sick child.

## PERTUSSIS

Pertussis, commonly known as whooping cough, is a respiratory tract infection caused by the gram-negative organism *Bordetella pertussis*. Pertussis is highly contagious. Infection occurs through exposure to contaminated respiratory droplets after close contact with an infected individual. The incubation period for pertussis is usually 7–10 days after exposure but may last as long as 21 days (Reference 36). Infected individuals are most contagious during the first 1–2 weeks of infection (known as the catarrhal phase) and within 2 weeks of the onset of cough (Reference 36).

## Epidemiology

Before a pertussis vaccine became available in the 1940s, more than 200,000 people became infected with *B. pertussis* annually in the United States (Reference 37). Pertussis infections decreased dramatically after routine use of the pertussis vaccine; however, the number of pertussis infections reported to the Centers for Disease Control and Prevention (CDC) has been increasing since the 1980s, reaching a high of 8.88 cases per 100,000 people in 2004 (References 37, 38). Pertussis infection rates declined after the 2004 peak; however, the incidence is again on the rise, with a new high of 8.97 cases per 100,000 people reported in 2010 (Reference 39).

Before the availability of a vaccine, pertussis was a disease primarily found in school-aged children. Since the early 2000s, the incidence of pertussis has increased in infants (younger than 12 months), adolescents, and adults (Reference 37). The highest incidence of pertussis during 2009 occurred in infants, especially those younger than 6 months (126.9 per 100,000); however, adolescents and adults accounted for almost 50% of pertussis cases reported to the CDC in 2009 (Reference 38).

During the first half of 2010, a significant increase in the number of individuals infected with pertussis was documented in the state of California. From January through June, more than 1300 pertussis cases were reported to the California Department of Public Health, representing a 418% increase from the 258 cases reported during the same period in 2009 (Reference 40). During the California outbreak, the highest incidence of pertussis occurred in infants younger than 12 months (38.5 cases per 100,000 people), with infants younger than 6 months representing 89% of the cases reported (Reference 40). Five deaths were reported, all of which occurred in Hispanic infants younger than 2 months (Reference 40).

For several reasons, a shift in disease burden away from school-aged children has been observed. First, an improvement in the ability to reliably diagnose pertussis and an increase in its awareness, both in the lay public and in health care practitioners, likely contributed to an increase in the diagnosis of pertussis in other populations (Reference 41). Additional factors that have been suggested as contributors to the shift in disease burden include a decrease in vaccine coverage (i.e., fewer people receiving the vaccine) and waning of vaccine-induced immunity over time (Reference 41). Unvaccinated or under-vaccinated adolescents and adults often serve as the reservoir for infants infected with *B. pertussis*.

The most common complication of pertussis is pneumonia. About 5% of all individuals with pertussis whose cases were reported to the CDC between 1997 and 2000 developed pneumonia (Reference 37). The incidence of pneumonia in infants younger than 6 months was 11.8%, more than twice the rate of pneumonia for

all individuals during that time (Reference 37). Other pulmonary complications that have been described with pertussis include cyanosis, apnea, pulmonary hypertension, hypoxia, and need for oxygen supplementation or mechanical ventilation (References 37, 42, 43). Other complications reported in infants include poor feeding, anorexia, seizures, and encephalopathy, possibly because of hypoxia caused by coughing (References 37, 42).

Infants are at the highest risk of death from pertussis infection, especially those who are too young to be vaccinated (or completely vaccinated) against pertussis. During the 1980s, 77 deaths were reported to the CDC, 61 (79%) of which occurred in infants younger than 12 months (Reference 44). Forty-nine (80%) of the infant deaths occurred in infants younger than 4 months (Reference 44). Between 1990 and 1999, 103 deaths from pertussis were reported to the CDC, 90% of which occurred in infants (Reference 44). Eighty-four of the infants who died were younger than 4 months, representing 90% of the infant deaths (Reference 44). Hispanic ethnicity has also been identified as a risk factor for death from pertussis (References 42, 43).

Adolescents and adults are much less likely to exhibit significant morbidity because of pertussis. Pertussis also has a much lower mortality rate in adolescents and adults, occurring in only 0.1% of infected individuals in these age ranges (Reference 45). Pneumonia has been reported in 2% to 9% of adolescents and adults infected with pertussis, with the highest rates reported in older individuals (Reference 45). The most common complications of pertussis reported in adolescents and adults include loss of bladder control, rib fractures, pneumothoraces, anorexia, and weight loss (References 37, 45, 46). Rib fracture is more likely to occur in individuals with profound paroxysmal coughing and in those with osteoporosis (Reference 45). Intracranial hemorrhages have also been reported but are more common in individuals who receive anticoagulants (Reference 45). Seizures and encephalopathy have also been reported in this population, but they occur in less than 1% of those infected (Reference 45).

### Etiology

Disease from pertussis is primarily caused by toxin production by the organism, which causes impaired mucociliary function and lung inflammation (Reference 47). This leads to an inability to clear respiratory secretions and the associated cough.

### Clinical Presentation

Pertussis infection has three phases: catarrhal, paroxysmal, and convalescent. The catarrhal phase usually lasts 1–2 weeks, and symptoms generally mimic those of the common cold (e.g., rhinorrhea, sneezing, cough, and

low-grade fever) (Reference 37). Infected individuals are most likely to be contagious during this phase of the disease. The next phase, the paroxysmal phase, may last anywhere between 1 and 6 weeks and is when the classic paroxysmal cough, followed by an inspiratory whoop, occurs (Reference 37). The cough is characterized by a burst of persistent, rapid coughs (known as paroxysms) and the accompanying whoop that is caused by a narrowed glottis during a prolonged inspiratory period. Children, especially young infants, can become cyanotic and may appear visually ill during these episodes (Reference 37). The paroxysms are more frequent at night and increase in frequency throughout this phase of the disease. Posttussive emesis is also common during this phase, especially in adolescents (Reference 48). The convalescent, or recovery, phase, during which symptoms slowly improve as the paroxysms begin to resolve, may last weeks to months (Reference 37). Unvaccinated infants and children are more likely to have severe disease. Older children who have been vaccinated, adolescents, and adults typically have less severe disease and may not present with the classic symptoms of pertussis, although they often present with a nagging cough that has persisted for several weeks (References 37, 48).

### Diagnosis

The diagnosis of pertussis is often made using a combination of clinical presentation and microbiologic tests. Pertussis should be highly suspected in any child or adolescent who presents with a cough of greater than 2 weeks' duration (Reference 48). White blood cell counts are often elevated during pertussis and show lymphocyte predominance on a differential diagnosis (References 37, 48).

Several laboratory tests may be used to confirm the presence of *B. pertussis*. Bacterial culture is considered the gold standard for diagnosing pertussis; however, isolating *B. pertussis* by culture is often difficult because it is a fastidious organism. Bacterial cultures are much less sensitive over time. Once an infected individual has been symptomatic for 3 weeks, bacterial culture detects *B. pertussis* in only 1% to 3% of cases (Reference 49). Polymerase chain reaction is a more sensitive testing method, especially if the individual presents later in the disease course (References 37, 48, 49). Polymerase chain reaction also has the advantage of a rapid turnaround time because it does not measure the presence of living organisms. For children or adolescents who present late in the disease course, measuring antibody levels to pertussis antigens may be useful in confirming infection. Serology (or antibody) testing can be difficult to interpret in vaccinated individuals because positive serologies confirm only exposure to pertussis antigens. As a result, serologies should not be used routinely to confirm the diagnosis of pertussis (Reference 37).

## Prevention

The primary mode for preventing the spread of pertussis is through vaccination of susceptible individuals against *B. pertussis*, especially those who may be exposed to infants who are not fully vaccinated. Several vaccines are available to protect against pertussis. Confusion regarding the various acronyms used to discuss the available pertussis vaccines is common, so it is important for health care practitioners to understand the differences and indications for each vaccine. Further information regarding the pertussis-containing vaccines may be found in the Pediatric Vaccines chapter.

## Treatment

The primary goal of treatment for pertussis is to reduce transmission to infants and children at high risk of significant morbidity or mortality, such as infants younger than 4 months and children who are immunocompromised. Antimicrobial therapy initiated during the catarrhal phase of pertussis can hasten recovery from the disease. Once a cough has developed, antimicrobial therapy will not contribute to symptomatic improvement, but it can limit the spread of disease to susceptible individuals (Reference 36). Macrolide antibiotics are the treatment of choice for pertussis.

Erythromycin is the oldest macrolide antibiotic on the market in the United States and has, historically, been used first line in the treatment of pertussis. Erythromycin is the only macrolide antibiotic labeled for use in infants younger than 6 months; however, when used in young infants, it has been associated with an increased risk of infantile hypertrophic pyloric stenosis (References 36, 50). This risk appears to be highest during the first 2 weeks of life and when given for 14 or more days (Reference 50). Erythromycin, which should be administered four times/day, has a high rate of gastrointestinal adverse effects, including abdominal cramping, nausea, vomiting, and diarrhea. Erythromycin is a potent inhibitor of the cytochrome P450 (CYP) 3A subclass with many drug-drug interactions (Reference 51). Although QT prolongation has been associated with all the macrolide antibiotics, erythromycin has the highest risk of QT prolongation (Reference 51). Because of these factors, erythromycin is no longer the macrolide antibiotic of choice for pertussis.

Azithromycin is generally better tolerated than the other macrolide antibiotics. Azithromycin has the advantages of once-daily dosing and a shortened length of therapy of only 5 days. The most common adverse effects include gastrointestinal upset, diarrhea, vomiting, headache, and dizziness. Azithromycin is a less potent inhibitor of the CYP system than the other macrolide antibiotics and has fewer drug-drug interactions. Although pyloric stenosis in young infants has been

reported with azithromycin, the incidence appears to be much lower than that associated with erythromycin (Reference 36). For these reasons, azithromycin is often used as the first-line agent for pertussis, even in infants younger than 6 months. Infants younger than 6 months receiving azithromycin therapy should be closely monitored for signs of pyloric stenosis (References 50, 51).

Clarithromycin is structurally similar to erythromycin. As such, it has similar effects on the CYP system and similar drug-drug interactions (Reference 51). Like erythromycin, clarithromycin is associated with substantial gastrointestinal adverse effects. It has the advantage over erythromycin of requiring only twice-daily dosing and a shorter therapy (7 days with clarithromycin vs. 14 days for erythromycin); however, it must be administered more frequently and for a longer duration than azithromycin. For these reasons, its use is limited in children.

For children or adolescents allergic to or intolerant of macrolide antibiotics, trimethoprim/sulfamethoxazole (TMP/SMX) may be used as an alternative (Reference 51). Infants younger than 2 months should not receive TMP/SMX unless the benefits of therapy outweigh the risks of hyperbilirubinemia and kernicterus that can result from the displacement of bilirubin from its protein-binding site. Information regarding the dose and duration of antibiotics for pertussis treatment is available in Table 2.

## Postexposure Prophylaxis

Pertussis is a highly contagious, infectious disease. Up to 80% of people who have close contact with an infected person also contract pertussis; as a result, preventive antibiotics should be considered in certain situations (Reference 51). Close contact is defined in several ways. The CDC considers a close contact anyone who has face-to-face contact within 3 ft of an infected person (Reference 51). Anyone who has been exposed to an infected person's oral, nasal, or respiratory secretions (e.g., nurse, parent, day care provider) also qualifies as a close contact (Reference 51). Anyone who shares a confined space (e.g., car, bed, crib) with an infected person for at least 1 hour also qualifies as a close contact (Reference 51). If a household contact of an infected person develops a cough, he or she should receive a course of antibiotics for pertussis (Reference 51). If someone develops pertussis in a household with an infant younger than 12 months or a pregnant woman in her third trimester, all members of the household should receive preventive antibiotics (Reference 51). Preventive antibiotics may also be considered in close contacts at high risk of developing severe disease or complications from pertussis, such as children who are immunocompromised or who have chronic lung disease (Reference 51). Preventive antibiotics may be considered in other individuals who have had

**Table 2.** Antibiotics for Pertussis: Dosing and Duration of Therapy (Reference 51)

Antibiotic	Dose for Infants	Dose for Infants/Children	Dose for Adolescents/Adults	Therapy Duration (days)
	≤ 5 Months	≥ 6 Months		
Azithromycin	10 mg/kg/day	10 mg/kg on day 1; then 5 mg/kg/day on days 2–5	500 mg on day 1; then 250 mg/day on days 2–5	5
Clarithromycin <sup>a</sup>	7.5 mg/kg/dose BID	7.5 mg/kg/dose BID	500 mg BID	7
Erythromycin <sup>a</sup>	10 mg/kg/dose QID	10 mg/kg/dose QID	500 mg QID	14
TMP/SMX <sup>b,c,d</sup>	4 mg/kg/dose BID	4 mg/kg/dose BID	160 mg (1 double-strength tablet) BID	14

<sup>a</sup>Not recommended for infants younger than 1 month.

<sup>b</sup>Alternative agent for infants, children, or adolescents with an allergy or intolerance to macrolide antibiotics.

<sup>c</sup>Dosing is based on the trimethoprim component.

<sup>d</sup>Not recommended for infants younger than 2 months.

BID = twice daily; QID = four times/day; TMP/SMX = trimethoprim/sulfamethoxazole.

close contact with an infected person, but the benefits of therapy should be weighed against the risks of adverse effects before therapy is initiated. Antimicrobial therapy and duration of antimicrobials used for postexposure prophylaxis are the same as those used to treat pertussis.

## CONCLUSIONS

Anyone with a cough lasting more than 2 weeks should be presumed to have pertussis until proven otherwise. Macrolide antibiotics, especially azithromycin, are the mainstay of treatment for pertussis. Therapy duration ranges from 5 to 14 days, depending on the antibiotic selected. Preventing pertussis transmission to at-risk populations is the most important step in treating pertussis. Parents and caregivers should be encouraged to have their children vaccinated against pertussis on time and according to schedule. If a household contact of an infant younger than 12 months or a pregnant woman in her third trimester contracts pertussis, then all members of the household should receive preventive antibiotics.

## ACUTE BRONCHITIS

Acute bronchitis is a self-limited respiratory tract infection characterized by a cough lasting no more than 3 weeks (Reference 52). Acute bronchitis is usually triggered by a viral infection and is associated with inflammation of the bronchioles, airway hyperresponsiveness, and mucous production (Reference 53).

## Epidemiology

Between 2001 and 2002 in the United States, cough was the most common symptom cited for seeking care in the ambulatory care setting, accounting for 4.3% of

all outpatient visits by children and adults (Reference 54). Although acute bronchitis is largely caused by a viral infection, up to 80% of individuals with acute bronchitis inappropriately receive antibiotic therapy (Reference 52).

## Etiology

Acute bronchitis is usually the result of infection from respiratory viruses, such as influenza A and B, parainfluenza, and RSV; however, cultures are rarely performed at the time of diagnosis (Reference 52). Although *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *B. pertussis* have also been associated with bronchitis, bacterial causes have been implicated in less than 10% of those with a diagnosis of bronchitis (Reference 52).

## Clinical Presentation

Children who present with acute bronchitis typically have a cough with or without phlegm production. Because acute bronchitis is predominantly caused by respiratory viruses, its symptoms are often difficult to distinguish from those of the common cold. Acute bronchitis is a self-limited condition that should resolve within 3 weeks (Reference 52). A child who presents with a cough lasting more than 3 weeks should be evaluated for other conditions (e.g., pertussis).

## Diagnosis

In making a diagnosis of acute bronchitis, other explanations for the cough need to be evaluated and excluded (Reference 52). A child with a cold may present with a cough; however, other symptoms, such as rhinorrhea and congestion, are often present (Reference 55). Symptoms of a cold also usually resolve within 7–10 days. A child presenting with pneumonia usually has

additional signs or symptoms, such as fever, tachycardia, tachypnea, or diminished breath sounds on auscultation, which rule out acute bronchitis as the cause of the cough (References 52, 55). A child with a history of asthma who presents with a cough should be evaluated for an acute asthma exacerbation. Once other possible explanations for a cough have been excluded, the diagnosis of acute bronchitis can be made (Reference 52). Viral and bacterial cultures should not be performed routinely in children with the presumed diagnosis of acute bronchitis (Reference 52).

### Treatment

The primary treatment goal for acute bronchitis is to keep the child comfortable by ameliorating symptoms until the infection subsides. For most individuals with acute bronchitis, antibiotic therapy has limited benefit, if any. The American College of Chest Physicians does not recommend antibiotic therapy for individuals with the presumptive diagnosis of acute bronchitis (Reference 52). The overuse of antibiotics for conditions including acute bronchitis led to a campaign by the CDC called “Get Smart: Know When Antibiotics Work,” designed to educate the public and health care practitioners regarding the appropriate use of antibiotics. For more information about the Get Smart campaign, refer to the campaign Web page ([www.cdc.gov/getsmart/index.html](http://www.cdc.gov/getsmart/index.html)).

Medications attempting to alleviate the symptoms associated with acute bronchitis have largely proven ineffective and may cause more harm than good in children. Antitussive agents, such as dextromethorphan or codeine, have shown some limited efficacy in adults but should not be used in children (References 52, 55, 56). These agents have not shown efficacy in children; moreover, they have been associated with unintentional overdoses (Reference 56). Infants and young children are also at increased risk of adverse effects from codeine because of immature hepatic function. The performance of the glucuronidation pathway, which is necessary to metabolize codeine, is highly variable in children younger than 10 years (References 56, 57). Decongestants and other cough or cold products should also be avoided in children, especially those younger than 4 years. In January 2008, the U.S. Food and Drug Administration (FDA) issued a Public Health Advisory stating that over-the-counter (OTC) cough and cold products should not be used in children younger than 2 years because of serious adverse effects reported in this population (Reference 58). Later that year, members of the Consumer Healthcare Products Association voluntarily agreed to change the package labeling of pediatric OTC cough and cold products to state that they should not be used in children younger than 4 years (References 58, 59). An alternative to OTC cough

products, honey, when administered before bedtime to a child with an acute cough, has shown some success in decreasing the frequency and severity of cough and in improving the sleep of both the child and the parent (Reference 60). Honey should not be given to infants younger than 12 months, however, because of the risk of developing infant botulism.

### CONCLUSIONS

Acute bronchitis is generally a self-limited condition that resolves on its own within 3 weeks of symptom development. Other possible explanations for cough (e.g., asthma, common cold, pneumonia) should be ruled out before a diagnosis of acute bronchitis is made. Antibiotic therapy is not warranted for children with acute bronchitis. Over-the-counter cough and cold products are not useful in children and are considered unsafe in children younger than 4 years. Parents and caregivers should be counseled that acute bronchitis is the result of a viral infection and that antibiotic therapy will not help relieve their child's symptoms.

### INFLUENZA

Influenza is transmitted through close contact with infected respiratory droplets. Infection usually occurs within 3–4 days of exposure (Reference 61). Infected individuals may remain symptomatic for up to 7 days (References 61, 62). Children who contract influenza may shed virus for 10 or more days (Reference 61). School-aged children have the highest attack rate and serve as the primary source of infection during influenza outbreaks (Reference 62). Influenza follows a seasonal pattern and typically occurs during the winter months.

#### Epidemiology

During 2009, more than 350 pediatric deaths were reported to the CDC, 81% of which were caused by the novel influenza A H1N1 strain (Reference 38). Children who died of influenza caused by this strain were older than those who died of a seasonal strain of influenza during the same year (9.3 years vs. 7.5 years) (Reference 38). Children who died secondary to novel H1N1 influenza infection were also more likely to have a comorbid condition than those who died secondary to seasonal influenza during 2009.

Children younger than 2 years and those with comorbid conditions, such as asthma or immunosuppression, are at highest risk of secondary complications from influenza (Reference 38). Children with a history of asthma and those younger than 5 years have a higher risk of developing pneumonia after infection with influenza (Reference 61). Children with influenza-associated pneumonia are at higher risk of admission

to an intensive care unit, respiratory failure, and death. Other complications of influenza infection in children include febrile seizures, myocarditis, pericarditis, encephalopathy, and Reye syndrome (Reference 61). Reye syndrome has been described in children younger than 18 years who were infected with influenza or varicella and who received aspirin therapy (Reference 62).

### Etiology

Most influenza infections worldwide are caused by influenza A or B (Reference 63). Influenza A causes moderate to severe disease in individuals of all ages (Reference 62). Influenza A infects humans, birds, or other animals. Influenza B typically causes milder disease, primarily affects children, and infects only humans (Reference 62). Over time, gene mutations in the surface proteins of influenza result in subtle changes to the influenza subtypes, which circulate worldwide; this is known as antigenic drift (Reference 63). These drifts can result in community epidemics and require annual changes to the influenza A and B subtypes contained within the influenza vaccine. Another type of gene mutation, known as antigenic shift, occurs only in influenza A viruses and results in dramatic changes in the hemagglutinin or neuraminidase surface proteins of the virus (Reference 63). This results in a new viral strain that can lead to a pandemic if the virus is able to sustain person-to-person transmission. This occurred in 2009 with the novel influenza A H1N1 pandemic, in which it was estimated that 60 million individuals contracted this strain in the United States (Reference 62). This resulted in more than 275,000 hospitalizations and 12,500 deaths in both children and adults (Reference 62).

### Clinical Presentation

The most common symptoms associated with influenza are fever, myalgias, sore throat, cough, rhinorrhea, and general malaise (Reference 61). Children infected with influenza may also present with otitis media, nausea, and vomiting. Children younger than 5 years are less likely to present with the classic symptoms of fever or cough (Reference 61). Signs and symptoms of influenza generally resolve within 3–7 days in uncomplicated cases.

### Diagnosis

Diagnosis of influenza in the outpatient setting may be made on the basis of clinical presentation and knowledge of the respiratory viruses circulating in the community. Clinical diagnosis is nonspecific and may be of limited benefit because many respiratory viruses present with similar signs and symptoms. Microbiologic testing to confirm the diagnosis of influenza is useful

to guide therapy. Microbiologic tests for influenza include viral culture, antigen testing, and PCR. The most common microbiologic tests used to detect influenza in the community are the rapid diagnostic tests, which can detect the presence of influenza from a nasopharyngeal swab within 15–30 minutes (Reference 64). Many of the rapid diagnostic tests can be used in any outpatient setting, making them convenient to use in a physician's office. The rapid diagnostic tests are immunoassays, which have a high degree of specificity (up to 95%) but a sensitivity of only 50% to 70% compared with viral culture or PCR (Reference 64). As a result, there is a higher possibility of yielding a false-negative result, especially when community rates of influenza are high (Reference 65). During community outbreaks of influenza, negative rapid diagnostic tests should be confirmed with a viral culture. False-negative results can be minimized by performing the rapid diagnostic test early in the course of illness (within 4–5 days) (Reference 65).

### Prevention

Vaccination of all individuals older than 6 months, including adults, against influenza is the most effective way to prevent transmission of the disease. Parents, caregivers, and children should also be instructed to wash their hands frequently to prevent the spread of disease. Refer to the Pediatric Vaccines chapter for a more detailed discussion of the influenza vaccines.

### Treatment

The goals of therapy for treating influenza in children are to alleviate the associated symptoms and prevent the spread of infection. Analgesic antipyretics such as acetaminophen are useful for managing fever and myalgias associated with influenza. Antiviral agents may also be beneficial in reducing the duration of symptoms in some children.

Two classes of antivirals have activity against influenza: the Adamantanes and the neuraminidase inhibitors. The Adamantanes (amantadine and rimantadine) do not have activity against influenza B, but until recently, they did exhibit activity against influenza A (Reference 61). Influenza resistance to the Adamantanes has been increasing for the past 5–10 years. During the 2009–2010 influenza season, 100% of the seasonal influenza A H3N2 viruses were resistant to the Adamantanes, whereas 99.8% of the pandemic influenza A H1N1 viruses tested were resistant to them (Reference 66). For this reason, the use of Adamantanes is not appropriate for the treatment or prevention of influenza infections.

The neuraminidase inhibitors (oseltamivir and zanamivir) have good activity against both influenza A and B, although influenza A resistance to oseltamivir has been documented. During the 2009–2010 influenza season, only 1.1% of the pandemic influenza A H1N1 viruses tested showed resistance to oseltamivir (Reference 66). None of the seasonal influenza A H3N2 or influenza B viruses showed oseltamivir resistance. All the viruses tested during the 2009–2010 season showed sensitivity to zanamivir, including those resistant to oseltamivir. The neuraminidase inhibitors are the agents of choice for the treatment and prevention of influenza in children.

Many children with suspected influenza infections who present with minor febrile illnesses will not require antiviral therapy. The use of oseltamivir in children 1–3 years of age reduced the duration of influenza symptoms to a median of 3.5 days when therapy was initiated within 24 hours of symptom onset (Reference 67). Because antiviral therapy may shorten the duration of influenza symptoms by only about 1 day on average, the decision to initiate antiviral therapy should consider the respiratory viruses circulating in the community, the individual's risk of developing complications of influenza infection, the severity of the individual's disease, and the duration of symptoms. The CDC recommends outpatient antiviral therapy be considered for previously healthy, symptomatic individuals who are at low risk of serious sequelae from influenza if therapy can be initiated within 48 hours of symptom onset (Reference 61). Once the decision to initiate therapy has been made, the antiviral should be continued for 5 days (Reference 61).

Individuals who are at highest risk of serious complications from influenza infection should receive antiviral therapy as early as possible after symptom onset, ideally within 48 hours (Reference 61). This includes all children younger than 2 years; children with other comorbid conditions (e.g., asthma, sickle cell disease, diabetes, seizure disorders, mental retardation, HIV [human immunodeficiency virus]); children 18 years and younger receiving chronic aspirin therapy; American Indians or Native Americans; and children who are residents of chronic care facilities. Early initiation of antiviral therapy for influenza may also reduce the risk of serious complications, such as influenza-associated pneumonia or death. Children who have severe, progressive disease or who have been hospitalized because of influenza should also receive antiviral therapy (Reference 61). A longer therapy duration may be warranted for critically ill children who have been admitted to the hospital or for immunocompromised children (Reference 61).

Oseltamivir is an oral agent that is generally well tolerated. Oseltamivir is available as an oral solution, which makes it the treatment of choice for influenza in infants and young children. Oseltamivir is not labeled

for use in infants younger than 1 year, but dosing information for infants is available. During the 2009 H1N1 pandemic, the FDA provided dosing recommendations for infants as part of an Emergency Use Authorization. Although the authorization has now expired, the dosing information provided through the authorization is useful for practitioners who decide the risk of influenza-associated morbidity or mortality for a particular infant is higher than the potential risks of antiviral therapy for that infant. This information has been archived on the CDC's Web site ([www.cdc.gov/h1n1flu/recommendations.htm](http://www.cdc.gov/h1n1flu/recommendations.htm)). In 2011, the makers of oseltamivir changed the concentration of the oral solution from 12 mg/mL to 6 mg/mL because of excessive frothing with the higher concentration, which resulted in difficulty measuring accurate doses of the drug (Reference 68). Some wholesalers may still have the 12-mg/mL solution in supply, so pharmacists should carefully counsel parents or caregivers regarding the appropriate volume of medication to give their child. In recent years, nationwide shortages of the oral solution have also occurred. During times of shortage, an extemporaneous product with the final concentration of 15 mg/mL may be compounded from oseltamivir capsules using a recipe from the package insert. The most common adverse effects associated with oseltamivir use in children are nausea, vomiting, and diarrhea (Reference 69). Children and adolescents may also be at increased risk of neuropsychiatric disorders, such as hallucinations and abnormal behaviors that may result in harm, after oseltamivir administration (Reference 70). Table 3 describes appropriate oseltamivir dosing for children.

Zanamivir is available as a powder for inhalation and is packaged in its own unique delivery device called a Rotadisk (Reference 71). It is labeled for the treatment of influenza in children 7 years or older and for prophylaxis of influenza in children 5 years or older. Because of the device in which zanamivir is packaged, it cannot be nebulized into ventilators and is not effective for intubated children. Zanamivir's Rotadisk is also difficult for young children to use. It is not a pressurized canister and requires the recipient to inhale a forceful breath, which is difficult for young children to perform. Zanamivir is generally well tolerated. Phase III studies of children showed no significant difference in the adverse effects of zanamivir compared with placebo (Reference 71). Postmarketing surveillance of zanamivir use has shown a risk of bronchospasm after administration (Reference 71). As a result, zanamivir should not be used in children with preexisting pulmonary disease, such as asthma. Table 4 describes appropriate zanamivir dosing for children.

**Table 3.** Dosing of Oseltamivir for Children (Reference 61)

Age	Treatment	Postexposure Prophylaxis
< 14 days	3 mg/kg/dose daily	Not recommended unless critical situation
14 days to 2 months	3 mg/kg/dose twice daily	Not recommended unless critical situation
3–5 months	3 mg/kg/dose twice daily	3 mg/kg/dose daily
6–11 months	3 mg/kg/dose twice daily	3 mg/kg/dose daily
≥ 12 months	≤ 15 kg	30 mg twice daily
	15.1–23 kg	45 mg twice daily
	23.1–40 kg	60 mg twice daily
	> 40 kg	75 mg twice daily

**Table 4.** Dosing of Zanamivir for Children (Reference 61)

Age	Treatment	Postexposure Prophylaxis
Children < 5 years	Not recommended	Not recommended
Children 5–6 years	Not recommended	10 mg (2 inhalations) daily
Children ≥ 7 years	10 mg (2 inhalations) twice daily	10 mg (2 inhalations) daily

### Prophylaxis

Some children may benefit from antiviral prophylaxis with either oseltamivir or zanamivir when a community outbreak of influenza occurs. Children who should receive antiviral prophylaxis during community outbreaks (i.e., preexposure prophylaxis) include children at high risk of influenza complications with a contraindication to influenza vaccine, children at high risk of influenza complications if an outbreak occurs within 2 weeks of influenza vaccination, household contacts of unimmunized children at high risk of influenza complications, and household contacts of infants and children younger than 2 years (Reference 72). Once initiated, preexposure prophylaxis is most beneficial if administered for the duration of influenza activity in the community (Reference 61). When contemplating the initiation of postexposure prophylaxis, the practitioner should consider the exposed individual's risk of developing serious complications from influenza infection and the length of exposure to the infected individual. Postexposure prophylaxis should only be considered if antiviral therapy is initiated within 48 hours of exposure to the infected individual (Reference 61). Once postexposure prophylaxis is initiated, it is generally continued until 10 days after the last known exposure to an infected individual.

### CONCLUSIONS

Otherwise-healthy children will receive only limited benefit, if any, from antiviral therapy. Antiviral therapy should be initiated in all children at high risk of complications from influenza infection, including those younger than 2 years and those with other comorbid conditions. Only the neuraminidase inhibitors (oseltamivir and zanamivir) should be used for the treatment or prophylaxis of influenza. Oseltamivir is the preferred antiviral agent in young children because it is available in an oral solution, and dosing information is available.

### COMMUNITY-ACQUIRED PNEUMONIA

#### Epidemiology

According to the World Health Organization (WHO), pneumonia is the most common illness worldwide to cause death in children younger than 5 years (Reference 73). The WHO estimates that 1.8 million children died of pneumonia worldwide in 2009 (Reference 73). Mortality is highest in impoverished children who lack adequate resources to provide good nutrition or health care. Pulmonary complications that may result from pneumonia include pleural effusions, empyemas, lung abscesses, and necrotizing pneumonias. These complications often result in the need for admission to the intensive care unit and

mechanical ventilation. Children infected with typical bacterial organisms, such as *Streptococcus pneumoniae*, and those with mixed bacterial and viral infections are more likely to develop pleural effusions (Reference 74). Bacteremia can also result from pneumonia and lead to metastatic complications, such as meningitis, pericarditis, and septic arthritis (Reference 75). Adults who had childhood pneumonia before 7 years of age have been noted to have reduced pulmonary function (Reference 76). Factors that increase the risk of developing pneumonia in children include age younger than 5 years, recurrent upper respiratory tract infections, otitis media before 2 years of age, and a history of wheezing (Reference 77).

## Etiology

The most common organism responsible for causing community-acquired pneumonia (CAP) in children varies by the child's age. Table 5 describes the most common organisms that cause pneumonia in children.

## VIRAL PNEUMONIA

Viruses that commonly cause pneumonia in children include influenza A and B, RSV, human metapneumovirus, parainfluenza, adenovirus, human bocavirus, coronaviruses, and rhinoviruses (References 80–82). Viral and bacterial coinfection is common in children with pneumonia (Reference 74).

**Table 5.** Empiric Treatment of Community-Acquired Pneumonia in Children (References 75, 78, 79)

Age	Causative Organisms	First-line Therapy	Second-line Therapy
Birth to 3 weeks	<i>Escherichia coli</i>	Ampicillin + gentamicin	Ampicillin + cefotaxime
	Group B <i>Streptococcus</i>		
	<i>Listeria monocytogenes</i>		
	<i>Haemophilus influenzae</i>		
3 weeks to 3 months	Viruses	Supportive care	
	<i>Chlamydia trachomatis</i>	Azithromycin	
	<i>Streptococcus pneumoniae</i>	High-dose amoxicillin	Azithromycin, oral third-generation cephalosporin, clindamycin
		Third-generation cephalosporin in hospitalized infants	Vancomycin
	<i>H. influenzae</i>	Third-generation cephalosporin	
4 months to 4 years	Viruses	Supportive care	
	<i>Chlamydia pneumoniae</i> <i>Mycoplasma pneumoniae</i>	Azithromycin	Doxycycline, <sup>a</sup> fluoroquinolone <sup>b</sup>
	<i>S. pneumoniae</i>	High-dose amoxicillin	Azithromycin, oral third-generation cephalosporin, clindamycin, levofloxacin <sup>b</sup>
		Third-generation cephalosporin in hospitalized infants	Vancomycin, levofloxacin <sup>b</sup>
		Third-generation cephalosporin	
≥ 5 years	<i>C. pneumoniae</i> <i>M. pneumoniae</i>	Azithromycin	Doxycycline, <sup>a</sup> fluoroquinolone <sup>b</sup>
	<i>S. pneumoniae</i>	High-dose amoxicillin	Azithromycin, oral third-generation cephalosporin, clindamycin, levofloxacin <sup>b</sup>
		Third-generation cephalosporin in hospitalized infants	Vancomycin, levofloxacin <sup>b</sup>
		Third-generation cephalosporin	
Empyema, lung abscess, necrotizing pneumonia	<i>S. pneumoniae</i>	Vancomycin Clindamycin	Ceftriaxone, <sup>c</sup> doxycycline, <sup>a</sup> levofloxacin <sup>b</sup>
	<i>S. aureus</i> (including MRSA)	Vancomycin Clindamycin	Doxycycline, <sup>a</sup> linezolid

<sup>a</sup>Doxycycline should not be used in children < 8 years because of discoloration of permanent teeth.

<sup>b</sup>The use of fluoroquinolones in children should be avoided unless no other safe alternatives are available.

<sup>c</sup>Ceftriaxone should only be used if cultures show the absence of MRSA.

MRSA = methicillin-resistant *Staphylococcus aureus*.

## BACTERIAL PNEUMONIA

During the neonatal period, group B *Streptococcus* and gram-negative enteric organisms, especially *Escherichia coli*, are the most common causes of pneumonia (Reference 75). *S. pneumoniae* is the most likely bacterial cause of pneumonia in infants and children (Reference 75). *M. pneumoniae* and *C. pneumoniae* are common causes of bacterial pneumonia in children older than 5 years (Reference 78). Other, less common bacteria associated with pneumonia in children include *Staphylococcus aureus*, *B. pertussis*, group A *Streptococcus*, *Moraxella catarrhalis*, *Haemophilus influenzae*, and *Mycobacterium tuberculosis* (References 75, 78). Tuberculosis will not be discussed in this chapter. Refer to the CDC guidelines at [www.cdc.gov](http://www.cdc.gov) for information regarding the proper assessment and medical management of a child with tuberculosis.

### Clinical Presentation

The most common symptoms associated with pneumonia in children are fever and cough, with fever present in more than 90% of children with pneumonia (References 75, 78, 80). Bacterial pneumonia usually has a rapid onset and may include productive cough and chest pain (Reference 75). Other signs or symptoms of pneumonia that may be present include tachypnea, difficulty breathing, retractions, grunting, wheezing, and crackles (References 75, 80). In children, tachypnea is defined as greater than 50 breaths/minute in infants 2–12 months of age, greater than 40 breaths/minute in children 1–5 years of age, and greater than 20 breaths/minute in children 6 years and older (Reference 78). Some children with pneumonia may have nonspecific symptoms of nausea, vomiting, and abdominal pain (Reference 75). Children who develop pneumonia from atypical organisms may present with symptoms of fever, cough, sore throat, and malaise that develop slowly, usually over 3–5 days (Reference 83).

### Diagnosis

The presence of infiltrates on chest radiograph is considered the gold standard for diagnosing pneumonia (Reference 80). For an afebrile child with a clinical presentation strongly suggestive of pneumonia, radiography is not necessary for determining proper outpatient management. Chest radiography is recommended for infants and children with hypoxia or respiratory distress, for infants or children who do not respond to an initial course of antibiotics, and for all infants or children admitted to the hospital with pneumonia (Reference 83). Bacterial pneumonias often exhibit lobar infiltrates, whereas atypical pneumonias often exhibit perihilar infiltrates, although these findings are nonspecific and can also be seen in viral pneumonias (Reference 75).

Pneumonias caused by atypical organisms may exhibit patchy infiltrates bilaterally (Reference 78). Children with pneumonia often have elevated white blood cell counts and C-reactive protein; however, these laboratory parameters are nonspecific and not helpful in differentiating bacterial from viral pneumonia (References 75, 78, 80).

Blood cultures are positive less than 10% of the time when pneumococcal pneumonia is present (Reference 78). As a result, they should not be obtained routinely in children who are treated for CAP as outpatients. Blood cultures should be performed if a child fails to improve on antimicrobial therapy, shows clinical deterioration, or has disease progression (Reference 83).

Sputum cultures are not routinely performed in children. Obtaining a culture of the throat or respiratory secretions may not accurately reflect the organisms that are causing infection in the lower respiratory tract and may result in the inappropriate use of antimicrobials (Reference 84). Unfortunately, for most bacteria, the only way to confirm the causative organism is to obtain a bacterial culture from pleural fluid or an empyema, if present. Polymerase chain reaction tests that measure the presence of DNA are available for some organisms, such as *M. pneumoniae*, and should be used when a child presents with symptoms consistent with pneumonia from atypical organisms (References 83, 84). Viral antigen testing is not helpful in differentiating bacterial from viral pneumonia because the presence of a virus does not exclude a bacterial process, although it may be useful for infection control in a hospital setting.

### Prevention

Vaccination against influenza, *S. pneumoniae*, and *H. influenzae* type B can markedly decrease a child's risk of developing pneumonia. Since the introduction of the pneumococcal conjugate vaccine in 2000, the incidence of hospitalization because of pneumonia from any cause has decreased by 33% in children, and the incidence of hospitalization from pneumococcal pneumonia has decreased by 61% (Reference 85). Refer to the Pediatric Vaccines chapter for a more detailed discussion of these vaccines.

### Treatment

The primary goals of therapy for CAP are to eradicate the infection and prevent the development of complications, such as empyema, necrotizing pneumonia, or death. Children who are afebrile and not critically ill (e.g., without hypoxia or signs of respiratory distress) may be treated as outpatients. Infants and children with suspected pneumonia in the following situations should be hospitalized: those younger than 6 months; those who appear dehydrated or cannot tolerate oral liquids;

those with respiratory distress or persistent hypoxia; those with CAP caused by a highly virulent organism (e.g., community-associated methicillin-resistant *S. aureus* [CA-MRSA]); and those who may have unreliable family or social situations that make follow-up difficult (References 75, 78, 83). Hospital admission should also be considered for children with underlying chronic medical conditions or children whose outpatient management has failed. Because recovery of the causative organism is rare in children with CAP, treatment is usually empiric and should include coverage of the organisms most likely to cause pneumonia in the child's age group.

### VIRAL PNEUMONIA

Children who are younger than 5 years typically develop pneumonia from viral pathogens. A child with viral pneumonia should be treated with supportive care because antibiotics are not effective in this situation. Antipyretics such as acetaminophen or ibuprofen may be useful for children with a low-grade fever. Children with viral pneumonia should be encouraged to maintain good fluid intake to avoid dehydration. Antivirals should be used in infants or children infected with influenza who are at high risk of complications from infection.

### NEONATAL PNEUMONIA

During the neonatal period (up to 1 month of age), pneumonia is typically caused by pathogens that colonize the genitourinary tracts of pregnant women, specifically group B *Streptococcus* and *E. coli*. Neonates with bacterial pneumonia should be hospitalized to manage potential respiratory distress and facilitate the use of intravenous antibiotics. Empiric therapy should consist of ampicillin and an aminoglycoside (usually gentamicin) or a third-generation cephalosporin (usually cefotaxime). Ceftriaxone should not be used in this population because of the risk of kernicterus.

### PNEUMOCOCCAL PNEUMONIA

The treatment of choice for pneumococcal CAP in children receiving outpatient therapy is amoxicillin (References 78, 83, 84). Amoxicillin should be administered at a dose of 80–100 mg/kg/day divided two or three times/day to adequately treat penicillin-resistant *S. pneumoniae* (PRSP) (References 78, 84). *S. pneumoniae* exhibits resistance to  $\beta$ -lactam antibiotics by alterations to penicillin-binding proteins, which often can be overcome by high doses of  $\beta$ -lactams (Reference 86). Because pneumococci do not produce  $\beta$ -lactamases, amoxicillin/clavulanate has no additional benefit in the

treatment of pneumococcal pneumonia (Reference 84). For children with an allergy or intolerance to amoxicillin, a second- or third-generation cephalosporin may be used unless the child has had a type 1 hypersensitivity reaction to  $\beta$ -lactam antibiotics (Reference 83). Other alternatives for outpatient management of CAP include levofloxacin (if susceptible) or linezolid. Clindamycin is another viable alternative if community resistance rates are low (typically, less than 10%). Once treatment is initiated, symptomatic improvement should occur within 48–72 hours. If a child does not respond to therapy, further evaluation is warranted to rule out other causes of the child's symptoms. Therapy duration for outpatient management of CAP in children is typically 7–10 days.

For children who require hospitalization, intravenous antibiotics should be used. If *S. pneumoniae* has been isolated in a child with CAP, therapy should be selected on the basis of the penicillin minimum inhibitory concentration (MIC) for the organism. For *S. pneumoniae* isolates with a penicillin MIC of 2 mcg/mL or less, ampicillin or aqueous penicillin G is preferred (Reference 83). Alternative for *S. pneumoniae* with a penicillin MIC of 2 mcg/mL or less are ceftriaxone, cefotaxime, clindamycin (if susceptible), or vancomycin. For *S. pneumoniae* isolates with a penicillin MIC of 4 mcg/mL or higher, ceftriaxone is the preferred agent. Alternative agents for isolates of *S. pneumoniae* with a penicillin MIC of 4 mcg/mL or higher include high-dose ampicillin, clindamycin (if susceptible), vancomycin, levofloxacin, or linezolid. For children hospitalized with CAP, the therapy duration is typically 10–14 days. Longer treatment durations may be necessary in children who develop complications, such as lung abscesses or necrotizing pneumonia.

### PNEUMONIA CAUSED BY ATYPICAL ORGANISMS

Empiric coverage of atypical organisms should be added to pneumococcal coverage in both the inpatient and outpatient management of CAP beyond the neonatal period whenever there is a high degree of suspicion that an atypical organism is present. Macrolide antibiotics are generally the preferred treatment for the atypical organisms (*M. pneumoniae*, *C. pneumoniae*, and *Chlamydia trachomatis*). Azithromycin is the preferred macrolide antibiotic in children because of its tolerability and shorter treatment duration. Azithromycin should be administered at a dose of 10 mg/kg on day 1 and then 5 mg/kg/day on days 2–5 (References 78, 84). For children who may be at risk of not adhering to therapy, azithromycin may alternatively be administered at 10 mg/kg/day for 3 days. For children unable to tolerate oral medications, azithromycin is also available in an injectable form. Because of increasing resistance rates of *S. pneumoniae* to macrolides, empiric therapy

for pneumonia beyond the neonatal period should include a  $\beta$ -lactam antibiotic in addition to azithromycin. For children in whom coverage of atypical organisms is warranted but who have an allergy or intolerance to macrolide antibiotics, doxycycline or a fluoroquinolone may be used (Reference 87). Doxycycline should not be used in children younger than 8 years because of the risk of permanent tooth staining. Fluoroquinolones have shown joint toxicities in studies of juvenile animals. Although permanent joint damage has not been observed in children, the AAP recommends that the use of fluoroquinolones be reserved for situations when safe alternative therapies are not available (Reference 88).

## CONCLUSIONS

Children who have viral pneumonia should be treated with supportive care. Antibiotics offer no benefit to children with viral pneumonia. Pneumococcus is a common cause of bacterial pneumonia in children and can be treated using high-dose amoxicillin in an ambulatory setting, even for penicillin-resistant *S. pneumoniae*. Empiric therapy for pediatric CAP should include amoxicillin and azithromycin when there is a high degree of suspicion that an atypical organism is contributing to disease.

## LUNG ABSCESSES, EMPYEMAS, AND NECROTIZING PNEUMONIAS

### Epidemiology

Lung abscesses, empyemas, and necrotizing pneumonias are some of the more serious complications associated with CAP in children. The incidence of these complications of CAP in children has increased during the past 10–15 years (References 85, 89–91). An increase in the incidence of complications of CAP from pneumococcal serotypes not contained in the heptavalent vaccine has also been reported (References 85, 92). One study reported that children who had been treated with antibiotics or ibuprofen for CAP before hospitalization had an increased risk of developing an empyema. In addition to having more severe disease, children with empyemas were more likely to have a fever lasting more than 7 days and the presence of chest pain, which suggests a more prolonged disease course (Reference 89). Additional risk factors for empyemas include children 3 years and older and children with varicella infection within 1 month of hospitalization (Reference 89).

### Etiology

Organisms most commonly associated with empyemas and necrotizing pneumonias are *S. pneumoniae*, *S. aureus* (including methicillin-resistant *S. aureus* [MRSA]), and group A *Streptococcus* (References 78, 85, 89–94). Other organisms that have been isolated in children

with empyemas or necrotizing pneumonia include *M. pneumoniae*, *Streptococcus milleri*, viridans streptococci, *H. influenzae*, *Fusobacterium* spp., *Eikenella* spp., *Pseudomonas aeruginosa*, other gram-negative organisms, and *M. tuberculosis* (References 78, 90, 94–98).

### Clinical Presentation

Symptoms of empyema or necrotizing pneumonia may be similar to those seen with CAP and include fever, tachypnea, and chest pain (References 78, 94). The development of symptoms in someone with an empyema or necrotizing pneumonia is generally a more insidious process than what is typically seen with CAP. A child with an empyema or necrotizing pneumonia will generally be more ill-appearing than will a typical child with CAP and may present with chest pain and splinting (Reference 78). On physical examination, absent or diminished breath sounds may be noted, as well as dullness upon percussion of the chest wall (References 78, 94). Empyemas rarely cause increased mortality in children (Reference 97).

### Diagnosis

Chest radiographs are often performed to document the presence of pneumonia, but they are not sensitive enough to confirm the presence of an empyema (Reference 97). Necrotizing pneumonias and cavitations may be detected by chest radiograph. Any child who presents with a cavitary lesion on chest radiography should be evaluated for tuberculosis. Ultrasonography may be useful for differentiating a pleural effusion from a loculated fluid collection, which may require surgical intervention (Reference 97). A chest computed tomography (CT) may also be helpful for diagnosing an empyema; however, it should not be used routinely for children with pneumonia because of the high-radiation exposure dose associated with CTs (Reference 97). Sputum and throat cultures are not helpful in identifying the organism responsible for causing empyema or necrotizing pneumonia in children. If surgical drainage of a fluid collection, empyema, or abscess is performed, the material should be sent to the microbiology laboratory for Gram stain and culture to provide targeted antimicrobial therapy.

### Treatment

The goals of therapy for the treatment of empyemas, lung abscesses, or necrotizing pneumonia are to limit the destruction of lung tissue and prevent further morbidity or mortality.

### Surgical Management

Many children with empyemas will require surgical intervention to improve lung function and speed the healing process. Whether to perform surgical drainage of an empyema early in the course of disease is controversial. In one study, about one-half of the children evaluated were

successfully treated with antibiotics alone (Reference 99). Children who were treated with only antibiotics had significantly shorter lengths of hospital stay, fewer days of fever during hospitalization, and fewer days of intravenous antibiotics (Reference 99). Children who required surgical drainage were more likely to be younger, have a large effusion, have a loculated effusion, have a mediastinal shift, or require mechanical ventilation (Reference 99). These data suggest children with small effusions who are not in danger of respiratory compromise can be managed with antibiotic therapy alone.

### Pharmacologic Therapy

Empiric therapy for children with empyemas or necrotizing pneumonias should include coverage of *S. pneumoniae* and *S. aureus*, including MRSA (Reference 101). If thoracentesis or a video-assisted thoroscopic surgical procedure is performed and bacterial cultures are obtained, then definitive antibiotic therapy should be targeted at the specific organisms identified once final identification and sensitivity results are known. The typical duration of therapy for an empyema or necrotizing pneumonia is 2–4 weeks.

### Antibiotics for the Management of Complications from CAP

#### Third-Generation Cephalosporins

Ceftriaxone is most commonly used as monotherapy for the treatment of empyemas and necrotizing pneumonias caused by *S. pneumoniae*, even when the penicillin MIC is 4 mcg/mL or greater (Reference 83) (Table 6). Cefotaxime is an acceptable alternative to ceftriaxone at institutions where ceftriaxone is not on formulary. Ceftriaxone has only moderate activity, at best, against *S. aureus*, and no activity against MRSA (References 78, 87). As a result, it should not be used as monotherapy for empiric therapy in a child with an empyema or necrotizing pneumonia. Ceftriaxone also shows good activity against many gram-negative organisms, except for *P. aeruginosa*, *Enterobacter* spp., and *Citrobacter* spp. Ceftriaxone should be administered at a dose of 100 mg/kg/day intravenously given once or twice daily and is generally well tolerated. Adverse effects may include cholelithiasis and gallbladder sludging. The second- and third-generation cephalosporins (e.g., cefpodoxime, cefuroxime, cefprozil) are acceptable agents for step-down oral therapy when a child with an empyema is stable enough to transition to outpatient therapy.

#### Vancomycin

Vancomycin is typically used empirically in combination with a third-generation cephalosporin for the treatment of empyemas and necrotizing pneumonias. Vancomycin has good coverage against *S. pneumoniae*, *S. aureus*,

and MRSA (References 81, 86). Vancomycin has lower tissue penetration and slower antibacterial activity than other antibiotics typically used for pneumonia. As a result, vancomycin should be discontinued if an organism other than MRSA is identified and the child can tolerate the antibiotic of choice, or a reasonable alternative, for the identified organism. Vancomycin should be initiated at a dose of 15 mg/kg intravenously every 6 hours in most children (Reference 101). Some clinicians may prefer to initiate vancomycin at 8-hour intervals, especially in adolescents. Vancomycin peaks should not be monitored routinely. Vancomycin troughs should target a goal of 15–20 mcg/mL (Reference 102). The most common adverse effect associated with vancomycin is red man syndrome, which may include flushing of the face and neck from histamine release. Extending the vancomycin infusion time generally prevents further episodes of red man syndrome. Nephrotoxicity has also been associated with vancomycin administration, although this effect is more common with the concurrent administration of other nephrotoxic agents or in children who become dehydrated (Reference 102).

#### Clindamycin

Clindamycin is a reasonable alternative to vancomycin for the treatment of empyemas and necrotizing pneumonias caused by *S. pneumoniae* or *S. aureus* (if susceptible). It can be used in combination with a third-generation cephalosporin for empiric therapy or as monotherapy, if the causative organism is susceptible. Clindamycin has excellent oral bioavailability, so it has the advantage of offering an oral dosage form in children who are stable and can tolerate oral therapy. Clindamycin has good activity against staphylococci and streptococci, but CA-MRSA resistance is increasing. The Infectious Diseases Society of America recommends clindamycin not be used empirically when community resistance rates for MRSA are greater than 10% (Reference 101). If *Staphylococcus* is identified from a child with an empyema or necrotizing pneumonia, the practitioner should note the erythromycin susceptibility results in addition to the clindamycin susceptibility results. Methicillin-resistant *S. aureus* has the potential to carry a gene (*erm*) that codes for inducible clindamycin resistance (Reference 103). If a MRSA strain shows erythromycin resistance but is susceptible to clindamycin during the initial susceptibility testing, a disk diffusion test (also called a D-test) should be performed to rule out the presence of inducible clindamycin resistance (References 101, 103). Clindamycin is an acceptable choice for step-down oral therapy in children ready to transition to oral therapy, if the organism is susceptible. Clindamycin is typically administered at a dose of 40 mg/kg/day intravenously

**Table 6.** Dosing of Antibiotics Used for Pediatric Respiratory Tract Infections (References 83, 100)

<b>Antibiotic</b>	<b>Neonates<sup>a</sup></b>	<b>Infants and Children</b>
Amoxicillin	30 mg/kg/day divided BID	80–100 mg/kg/day divided TID
Amoxicillin/ Clavulanate	30 mg/kg/day divided BID	80–100 mg/kg/day divided TID
Ampicillin	50–100 mg/kg/day divided BID or QID	150–200 mg/kg/day divided QID 300–400 mg/kg/day divided QID for PRSP
Azithromycin	10 mg/kg/day	10 mg/kg on day 1; then 5 mg/kg day on days 2–5; OR 10 mg/kg/day for 3 days
Aztreonam	60–90 mg/kg/day divided BID or TID	90–120 mg/kg/day divided TID or QID
Cefazolin	40–60 mg/kg/day divided BID or TID	50–100 mg/kg/day divided TID
Cefepime	30 mg/kg/dose BID	50 mg/kg/dose BID
Cefotaxime	100 mg/kg/day divided BID	100–200 mg/kg/day divided TID
Ceftazidime	100 mg/kg/day divided BID	100–150 mg/kg/day divided TID
Ceftriaxone	Avoid	50–100 mg/kg/day QD or divided BID
Ciprofloxacin	Avoid	20–30 mg/kg/day divided BID
Clindamycin	15–30 mg/kg/day divided TID or QID	30 mg/kg/day divided TID or QID
Doxycycline	Avoid	2–4 mg/kg/day QD or BID
Gentamicin	3.5–5 mg/kg/day QD	2.5 mg/kg/dose TID or 5–7.5 mg/kg/day QD
Levofloxacin	Avoid	10 mg/kg/dose BID for children younger than 5 years; 10 mg/kg/dose QD for children 5 years and older
Linezolid	10 mg/kg/dose BID or TID	10 mg/kg/dose TID for children younger than 12 years, 10 mg/kg/dose BID for children 12 years and older
Meropenem	20 mg/kg/dose BID or TID	20 mg/kg/dose TID
Nafcillin	75–140 mg/kg/day divided TID or QID	100–200 mg/kg/day divided QID
Oxacillin	100–200 mg/kg/day divided TID or QID	150–200 mg/kg/day divided QID
Piperacillin/ Tazobactam	150–300 mg/kg/day divided TID or QID	200–300 mg/kg/day divided TID or QID
Ticarcillin/ Clavulanate	225–300 mg/kg/day divided TID	200–300 mg/kg/day divided QID
TMP/SMX <sup>b</sup>	Avoid	10–12 mg/kg/day divided BID
Tobramycin	3.5–5 mg/kg/day QD	2.5 mg/kg/dose TID or 5–7.5 mg/kg/day QD

<sup>a</sup>Dosing for full-term neonates.

<sup>b</sup>Dosed on the basis of the TMP component.

BID = twice daily (or every 12 hours); PRSP = penicillin-resistant *Streptococcus pneumoniae*; QD = daily; QID = four times/day (or every 6 hours); TID = three times/day (or every 8 hours); TMP/SMX = trimethoprim/sulfamethoxazole.

divided every 6–8 hours. The most common adverse effects associated with clindamycin are diarrhea (including *Clostridium difficile*-associated diarrhea) and taste intolerance for children who receive the oral liquid.

### **Doxycycline**

Doxycycline generally has good coverage against *S. aureus*, including MRSA, but it is not a good empiric choice for empyemas or necrotizing pneumonia in most children because of the risk of tooth discoloration and possible resistance. If a MRSA isolate sensitive to doxycycline is recovered in a child with an empyema, doxycycline is a reasonable alternative to vancomycin for step-down oral monotherapy. It is also a reasonable alternative to macrolides if coverage of atypical organisms is desired in a child who is allergic or intolerant. Doxycycline also has excellent oral bioavailability, and when the child can tolerate oral antibiotics, it can easily be transitioned to oral therapy. Doxycycline should be administered orally or intravenously at a dose of 2 mg/kg every 12 hours.

### **Linezolid**

Linezolid has good activity against most staphylococcal and streptococcal species, including MRSA, PRSP, and vancomycin-resistant enterococci. It has excellent oral bioavailability and offers an acceptable alternative to oral monotherapy on an outpatient basis. Although resistance to linezolid is rare, its use is limited by its high cost and high rate of thrombocytopenia, especially when used for more than 2 weeks (Reference 101). The average wholesale price of linezolid is around \$460 for a 150-mL bottle of 100 mg/5 mL suspension and around \$92 per tablet (600 mg) (Reference 22). For children younger than 12 years, linezolid is typically administered at a dose of 10 mg/kg every 8 hours. For children 12 years and older, it is typically administered at a dose of 10 mg/kg every 12 hours.

### **Fluoroquinolones**

Fluoroquinolones have broad-spectrum activity against many gram-positive and gram-negative organisms, with the exception of ciprofloxacin, which predominantly has gram-negative activity. Levofloxacin is the fluoroquinolone with gram-positive activity that is most often used in children because of its well-established dosing information. Levofloxacin generally has good activity against *S. pneumoniae* and may exhibit in vitro activity against MRSA; however, it should not be used routinely for MRSA because resistance develops when used as monotherapy (Reference 101). Ciprofloxacin is a reasonable choice for the treatment of an empyema or necrotizing pneumonia caused by gram-negative organisms such as *P. aeruginosa*; however, it lacks activity against *S. pneumoniae*. The fluoroquinolones also have very good oral bioavailability and may be used as

step-down therapy for children who are transitioning to outpatient therapy. For children 5 years and older, levofloxacin is typically administered at 10 mg/kg once a day. Ciprofloxacin may be administered at a dose of 10–15 mg/kg/dose every 12 hours, regardless of the child's age.

## **CONCLUSIONS**

Empiric therapy for empyemas, lung abscesses, and necrotizing pneumonias should include coverage of the organisms most commonly associated with these processes—*S. pneumoniae*, group A *Streptococcus*, and *S. aureus* (including MRSA). Many treatment options exist for these complications of CAP. Vancomycin in combination with a third-generation cephalosporin is often the mainstay of therapy until a definitive organism and its susceptibilities are identified. Therapy duration for these complications of CAP is not well defined and should be individualized on the basis of the child's response. Treating a child with 3–4 weeks of antibiotics for an empyema, lung abscess, or necrotizing pneumonia is common.

## **CHAPTER CONCLUSIONS**

Lower respiratory tract infections are a significant cause of hospitalizations in children and are among the most common reasons for a child to be seen in a primary care physician's office. Many LRTIs that are caused by viral infections respond well to symptom management. Bacterial LRTIs often require antibiotic therapy to prevent the transmission of the disease to other susceptible individuals and to limit the development of complications.

# CHAPTER 38

## INFECTIOUS DIARRHEA

Heather L. VandenBussche, Pharm.D.

### LEARNING OBJECTIVES

1. Describe the epidemiology of and risk factors for infectious diarrhea in children.
2. Identify when oral rehydration solutions are appropriate for treating dehydration in children with infectious diarrhea.
3. Describe the clinical presentation of each gastrointestinal infection in children.
4. Recommend appropriate therapies for children with infectious diarrhea.
5. Discuss preventive measures that can protect children from gastrointestinal infections.

### ABBREVIATIONS IN THIS CHAPTER

CDI	<i>Clostridium difficile</i> infection
EAEC	Enteraggregative <i>Escherichia coli</i>
EHEC	Enterohemorrhagic <i>Escherichia coli</i>
EIEC	Enteroinvasive <i>Escherichia coli</i>
EPEC	Enteropathogenic <i>Escherichia coli</i>
ETEC	Enterotoxigenic <i>Escherichia coli</i>
HUS	Hemolytic-uremic syndrome
ORS	Oral rehydration solution
ORT	Oral rehydration therapy

### INTRODUCTION

Infectious diarrhea accompanied by dehydration is the second leading cause of global pediatric morbidity and mortality, resulting in more than 1.5 million deaths annually in children younger than 5 years (Reference 1). More than 80% of pediatric deaths from infectious diarrhea occur in Africa and South Asia (Reference 1). In the United States, acute gastrointestinal infections are less common than in the developing world, and the elderly are at the highest risk of death. However, infectious diarrhea and dehydration still account for about 200,000 hospitalizations and 300 deaths annually among children in the United States (Reference 2).

Diarrhea, defined as having unusually loose or watery stools at least three times/day or more than usual for an individual, is frequently a symptom of gastrointestinal infections. Viruses are the most common cause of pediatric infectious diarrhea worldwide, but bacteria and parasites also play a role. Significant diarrhea can

lead to dehydration, which commonly occurs with cholera or after infection with rotavirus or enterotoxigenic *Escherichia coli* (ETEC). Management of infectious diarrhea focuses on preventing and treating dehydration and its complications in addition to limiting the spread of infection to others, which occurs mainly by the oral-fecal route.

Several factors increase the risk of spreading gastrointestinal infections and developing diarrhea and its complications. The most significant risk factor for contracting infection is behavior that increases the likelihood of fecal contact, including lack of handwashing after defecation or handling feces before handling food. In addition, day care attendance and living in crowded conditions increase the risk of contact with contaminated excrement. Ingestion of certain foods and exposure to reptiles or other pets increase the risk of exposure to specific infecting pathogens. In developing countries, polluted water sources, poor sanitation practices, contaminated food, and malnutrition contribute to the spread and severity of infectious diarrhea (Reference 1). International travel to developing countries can result in traveler's diarrhea after the consumption of contaminated food or water.

Children and immunocompromised individuals have an increased risk of dehydration and severe disease from gastrointestinal infections. Water makes up a greater proportion of body weight in children than in adults, and children use more water to support metabolism and conserve less water through their kidneys. Thus, acute body water losses that occur with diarrhea have a greater effect in children, increasing the risk of dehydration. Immunocompromised conditions and the relatively immature immune system in young children contribute to more severe illness from gastrointestinal infections.

### REHYDRATION THERAPY

Fluid replacement, electrolyte balance, and maintenance of normal feeding are vital components for managing dehydration from infectious diarrhea, regardless of the cause. The appropriate route of administration for replacement fluids depends on the severity of dehydration, as characterized by percent loss in body weight and clinical presentation. Table 1 displays the clinical signs and symptoms that are useful for categorizing dehydration in children and the recommended

**Table 1.** Clinical Signs and Symptoms and Fluid Replacement Therapies Associated with Degree of Dehydration in Children

Sign or Symptom or Therapy	Minimal or No Dehydration (< 3% Loss of Body Weight)	Mild to Moderate Dehydration (3% to 9% Loss of Body Weight)	Severe Dehydration (> 9% Loss of Body Weight)
Mental status	Normal; alert	Normal to fatigued or irritable	Lethargic, apathetic; unconscious
Fontanelle	Normal	Normal to sunken	Sunken
Eyes	Normal	Sunken orbits; decreased tears	Deeply sunken orbits; absent tears
Mucous membranes	Normal; moist	Slightly dry to dry	Parched
Thirst	Normal	Thirsty	Too lethargic to drink
Heart rate	Normal	Normal to increased	Increased; bradycardia in severe cases
Quality of pulse	Normal	Normal to decreased	Weak or not palpable
Blood pressure	Normal	Normal	Normal to reduced
Respirations	Normal	Normal to fast	Deep
Skin turgor	Normal recoil	Decreased recoil < 2 seconds	Recoil > 2 seconds
Extremities	Warm; normal capillary refill	Cool; delayed capillary refill	Cold, mottled, cyanotic; prolonged capillary refill
Urine output	Normal to decreased	Decreased	Minimal
Fluid replacement therapy	None	Oral rehydration therapy (ORT) at 50–100 mL/kg over 2–4 hours	Intravenous (IV) bolus of lactated Ringer's solution or normal saline 20 mL/kg (over 15–30 minutes) until perfusion and mental status improve; then IV fluids (5% dextrose with ½ normal saline) at twice maintenance rate or ORT 100 mL/kg over 4 hours

Adapted from References 2 and 3.

replacement fluids for each stage. Severe dehydration should be treated initially with intravenous fluids, whereas mild to moderate dehydration is best managed with oral rehydration therapy (ORT) (References 2–6).

### Severe Dehydration

Severe dehydration is a medical emergency that requires immediate and rapid rehydration to avoid vital organ damage from low tissue perfusion. Intravenous resuscitation should occur with lactated Ringer's solution or normal saline using an initial bolus dose of 20 mL/kg for most children. Children who are frail or malnourished should receive 10 mL/kg to avoid edema from reduced cardiac output (Reference 2). Several bolus doses may be necessary and should be given until pulse, perfusion, and mental status are normalized. Once these parameters have stabilized, rehydration therapy can be switched to the oral route when tolerated.

### Mild to Moderate Dehydration

Oral rehydration is highly effective for treating mild to moderate dehydration and has the advantages of being noninvasive, inexpensive, and capable of being administered at home (References 2, 3). Development

of glucose-based oral rehydration solutions (ORS) was based on the principle of coupled glucose and sodium transport. These nutrients are co-absorbed across intestinal brush border luminal cell membranes into enterocytes, where they are then pumped into the bloodstream through different transmembrane transporter systems. Water reabsorption occurs because of the osmotic gradient generated by these transport systems, which remain intact even in severe diarrhea (Reference 2). Mixtures of ORS, which contain water, salts, and glucose, are recommended to have low osmolality (about 245 mmol/L) to reduce the stool output and vomiting associated with solutions with high osmolality (Reference 6). Additional information on the management of dehydration from diarrhea can be found in the Diarrhea and Constipation chapter.

## NONBACTERIAL CAUSES OF INFECTIOUS DIARRHEA

### Viral Gastroenteritis

Viruses cause more than one-half of all pediatric diarrheal illnesses, which can occur in epidemics or as sporadic illnesses. Viruses that cause gastroenteritis include rotavirus, noroviruses, enteric adenoviruses, astroviruses,

and coronaviruses. Rotavirus is a predominant cause of infectious diarrhea worldwide, infecting all children by age 5 years (Reference 7; more information can be found in the Pediatric Vaccines chapter). Immunity is usually incomplete after an initial rotavirus infection, but it may be protective against more severe illness after subsequent infection. Noroviruses are responsible for around 50% of all gastroenteritis outbreaks, and they were recently reported as the leading cause of acute infectious diarrhea in the United States in all age groups (Reference 8). Noroviruses are highly contagious and are spread through contaminated food and water, creating outbreaks in institutions such as health care facilities, schools, and child care centers, as well as on cruise ships. Immunity to norovirus infection is complex and may depend more on innate host factors (such as cell receptor mutations that block viral entry into host cells) than on antibody development.

Ingestion of viruses through contaminated food or water or after contact with contaminated surfaces can lead to significant diarrhea and dehydration. Viruses directly damage the intestinal lining, leading to impaired absorption and subsequent fluid and electrolyte loss. Brush border enzyme activity is reduced, which can result in transient lactose intolerance. After an incubation of 12 hours to 3 days, clinical manifestations of viral gastroenteritis develop, which often begin with vomiting. Nonbloody diarrhea, abdominal cramping, and nausea are usually present. Viral gastrointestinal infection can also be asymptomatic or associated with extraintestinal symptoms such as fever, myalgia, headache, or malaise. Symptoms typically resolve in 12–48 hours for norovirus infection or 3–7 days for rotavirus. Diagnosis of viral gastroenteritis is made by detecting stool viral antigens through enzyme immunoassay, latex agglutination assay, or polymerase chain reaction (PCR).

Treatment of viral diarrhea is mainly supportive. Rehydration with ORS or intravenous solutions replaces fluids and electrolytes lost through stool or vomitus. Children should continue their normal diet when possible, but foods and liquids high in simple sugars should be avoided because they can aggravate diarrhea. Probiotics containing *Lactobacillus rhamnosus* GG in doses of 10 billion colony-forming units have been shown to reduce the amount and duration of diarrhea by about 1 day when given to children early in the course of rotavirus infection (References 9–11). Probiotics should not be used in children with short gut syndrome or immunodeficiencies because of the risk of bacteremia and sepsis from probiotic strains. Loperamide, an opioid antiperistalsis agent, may reduce the duration of viral diarrhea, but it is not recommended for children younger than 3 years or in those who are malnourished, who are moderately to severely dehydrated, or who have bloody

diarrhea (Reference 12). These patient groups are at high risk of adverse events such as lethargy, ileus, and respiratory depression. Antimicrobials have no role in the management of viral gastroenteritis.

Zinc supplementation may reduce the duration of acute viral diarrhea in children who are at least 6 months of age and at risk of zinc deficiency (References 2, 13). Developing countries have high rates of malnutrition and zinc deficiency; zinc is poorly absorbed from grains, nuts, and legumes, whereas high levels of zinc are found in meat and fish. Zinc promotes a healthy gastrointestinal tract mucosa and restores brush border enzyme activity in addition to stimulating immunity against gastrointestinal pathogens (References 6, 13). Zinc doses of 10–20 mg/day given for 10–14 days should be considered for children with acute viral diarrhea, particularly those who are malnourished or at risk of zinc deficiency (References 6, 13).

Prevention of viral gastroenteritis focuses on proper hygiene and vaccination. Handwashing with plain soap and running water for at least 20 seconds is essential for caregivers and individuals with diarrheal illness, particularly after defecation or potential contact with feces and before food preparation and ingestion. Hand sanitizers are an alternative to handwashing but should not be considered a substitute (Reference 8). Handwashing may be more effective at removing viral organisms from the skin through its mechanical process than alcohol-based hand sanitizers. The only vaccine available to protect against diarrheal illness is the rotavirus vaccine recommended for infants (refer to the Pediatric Vaccines chapter for more information).

### Parasitic Gastrointestinal Infections

Infectious diarrhea can be caused by parasites in both the developing world and industrialized nations. In the United States, *Giardia lamblia* and *Cryptosporidium* are two protozoan parasites that commonly infect immunocompromised and immunocompetent children. Giardiasis is reviewed in the Parasitic Infections in Pediatrics chapter; thus, this section will focus on cryptosporidiosis.

Cryptosporidiosis is widespread in the United States and has increased in all states in recent years. In 2008, 3.5 cases were reported per 100,000 population; the highest incidence was in children between 1 and 9 years of age, and the peak time for infection was during summer and early fall (Reference 14). *Cryptosporidium* is often transmitted through recreational water such as swimming pools or through exposure to infected animals, particularly cattle. Risk factors for cryptosporidiosis include the use of public swimming pools or other freshwater sources, contact with cattle or incontinent children, international travel to areas of high endemicity, immunodeficiency, and consumption of a large amount of unboiled well water.

Cryptosporidiosis occurs after the ingestion of *Cryptosporidium* oocysts found in fecally contaminated food or water or through direct person-to-person contact. Infection is usually limited to the intestinal surface epithelia where the parasite attaches, causing a loss of microvilli, inflammation, and subsequent malabsorption and enhanced secretion. As few as 10–30 ingested oocysts can cause infection that can persist in an individual because of repeated life cycles within the gastrointestinal tract (Reference 15). Oocysts are shed in feces for up to 2 months after diarrhea subsides and are infectious immediately upon excretion (Reference 14). Although some infections may be asymptomatic, most individuals have profuse, watery diarrhea that contains mucus and lasts for about 2 weeks. Nausea, vomiting, and abdominal cramping may accompany the diarrhea, and fever may also be present. Patients with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) can have a severe, cholera-like presentation that can persist for the patient's lifetime. Diagnosis of cryptosporidiosis is made when oocysts are identified on acid-fast staining of stool or when stool antigens are identified through immunoassay techniques.

Treatment of cryptosporidiosis does not routinely eradicate the infection, particularly in immunocompromised hosts. Immunocompetent individuals and those who are asymptomatic generally do not need antimicrobial therapy because the infection is self-limiting. Nitazoxanide (100 mg orally twice daily for 3 days) may be considered for treatment of malnourished immunocompetent children with prolonged diarrhea because it has been shown to induce a positive parasitologic response and reduction in diarrhea (References 16, 17). Nitazoxanide has a unique mechanism of action involving interference with anaerobic energy metabolism through the disruption of electron transport, and it is not associated with any significant adverse effects. Optimal therapy in patients with HIV/AIDS is to restore immune function through the use of highly active antiretroviral therapy; if this is not possible or if it fails, antimicrobial and antidiarrheal therapies are recommended (Reference 15). Paromomycin, azithromycin, and nitazoxanide have been used but are only modestly effective in this population because of a sustained immunodeficient state.

Efforts to control cryptosporidiosis are best aimed at preventing oocyst transmission. Oocysts are resistant to many disinfectants and antiseptics, including chlorine, alcohol, and alkaline chemicals (Reference 14). Severely immunocompromised patients should avoid water from lakes or streams and contact with young animals, and all water should be boiled before consumption (Reference 15). All individuals should practice proper hygiene to prevent the spread and ingestion of oocysts and avoid swallowing water from swimming pools, lakes, ponds, streams, or other untreated water sources.

## BACTERIAL CAUSES OF INFECTIOUS DIARRHEA

Bacterial causes of infectious diarrhea are less common than viral causes, but their associated syndromes are well characterized. Two main categories of infection occur: enterotoxigenic (or watery diarrhea) and dysentery (or invasive diarrhea). Enterotoxigenic diarrhea is often self-limiting, whereas dysentery requires close monitoring of patients who have fever with stools containing blood and pus. Bacterial diarrhea is more common in summer months, whereas viral diarrhea is more common in winter and spring. Antibiotic therapy, outlined in Table 2, may be indicated for certain infections.

### Shigellosis

Shigellosis, or bacillary dysentery, is a common cause of mortality from diarrhea. It affects around 165 million people worldwide, mostly children, and leads to more than 1 million deaths, 60% of which are in children younger than 5 years (References 18, 19). In the United States, 450,000 people are infected annually, with most cases caused by person-to-person transmission in day care centers and crowded living areas (Reference 18). Transmission occurs easily, requiring as few as 10–100 organisms to cause infection after ingestion (Reference 19). Shigellosis can also be spread through contaminated food and water, leading to large outbreaks.

*Shigella* spp. are nonmotile, gram-negative bacilli in the Enterobacteriaceae family. The four species most commonly associated with disease are *Shigella dysenteriae* type 1, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*. The most common species in the United States are *S. sonnei* and *S. flexneri*. After ingestion, bacterial replication and spread occur within intestinal epithelial cells and bowel mucosa and submucosa, leading to inflammation, ulceration, tissue sloughing, and bloody mucosal exudates. The entire colon is usually involved, but the infection seldom spreads to the bloodstream; bacteremia is more likely in malnourished and immunocompromised children. *S. dysenteriae* type 1 produces Shiga toxin, a virulence factor that causes more severe disease, and is associated with complications such as toxic megacolon and hemolytic-uremic syndrome (HUS). This syndrome is characterized by hemolytic anemia, thrombocytopenia, and renal failure; although rare, HUS can be fatal. Diagnosis of shigellosis is made after the development of dysentery and is confirmed by stool culture or PCR.

Shigellosis usually follows a biphasic pattern, with initial signs and symptoms including abdominal pain and cramping, fever, and frequent watery diarrhea. Within 48 hours, severe abdominal pain and tenderness develop, followed by bloody diarrhea and tenesmus, or a feeling of incomplete defecation with rectal pain. Fluid and electrolyte losses can be severe in infants and young children. If left

**Table 2. Antibiotic Therapy for Bacterial Infectious Diarrhea in Children**

<b>Infection Type</b>	<b>Indications for Antibiotics</b>	<b>Antibiotic Regimens</b>	<b>Considerations</b>
Shigellosis	Severe infection, immunocompromised, malnourished, day care attendance	Azithromycin 10 mg/kg/day orally × 3 days	Resistance rates unknown because of lack of reliable testing
		Ciprofloxacin 10–15 mg/kg twice daily orally × 3–5 days	Reserve for cases of multidrug resistance
		Ceftriaxone 50 mg/kg once daily intramuscularly × 2–5 days	Must be given parenterally; reaches gastrointestinal tract because of biliary excretion
<b>Salmonellosis</b>			
Gastroenteritis	Infants younger than 3 months, immunocompromised, hemoglobinopathies, malignancies, chronic gastrointestinal diseases	Trimethoprim/sulfamethoxazole 4–5 mg/kg (of trimethoprim) orally twice daily × 5 days	Avoid in children younger than 2 months; increased risk of kernicterus
		Ampicillin 25 mg/kg orally four times/day × 5 days	Local resistance rates to ampicillin may be high
Enteric (typhoid) fever, uncomplicated	All patients	Azithromycin 20 mg/kg orally once daily × 5–7 days	Resistance rates unknown because of lack of reliable testing
		Ceftriaxone 75 mg/kg intravenously once daily × 5–7 days	
Complicated enteric fever, extraintestinal infection	All patients	Ceftriaxone 75 mg/kg intravenously once daily × 10–14 days (4–6 weeks if endovascular infection, osteomyelitis, or meningitis)	Ampicillin can be used if isolate is susceptible
Enterotoxigenic <i>Escherichia coli</i>	Moderate to severe diarrhea	Azithromycin 10 mg/kg/day orally × 1–3 days	Drug of choice for children
		Rifaximin 200 mg three times/day orally × 3 days	Indicated only for children 12 years and older
Campylobacteriosis	Severe bloody stools, elevated temperature, prolonged illness, pregnancy, immunocompromised	Azithromycin 20–30 mg/kg/day orally × 1 dose or 10 mg/kg/day orally × 3 days	Drug of choice
Cholera	Severe infection	Doxycycline 4 mg/kg orally once	Avoid in children younger than 8 years because of effects on tooth formation and bone growth
		Azithromycin 20 mg/kg orally once	
<i>Clostridium difficile</i> infection	Moderate illness or mild-moderate illness that persists after discontinuing antibiotic therapy	Metronidazole 7.5 mg/kg orally four times/day × 10–14 days	Drug of choice; can be given intravenously if oral administration is not an option
	Severe illness or failure of metronidazole	Vancomycin 10 mg/kg orally four times/day × 10–14 days	Reserved for severe illness because of high cost and concern for vancomycin resistance emergence

untreated, shigellosis lasts about 1 week, but organisms can be excreted for up to 30 days after illness onset (Reference 19). Complications that are more common in children include rectal prolapse, seizures, and malnutrition.

Shigellosis is generally self-limiting and may require fluid replacement therapy if dehydration becomes significant. Antibiotic therapy is usually not indicated unless the infection is severe or occurs in a child who attends day care, is immunocompromised, or is malnourished. Antibiotics shorten the duration of diarrhea and reduce infectivity by minimizing fecal shedding; however, antimicrobial resistance among *Shigella* is a growing concern and is well documented worldwide (Reference 19). Nationwide, more than 60% of strains are resistant to ampicillin, and more than 40% are resistant to trimethoprim/sulfamethoxazole; however, there is minimal resistance to ceftriaxone and fluoroquinolones (Reference 20). Higher resistance rates may occur in certain geographic locations, so clinicians should request culture and susceptibility results when antibiotic therapy is indicated (Reference 21). Empiric antibiotic regimens for shigellosis in children can be found in Table 2. Azithromycin is the empiric drug of choice, but susceptibility breakpoints have not been established by the Clinical and Laboratory Standards Institute, so detection of resistance is not routinely identified (Reference 21). Ciprofloxacin should be reserved for cases of multidrug resistance, and parenteral ceftriaxone can be given to children who are unable to tolerate oral antibiotics (Reference 22). If susceptible, ampicillin or trimethoprim/sulfamethoxazole can be used. Antimotility agents are not recommended for shigellosis because they can worsen dysentery and increase the risk of complications such as toxic megacolon.

Preventing the spread of shigellosis is important to minimize outbreaks. Control measures should include strict hand hygiene, proper food cooking and storage, avoidance of recreational water or day care attendance for at least 1 week after diarrhea resolution, exclusion of infected individuals from handling food, and preventing child care workers from preparing food if they change diapers. No vaccines are currently available for preventing shigellosis.

### Salmonellosis

Salmonellosis is a common foodborne illness in the United States, in which nontyphoidal strains cause more than 1 million infections annually, leading to 16,000 hospitalizations and 600 deaths (Reference 23). The incidence is highest in children younger than 1 year, which may be related to their reduced gastric acidity, gut immaturity, or underdeveloped immune systems (Reference 24). Outbreaks are associated with contaminated food or water, but fecal-oral transmission is also likely in children. Infection typically results from the ingestion of contaminated vegetables or fruits; undercooked pork, poultry, or beef; or

unpasteurized dairy products. Accounting for up to 5% of cases, exotic pets including snakes, turtles, and iguanas are also an important source of infection because they are often carriers of *Salmonella* in their gastrointestinal tracts.

*Salmonella enterica* are motile, gram-negative bacilli in the Enterobacteriaceae family. Serotypes Typhi and Paratyphi are the most prevalent worldwide and cause enteric fever, or typhoid, from bacteremia. The nontyphoidal strains, serotypes Typhimurium and Enteritidis, are most common in the United States and primarily cause gastroenteritis, but they can lead to bacteremia and localized extraintestinal infections. The infectious dose of *Salmonella* (around 1 million organisms) is higher than with *Shigella* but is lower in people with reduced gastric acidity. Once ingested, the organisms penetrate the epithelial lining of the distal ileum and colon, causing inflammation, tissue damage, and fluid secretion across the intestinal mucosa. In certain individuals or with certain serotypes, bacteremia may occur after translocation through the intestinal wall and can lead to localized extraintestinal infections in areas such as bone, heart, central nervous system, or spleen. Diagnosis of salmonellosis is made upon isolating the organism from the stool in patients with gastroenteritis, or from blood or bone marrow in those with enteric fever. Recovery of *Salmonella* from stool is most likely early in the course of illness, but bacteria may continue to be shed for up to 12 weeks in children (Reference 25). About 1% of infected individuals become chronic carriers and shed organisms for more than 12 months because of biliary tract carriage (Reference 25).

Clinical manifestations of salmonellosis depend on the infecting serotype and the host. After the ingestion of nontyphoidal *Salmonella*, symptoms typically occur within 72 hours. Most patients experience nausea, vomiting, and abdominal cramping, followed by fever, headache, and diarrhea that is usually nonbloody. Gastroenteritis is often self-limiting and resolves in 3–7 days. Invasive disease and extraintestinal infections are more likely in infants younger than 3 months and in children with immunodeficiencies, malignancy, sickle-cell disease, or inflammatory bowel disease. After typhoidal strains are ingested, fever and non-specific systemic symptoms, including profuse sweating, headache, chills, anorexia, myalgias, and malaise, develop within 5–21 days. Diarrhea may be present in enteric fever, and sequelae such as intestinal bleeding or perforation, delirium, or hepatosplenomegaly can develop within 3 weeks of illness onset. *Salmonella* infection can also be asymptomatic, leading to a chronic carrier state.

Treatment of *Salmonella* infection depends on the clinical severity and host. Most cases of gastroenteritis do not require antibiotics, and their use may result in prolonged fecal shedding and a higher rate of chronic carriage. Supportive treatment with ORT is usually beneficial. Antibiotics are recommended for high-risk patients with nontyphoidal *Salmonella* infection: children

younger than 3 months or those with immunodeficiencies, hemoglobinopathies, malignancy, or chronic gastrointestinal tract disease (Reference 25). For typhoid fever and invasive *Salmonella* infections, antibiotic therapy is warranted. Empiric regimens for salmonellosis, found in Table 2, should consider geographic resistance patterns. Typhoidal strains, which tend to be more drug resistant, should be treated empirically with broad-spectrum agents (Reference 20). Culture and susceptibility results should be used to minimize broad-spectrum antibiotic use and to monitor for drug-resistant strains. On the basis of susceptibility testing, children who are chronic carriers should be treated with an antibiotic such as amoxicillin or trimethoprim/sulfamethoxazole for 3 months to eradicate the carrier state that promotes spread to others.

*Salmonella* infection can be prevented with a variety of approaches. These methods include meticulous hand hygiene, sanitary food preparation and water supplies, and sanitary sewage and waste disposal, as well as excluding infected individuals from handling food or attending day care. Children younger than 5 years and immunocompromised patients should avoid contact with reptiles and rodents. Eggs and meat should be cooked thoroughly, and foods containing raw eggs should not be ingested. Breastfeeding is protective against infantile salmonellosis because it provides passive immunity and limits exposure to potentially contaminated formula or water. Typhoid fever can be prevented through vaccination using one of two typhoid vaccines: an oral live-attenuated vaccine or an injectable capsular polysaccharide vaccine. Vaccination is recommended for children who are traveling to an endemic area such as Africa, Asia, or Latin America or who are household contacts of chronic carriers. The oral vaccine can be given to children 6 years and older (four doses given every other day), whereas the injectable vaccine can be used in children as young as 2 years (a single dose). The oral vaccine should not be used in children who are immunocompromised or who have an active gastrointestinal tract illness.

### *E. coli*

Infectious diarrhea caused by *E. coli* is categorized on the basis of pathogenic characteristics. Enterotoxigenic *E. coli* (ETEC) is the most common form of *E. coli* diarrhea worldwide, with around 80,000 cases occurring annually in the United States mainly from international travel (Reference 26). Enterotoxigenic *E. coli* causes watery diarrhea and is associated with foodborne outbreaks and traveler's diarrhea in areas where sanitation is inadequate. Person-to-person transmission is uncommon because infection requires a relatively large inoculum. In contrast, enterohemorrhagic *E. coli* (EHEC) causes bloody diarrhea, which can result in hemorrhagic colitis, HUS, and potentially death. Interpersonal spread occurs easily with EHEC because ingestion of only a few

organisms can lead to infection. In the United States, EHEC is often caused by *E. coli* 0157:H7. Outbreaks of EHEC are associated with contaminated beef or vegetables, unpasteurized dairy products or apple cider, and exposure to animals in petting zoos. Enteroinvasive *E. coli* (EIEC) and enteropathogenic *E. coli* (EPEC) occur mainly in children in developing countries. Enteroregative *E. coli* (EAEC) is common in HIV infection and usually leads to persistent watery diarrhea.

*E. coli* is a gram-negative bacillus found in the intestinal tract of humans, cattle, deer, and other farm animals. Gastrointestinal damage from *E. coli* infection varies depending on the infecting organism. Enterotoxigenic *E. coli* have the ability to produce cholera-like enterotoxins that cause profuse secretory diarrhea. Enterohemorrhagic *E. coli* produces Shiga-like toxins that disrupt large intestinal mucosa, creating bloody diarrhea. These toxins can invade the bloodstream and damage the vascular supply to the gastrointestinal tract and kidneys, resulting in HUS. Enteroinvasive *E. coli* resemble *Shigella* and cause intestinal damage and symptoms similar to dysentery. Enteropathogenic *E. coli* adhere to intestinal epithelial cells, which disrupts their integrity, leading to watery diarrhea. Enteroregative *E. coli* adhere to mucosal cells in a biofilm layer that causes persistent colonization, epithelial damage, and watery diarrhea. Diagnosis of *E. coli* diarrhea is complicated by the inability to differentiate between normal *E. coli* stool flora and diarrhea-associated strains. *E. coli* 0157:H7 can be detected by its inability to ferment sorbitol, followed by subsequent serotyping. Shiga-like toxins from EHEC can be detected with immunologic assays.

Clinical presentation of *E. coli* diarrhea manifests in different ways. Enterotoxigenic *E. coli* and other nonhemorrhagic strains cause abrupt watery diarrhea, nausea, and abdominal cramping that usually resolve in 24–48 hours. Enteropathogenic *E. coli* often cause low-grade fever and vomiting, whereas EAEC diarrhea is persistent and watery with minimal or no vomiting. Enteroinvasive *E. coli* can present with dysentery symptoms of bloody diarrhea that contains mucus and pus, tenesmus, and fever. Enterohemorrhagic *E. coli* is associated with severe symptoms that begin as abdominal cramping and distension, watery diarrhea, and nausea or vomiting but then progress to bloody diarrhea, with increased abdominal pain within 48 hours. Fever is not a common feature of EHEC. Although most cases resolve after 1 week, HUS can develop in up to 10% of patients with EHEC and is most common in children between 1 and 5 years of age (Reference 27).

All forms of *E. coli* diarrhea should be managed with fluid and electrolyte therapy to prevent dehydration. Enterohemorrhagic *E. coli* should not be treated with antibiotics because they may increase the release of toxins upon bacterial lysis, increasing the risk of HUS

(Reference 28). Antimotility agents should also not be used in EHEC because they can reduce the clearance of the organisms and toxins. For other forms of *E. coli* diarrhea, particularly those associated with travel, antibiotics may be considered for moderate to severe diarrhea, but antimicrobial resistance can affect treatment success. Table 2 lists empiric agents that can be considered. Loperamide can reduce the severity of ETEC, but bismuth subsalicylate should be avoided because of the risk of Reye syndrome in children.

Preventing *E. coli* infection focuses on the avoidance of contaminated food and water sources. Methods to prevent infection include proper cooking of ground beef, ingestion of only pasteurized milk or apple juice, and avoidance of tap water, uncooked or unpeeled foods, and inadequately stored foods during travel to developing countries. Use of proper hand hygiene and exclusion of symptomatic individuals from day care centers and recreational water sources are also helpful to prevent spread of infection. No vaccines are currently available to prevent *E. coli* infection.

### Campylobacteriosis

Campylobacteriosis is the most common bacterial cause of infectious diarrhea, accounting for up to 2.5 million cases annually in the United States (Reference 23). The two peak age groups for infection are children younger than 1 year and individuals between 15 and 44 years of age, and males are infected more commonly. Infection is transmitted through contaminated food or water and is often associated with poultry consumption. Risk factors for campylobacteriosis include exposure to chickens, other birds, or cats; consumption of undercooked poultry or other meats, unpasteurized milk, or contaminated water; international travel; and recent antimicrobial use.

*Campylobacter* spp. are motile, curved, gram-negative bacilli that are sensitive to gastric acid. The two most common species to cause diarrhea are *Campylobacter jejuni* and *Campylobacter coli*. Infectious doses are about 800 organisms but are lower in individuals with reduced gastric acidity. After ingestion, replication occurs in the small intestine, and organisms adhere to intestinal tissue in the jejunum, ileum, colon, and rectum, leading to local inflammation. Some strains of *C. jejuni* produce enterotoxins or cytotoxins that contribute to pathogenicity (Reference 29). Host immunity plays a role in the development of campylobacteriosis, and frequent exposure provides short-term protection against infection but not colonization (Reference 30). Diagnosis of campylobacteriosis is confirmed with stool culture or enzyme immunoassay.

Common clinical manifestations of campylobacteriosis occur within 1–7 days of ingestion and include fever, abdominal cramps, and diarrhea, which can be either watery or bloody. Dysentery occurs in around one-half of cases. Fever, headache, myalgia, and malaise

can also be present. Some patients may experience only abdominal pain with minimal diarrhea. Gastrointestinal symptoms usually resolve within 1 week or less. Extraintestinal infections may occur and are more common in immunocompromised children and neonates; these include sepsis, septic arthritis, meningitis, pancreatitis, cholecystitis, and osteomyelitis. Campylobacteriosis leads to about 30% of Guillain-Barré syndrome (GBS) cases, which occur within 3 weeks of infection, but the risk of developing GBS is less than 1 case per 1,000 *C. jejuni* infections (Reference 31).

The cornerstone of treatment of campylobacteriosis is ORT for hydration and electrolyte replacement. Antibiotics are usually unnecessary; they do not reduce illness duration or severity unless given within 4 days of symptom onset, but they can shorten the duration of bacterial shedding. Antibiotics should be considered in patients with severe bloody stools, elevated temperature, prolonged illness for longer than 1 week, pregnancy, and immunocompromised states (see Table 2). Macrolides are the agents of choice because of increasing fluoroquinolone resistance from overuse in enteric infections and use of fluoroquinolones in poultry. Severely ill children can be treated with intravenous gentamicin. Antimotility agents should be avoided because they prolong the duration of infection and enhance toxin retention.

Prevention of campylobacteriosis focuses on hand hygiene and avoiding contaminated food and water. Individuals should wash their hands, all utensils, and cutting boards after contact with uncooked poultry and avoid cross-contamination of vegetables and other foods with raw poultry juices. All poultry should be cooked thoroughly before eating. Hand hygiene is also important after defecation and contact with animal feces. Infected individuals should be excluded from food preparation and day care. No vaccine is currently available to prevent *Campylobacter* infection.

### Cholera

Cholera is uncommon in the United States but is endemic in areas of South Asia. Some strains cause pandemics, which have been reported mainly in parts of Africa and South America. Cholera causes loss of large volumes of watery stool, severe dehydration, and shock. It is transmitted through water or contaminated foods, especially undercooked shellfish or fish. Cholera grows well in warm temperatures and appears in moist grains stored at ambient temperatures. The infectious dose from environmental sources is around  $10^{10}$  organisms but is lower in those with reduced gastric acidity. Risk factors for cholera include the ingestion of undercooked seafood, low gastric acidity, and blood type O (Reference 32).

*Vibrio cholerae* is a motile gram-negative bacillus similar to Enterobacteriaceae, with several serogroups known to cause pandemics. Infection occurs when organisms colonize the small intestine after ingestion and penetrate the mucosal layer. Enterotoxin production is an important pathogenic feature of cholera that leads to excessive isotonic fluid loss in the small intestine, exceeding colonic absorptive capacity. Electrolyte-rich watery diarrhea develops, which is highly infectious and allows for person-to-person spread. Diagnosis is made upon request for isolation of vibrios from stool, which can be further serotyped at state laboratories.

Cholera occurs within a few hours to 5 days after ingestion. It is characterized by an abrupt onset of painless watery diarrhea and often vomiting. Stools are typically of large volume, reaching a loss of 1 L/hour, and have the consistency of rice water. Complications of cholera include hypoglycemia, seizures, renal failure, and mental status changes. Severe muscle cramps are common from electrolyte imbalances. Severe dehydration, metabolic acidosis, and shock occur rapidly and can progress to death within hours if untreated.

Rapid treatment of cholera with ORS is vital to replace fluids and electrolytes and thus prevent shock. Rice-based ORS is preferred because it is more effective than glucose-based ORS in reducing stool output and because it reduces overall fluid requirements (Reference 33). Intravenous rehydration with lactated Ringer's solution may need to be given before ORS if shock is present. Antibiotics should be given to children with severe disease because they can shorten the duration of diarrhea and reduce fluid loss (Table 2). Antibiotic resistance is common among endemic strains and should be monitored during outbreaks to ensure proper treatment is provided.

Prevention of cholera focuses on ensuring a safe water supply through proper sanitation, thorough cooking of seafood, and appropriate hand hygiene after defecation and before food preparation. Antibiotic prophylaxis for household contacts is not recommended because of resistance concerns. Two oral vaccines are available in other countries but not in the United States. Vaccination is not recommended for most travelers to endemic areas because the risk of infection is low, and the immunity provided by the vaccines is incomplete.

### ***Clostridium difficile* Infection**

*C. difficile* is the most common cause of nosocomial infectious diarrhea in the United States. Both the incidence of community-acquired disease and severe infection is increasing, and outbreaks from a single strain (North American pulsed-field type 1, or NAP-1) have emerged in recent years. *C. difficile* infection (CDI) is most common in adults, but the prevalence is increasing in children (Reference 34). Pediatric risk factors for CDI include solid-organ transplantation, presence of a gastrostomy or jejunostomy tube, recent receipt of

fluoroquinolone and other broad-spectrum antibiotics, inflammatory bowel disease, lack of previous hospitalization, and proton pump inhibitor or histamine-2 receptor antagonist therapy (References 34–36).

*C. difficile* is a gram-positive, spore-forming anaerobic bacillus that causes a toxin-mediated diarrhea. Infection occurs after the ingestion of organisms or spores that can survive harsh environmental conditions and are resistant to disinfectants, including alcohol. Ingested spores germinate in the small intestine and travel to the colon, where they can produce toxins A and B, which are responsible for disease. Toxin A, an enterotoxin, causes fluid and mucus secretion, mucosal damage, and inflammation, whereas toxin B, a cytotoxin, is more potent and causes mucosal damage. Pseudomembranous plaques form in the colon and enlarge with disease progression to affect the entire colon and rectum. Diagnosis of CDI is made by detecting toxin A or B in the stool of symptomatic individuals. Endoscopy may be needed to diagnose CDI in individuals with an ileus.

*C. difficile* infection varies in severity from mild diarrhea to life-threatening pseudomembranous colitis and toxic megacolon. For antibiotic-associated infections, CDI can occur on the first day of antibiotic therapy or as late as several weeks after completing antibiotics. Diarrhea is usually watery and can be mild with only a few loose stools per day, accompanied by abdominal pain, low-grade fever, and mild leukocytosis. Colitis is characterized by frequent watery diarrhea with up to 15 bowel movements per day, abdominal pain and distension, nausea, anorexia, fever, and leukocytosis. Fulminant disease involves severe abdominal pain, profuse diarrhea, elevated temperature, dehydration, tachycardia, marked leukocytosis, and possibly hypotension. Some patients develop pseudomembranous colitis or an ileus. Toxic megacolon can develop with acute colonic dilation, signs of systemic disease (elevated temperature, tachycardia, hypotension), and cessation of bowel movements. Mortality is high if toxic megacolon develops. Some patients are asymptomatic carriers of *C. difficile*, which has been noted in up to 70% of infants (Reference 37).

Initial treatment of CDI should include halting antibiotic therapy when possible. Although some patients may respond to discontinuing antibiotics alone, antimicrobial therapy directed at *C. difficile* is recommended for most cases (Table 2). Oral metronidazole and oral vancomycin have similar efficacy in mild illness, but vancomycin is preferred in severe illness. In patients who cannot receive oral therapy, intravenous vancomycin cannot be used because it does not achieve adequate concentrations in the gut; in these patients, intravenous metronidazole can be used with or without vancomycin enema, which is useful in cases of peristaltic ileus. Recurrent CDI occurs in about 20% of patients within 2–3 weeks of discontinuing treatment. Another course of the initial antibiotic is recommended in recurrent disease; relapse is not associated with antibiotic

resistance, but rather, failure to eradicate spores or re-infection from an environmental source. Newer antibiotics including fidaxomicin and nitazoxanide, which have been studied for CDI, may result in fewer recurrences, but their place in therapy is yet to be defined. Children with several relapses are difficult to manage; treatment options to consider are vancomycin pulse dosing, vancomycin tapers, intravenous immune globulin, or fecal bacteriotherapy (Reference 38). Adjunctive therapies for CDI, including cholestyramine and probiotics, have not consistently been proved beneficial. Antiperistaltic agents are contraindicated because they increase the risk of toxic megacolon, which often requires surgical intervention.

Measures to prevent *C. difficile* transmission focus on proper infection control methods. Handwashing with soap and water is necessary to prevent spread because alcohol-based products are not effective at eliminating spores. Health care providers should use contact precautions and wear gowns and gloves while caring for *C. difficile*-infected patients. Isolating infected patients should also be practiced in institutional settings. Chlorine-containing cleaners at a concentration of at least 1000 parts per million are effective in minimizing environmental contamination. Infected individuals should be excluded from day care settings until diarrhea subsides.

## TRAVELER'S DIARRHEA

Traveler's diarrhea occurs when people travel from industrialized nations to developing countries and consume contaminated water or food. Children with traveler's diarrhea are often infected with ETEC; *Campylobacter*, *Salmonella*, or *Shigella* spp.; or rotavirus. Risk factors for developing traveler's diarrhea include ingesting tap water, uncooked foods, and foods that are stored inadequately, such as buffet-style meals. Most cases occur within 2 weeks of travel and resolve in a few days. Typical signs and symptoms are malaise, nausea, anorexia, abdominal cramps, and mild to moderate diarrhea that can interfere with planned activities. Traveler's diarrhea is rarely life threatening.

Treatment focuses on avoiding dehydration with the use of ORS and returning to functional status as soon as possible. Antibiotics, which can reduce the duration of diarrhea, should be considered in children having diarrhea for longer than 24 hours (Reference 39). Azithromycin 10 mg/kg/day for 3 days is recommended for treating children instead of fluoroquinolones, which are typically used in adults (References 39, 40). In children 12 years and older, rifaximin is an alternative agent for use in travelers to Mexico or Jamaica, where *E. coli* is predominant. Antimotility agents are not recommended unless they are administered with antibiotics.

Prevention of traveler's diarrhea focuses on education and avoidance of high-risk foods and beverages. Antibiotic prophylaxis is not recommended because of antimicrobial resistance concerns. Bismuth subsalicylate taken four times/day for up to 3 weeks may inhibit enterotoxin activity, but it should not be used in children because of the risk of Reye syndrome. Probiotics may minimize infection from pathogenic organisms, but more studies are needed before they can be routinely recommended (Reference 39).

## CONCLUSIONS

Infectious diarrhea in children, which is caused by a variety of microorganisms, can result in significant dehydration and electrolyte disturbances. Although a large proportion of cases occur in developing countries, children in the United States are also susceptible because of contaminated food and water sources and international travel. Treatment should always involve rehydration, preferably with ORS, and antibiotics when appropriate. Knowledge regarding infectious sources and proper hygiene is vital to limiting the spread of infectious diarrhea.

# CHAPTER 39

## URINARY TRACT INFECTIONS IN CHILDREN

Juan Carlos Rodriguez, Pharm.D.

### LEARNING OBJECTIVES

1. Identify risk factors for the development of urinary tract infections (UTIs) in children.
2. Recognize the uropathogens and their mechanisms of entry into the urinary tract to cause infection.
3. Describe UTI classification systems, signs and symptoms, and diagnostic criteria in children.
4. Review the pharmacotherapeutic options employed in the treatment of pediatric UTIs.
5. Monitor pediatric UTI patients for drug efficacy and toxicity.

### ABBREVIATIONS IN THIS CHAPTER

CFU	Colony-forming unit(s)
LE	Leukocyte esterase
SPA	Suprapubic aspiration
US	Ultrasonography
UTI	Urinary tract infection
VCUG	Voiding cystourethrography
VUR	Vesicoureteral reflux
WBC	White blood cell

### INTRODUCTION

The urinary tract consists of the kidneys, ureters, bladder, and urethra. A urinary tract infection (UTI) occurs when pathogenic organisms infect any of the structural components of the urinary tract. Urinary tract infections are common in the pediatric population, leading to acute morbidity and potentially chronic medical sequelae, which include recurrent infections, acute renal injury, and potentially end-stage renal disease, which leads to hypertension, dialysis, and/or renal transplantation (Reference 1). Appropriate management of the pediatric UTI patient is directed at minimizing the risk for renal damage.

### Epidemiology

The overall incidence of UTIs in prepubertal children is reported to be 3% for females and 1% for males. However, UTI incidence varies with patient age and sex and, in males, whether the patient is circumcised. The incidence of UTI in females younger than 12 months ranges from 0.4% to 1%, whereas the rate is 0.188% in

circumcised and 0.702% in uncircumcised boys in this age group. In preschool children (1–5 years of age), the UTI incidence for girls is 0.9% to 1.4% and for boys, 0.1% to 0.2%. For school-aged children, there is a 0.7% to 2.3% incidence in females and a 0.04% to 0.2% incidence in males (References 1, 2).

Urinary tract infection prevalence is higher in children 12 months and younger who present with fever. One meta-analysis reported the UTI prevalence rates for girls as 7.5%, 5.7%, and 8.3% and for boys as 8.7%, 3.3%, and 1.7% for children younger than 3 months, 3–6 months, and 6–12 months, respectively. The prevalence varies significantly depending on the circumcision status of the males. The reported UTI prevalence for boys younger than 3 months is 2.4% if circumcised and 20.1% if uncircumcised. Urinary tract infection prevalence rate for boys 6–12 months of age is 0.3% if circumcised and 7.3% if uncircumcised. Mean UTI prevalence for pediatric patients younger than 19 years presenting with urinary symptoms and/or fever is reported as 7.8% overall in this meta-analysis (Reference 3).

### Etiology

The most common pathogens causing UTI are bacteria of enteric origin. *Escherichia coli*, a gram-negative rod, is the most prevalent pathogen, accounting for more than 80% of pediatric UTIs (References 4, 5). Other, less frequently isolated gram-negative urinary pathogens include *Citrobacter* spp., *Enterobacter* spp., *Klebsiella* spp., *Morganella morganii*, *Proteus mirabilis*, *Providencia stuartii*, *Pseudomonas aeruginosa*, *Serratia* spp., and *Neisseria gonorrhoea* (Reference 1). Gram-positive organisms that cause UTIs in children include *Enterococcus* spp., *Staphylococcus aureus*, *Staphylococcus saprophyticus*, *Staphylococcus epidermidis*, and group B and D streptococci (Reference 1). Less common uropathogens in children include *Candida albicans*, *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *Mycoplasma hominis*, and adenoviruses (Reference 6).

### Pathogenesis

The primary host defense mechanism against UTI is the continuous urine flow from the kidneys to the bladder, ultimately resulting in micturition and complete bladder emptying through the urethra. Normal urinary flow typically clears urinary tract pathogens. In addition, several antibacterial inhibitory factors in urine play protective

roles against UTIs. Inhibitory substances in urine include urea, organic acids, and salts. Urine pH and osmolarity also contribute to antibacterial activity. Low osmolarity inhibits bacterial growth; high osmolarity, if associated with low pH, is also inhibitory. Other substances that inhibit bacterial adherence to urinary tract mucosa include the Tamm-Horsfall protein, bladder mucopolysaccharide, low-molecular-weight oligosaccharides, secretory immunoglobulin A, and lactoferrin. The inflammatory response (e.g., polymorphonuclear neutrophils, cytokines) as well as humoral and cell-mediated immunity are other components involved in the urinary tract's host defense mechanism against invading pathogens (References 1, 4, 7). Specific host factors increase susceptibility to bacteriuria (References 1, 4, 7, 8). Table 1 summarizes the host factors and proposed mechanism of these factors in increasing the risk of UTI.

Bacterial factors also influence susceptibility to infection. Not all strains of bacterial species identified as UTI pathogens are capable of infecting the urinary tract. Specific virulence factors are necessary for bacteria to colonize cells of the urinary tract and facilitate ascension into the bladder (and potentially into the upper urinary tract) while evading the host defense mechanisms. Adhesins such as type 1 fimbriae and P fimbriae, which are commonly present in uropathogenic bacteria, promote urinary tract colonization. Type 1 fimbriae bind to mannose-containing receptors and are often found in *E. coli* strains that cause acute cystitis. Conversely, P fimbriae are mannose-resistant, and P fimbriated *E. coli* are strongly associated with acute pyelonephritis. After attachment to the uroepithelial mucosal surface, additional virulence factors (e.g., ureases, iron-scavenging proteins,  $\alpha$ -hemolysin, bacterial toxins) are produced to support continued bacterial growth within the urinary tract (Reference 4).

**Table 1.** Host Factors Associated with Increased Risk of UTIs in Children (References 1, 4, 7, 8)

Host Risk Factor	Proposed Mechanism/Supporting Observations
Younger age group (neonates and infants)	Incompletely developed immune system Breastfeeding may be protective by supplementing maternal IgA, lactoferrin, and anti-adhesive oligosaccharides.
Female sex	Periurethral and vaginal moisture promotes uropathogen growth. Shorter urethra increases probability of ascending infection.
Uncircumcised infants	Increased concentration of uropathogens in boys with foreskin
Fecal and perineal colonization	Colon and urogenital flora expressing specific virulence factors Antibiotic exposure may alter microflora, possibly resulting in more resistant microbial strains.
Constipation	Rectum chronically dilated by feces, leading to voiding dysfunction
Anatomic anomalies (e.g., posterior urethral valves, vesicoureteral reflux)	Inadequate clearance of uropathogens Surgical intervention may be required.
Functional abnormalities (e.g., neurogenic bladder)	Urinary retention, urinary stasis, and incomplete bladder emptying result in decreased urinary bacterial clearance.
Female sexual activity	Bowel and vaginal bacterial transfer to urethral meatus, leading to postcoital bacteriuria.
Spermicide use	Alteration of vaginal flora facilitating adherence of <i>Escherichia coli</i> to epithelial cells
HIV disease	Immunocompromised state
Renal transplantation	Immunocompromised state
Diabetes mellitus	Urine glucose supplies a growth medium for pathogens.
Genetic predisposition	White females are more likely to develop a UTI than their African American counterparts. Associations between specific blood group phenotypes and recurrent UTIs have been reported. Host cell receptors facilitating bacterial adherence to uroepithelium (e.g., $\alpha$ -Gal(14) $\beta$ -Gal receptor) have been identified.

HIV = human immunodeficiency virus; IgA = immunoglobulin A; UTI = urinary tract infection.

## Infection Pathways

Infection of the urinary tract typically occurs by one of four pathways. The most common pathway is retrograde ascent. Uropathogens associated with retrograde ascent usually originate from the host's gastrointestinal tract and colonize vaginal or periurethral areas. Vaginal flora may also serve as a reservoir for organisms causing UTIs. The pathogens enter the urinary tract through the urethra and migrate to the bladder, where they multiply and potentially progress to infect the upper urinary tract (i.e., kidney) (References 1, 7).

A second UTI pathway is nosocomial infection. Introduction of a foreign body or instrumentation (e.g., urethral catheterization) into the urinary tract increases the risk of UTI, particularly with longer durations of catheterization (References 1, 4). Nosocomial UTIs are associated with more resistant pathogens such as *Pseudomonas*, *Enterobacter*, *Citrobacter*, *Proteus*, *Providencia*, or *Enterococcus* spp. Candidal infections may also occur in catheterized children (Reference 8).

A third pathway for infection is the hematogenous route. The infecting organism originates from a nidus outside the urinary tract. The organism disseminates from its original nidus, resulting in a systemic infection with subsequent urinary tract seeding (e.g., staphylococcal bacteremia or endocarditis, neonatal sepsis) (Reference 6). This pathway is more common in infants and immunocompromised patients (References 1, 4). Finally, a fourth pathway of infection involves the development of a fistula between the urinary tract and the gastrointestinal tract or vagina (e.g., vesicointestinal, urethrorectal, or vesicovaginal fistulae). This mechanism is seldom encountered (Reference 1).

## Classification

There are several classification methods for UTIs. One method is based on the infection site. For example, the infection site may be in the bladder (cystitis), urethra (urethritis), urine (bacteriuria), or kidney (pyelonephritis). The infection site in the urinary tract may be more broadly classified as a lower or upper UTI. Cystitis and urethritis are examples of lower UTIs, whereas pyelonephritis is classified as an upper UTI (References 1, 2, 9).

A second method classifies UTIs as either complicated or uncomplicated. A complicated UTI describes genitourinary tracts with structural or functional abnormalities; it also includes UTIs attributed to instrumentation such as indwelling catheters. An uncomplicated UTI occurs in normal urinary tracts without prior instrumentation (Reference 2).

A third strategy to classify pediatric UTIs is based on history and subsequent patient evaluation and management. Using this method, UTIs are categorized as either a first infection or a recurrent infection. The first infection

is the initial UTI diagnosed by a reliable urine culture. Recurrent infections are further subcategorized as unresolved bacteriuria, bacterial persistence, or reinfection (Reference 10).

Unresolved bacteriuria is defined as persistent positive cultures with the same uropathogen isolated in the original culture. Unresolved infection is commonly the result of inadequate therapy (e.g., uropathogen resistance to selected antibiotic, patient nonadherence to prescribed antibiotic, intestinal malabsorption, subtherapeutic antibiotic urine levels). Once culture and antibiotic susceptibility results are available, unresolved bacteriuria is normally treated successfully if uropathogen resistance is identified (Reference 10).

In bacterial persistence, there is documentation of negative urine cultures after treatment of the initial UTI; however, because of incomplete eradication of the infection, the original infecting organism is isolated in subsequent episodes. Patients with documented bacterial persistence may have an underlying urinary tract abnormality (e.g., infected calculus, necrotic papillae, foreign objects), which may shield the uropathogen from antibiotic effects. It is important to identify these abnormalities, if present, given that many may be surgically treated (Reference 10).

With reinfection, there is also documentation of negative urine cultures after initial treatment, but subsequent infections are caused by organisms or strains different from the original pathogen isolated. Reinfection is usually acquired by periurethral colonization with perineal and rectal flora (i.e., retrograde ascent). Because *E. coli* is the most common infecting organism, distinguishing between reinfection and bacterial persistence can be challenging since there are several serotypes of *E. coli*. Serotyping the organism establishes reinfection if a different *E. coli* strain is isolated. However, serotyping is not commonly performed in routine clinical practice; therefore, a careful evaluation of antibiotic susceptibility patterns is helpful in distinguishing between reinfection and bacterial persistence (References 1, 4, 10). Relapse is also a term used to describe either reinfection or bacterial persistence (Reference 8).

## CLINICAL PRESENTATION AND DIAGNOSIS

### Signs and Symptoms

Children may not present with the classic UTI signs and symptoms reported by adults (e.g., urinary frequency, dysuria, hesitancy, flank pain, turbid urine). This is particularly true in younger age groups in which nonspecific signs and symptoms are more prevalent (Reference 4, 8, 11). Neonates may present with jaundice, failure to thrive, fever, difficulty feeding, irritability, or gastrointestinal symptoms such as vomiting and diarrhea. Infants and children younger than 24 months may present

with nonspecific signs and symptoms similar to those reported in neonates with the exception of jaundice, but patients in this age group may also present with cloudy or malodorous urine, hematuria, frequency, and dysuria. Children older than 2 years are more likely to present with fever, frequency, dysuria, enuresis (in a previously toilet-trained child), hematuria, costovertebral angle pain, and/or abdominal pain. Vomiting, diarrhea, and irritability are less frequent presentations for patients older than 2 years with UTI. Urinary tract infection symptomatology in adolescent patients is typically comparable to that of adults (References 4, 8, 9).

### Complications and Long-term Sequelae

Irreversible renal parenchymal damage as evidenced by renal scarring is a potential long-term complication in children having a diagnosis of pyelonephritis (i.e., upper UTI). Renal scarring may lead to end-stage renal disease (References 1, 4). Patients at risk of developing pyelonephritis include those with a diagnosis of vesicoureteral reflux (VUR), an anatomic and functional disorder whereby urine in the bladder flows retrograde into the ureter and often ascends into the kidney. If infected urine reaches the kidney, the result is acute pyelonephritis, a risk factor for renal scarring. Primary VUR (the most common type) is precipitated by a congenital defect, which results from a shortening of the submucosal ureter's longitudinal muscle; this compromises closure of the ureter with bladder filling and limits urination, thus facilitating the ascent of urine from the bladder into the ureter(s) and potentially the kidney(s). Vesicoureteral reflux is classified as grades I–V. Grades I–III are more likely to resolve spontaneously by 5 years of age than grade IV and V reflux. Probability of spontaneous resolution is lower in patients presenting at an older age and in those with bilateral reflux. More rapid resolution of VUR has been observed in African American children (References 9, 12).

Other risk factors for renal scarring include obstructive urinary tract anomalies and recurrent UTIs. The risk of renal damage is higher as the number of UTI recurrences increases. The risk of renal injury is greater for infants and young children compared with other pediatric age groups (References 1, 4, 11, 12).

Bloodstream infections associated with UTIs are more common in the younger age groups. They are reported in 18% of infants between 1 and 3 months of age, in 6% of infants between 4 and 8 months of age, and uncommonly in patients older than 1 year. Bloodstream infection may lead to meningitis, especially in patients younger than 3 months (Reference 12).

Other less common, yet serious UTI complications include pyonephrosis, renal, perirenal, and retroperitoneal abscesses; emphysematous and xanthogranulomatous pyelonephritis; and infective calculi (Reference 4).

## Diagnostic Criteria

### Rapid Urine Tests

Early diagnosis and appropriate treatment are essential to produce a positive outcome in the pediatric patient with UTI, particularly in infants and younger children. Because it typically takes 24 hours or more for final urine culture results to be reported by the microbiology laboratory, clinicians often employ rapid urine tests such as urine dipsticks or microscopy in evaluating a child with symptomatology suggestive of a UTI (Reference 13). Urine dipstick tests are performed at bedside, and results are available within minutes. For urine microscopy, the time it takes to receive the results varies because the sample is analyzed in the clinical laboratory; turn-around-time generally ranges between 15 minutes and 2 hours.

Dipstick analysis indirectly determines urine-specific gravity and pH as well as the presence of glucose, protein, blood, nitrites, and leukocyte esterase (LE). For the presumptive diagnosis of UTI, only nitrites and LE are associated with relatively high sensitivity (low percentage of false negatives) and high specificity (low percentage of false positives), as confirmed by bacteriuria from quantitative urine cultures. Most gram-negative urinary bacteria reduce dietary nitrates to nitrites; the positive nitrite test detects the presence of this substance and suggests a UTI. Gram-positive organisms (and some gram negatives) do not reduce nitrates to nitrites. Hence, a negative nitrite test does not rule out a UTI. Mean sensitivity for the nitrate test is 53% with a specificity of 98%. Lysed white blood cells (WBCs) release esterases. The LE test detects these substances in the urine sample and is therefore a surrogate marker for the presence of WBCs in the urine. Average sensitivity and specificity for the LE test are reported to be 83% and 78%, respectively. The combination of LE and nitrite tests increases sensitivity but not specificity (References 11, 13).

Microscopic analysis directly identifies crystals, red blood cells, WBCs (pyuria), casts, and bacteria. Of the microscopic analyses, quantification of WBCs and bacteria best correlates with a diagnosis of UTI. Pyuria is defined as 5 or more WBCs per high-power field of uncentrifuged urine sediment. Mean sensitivity for WBC microscopy is 73%, with a specificity of 81%. These values are comparable to the results reported for the less technically challenging and less costly dipstick test (i.e., LE). For bacterial microscopy, the reported mean sensitivity and specificity are 81% and 83%, respectively. Higher accuracy rates have been reported when microscopy for bacteria is performed with a Gram stain (References 8, 11, 14).

Rapid urine tests (whether dipstick or microscopic analysis) are not intended to replace urine culture as a

diagnostic tool. Rapid tests do not identify the infecting pathogen or yield antibiotic susceptibility results to guide antibiotic selection. In addition, negative rapid urine tests are reported in a significant percentage of children with a diagnosis of UTI (Reference 14).

### *Urine Cultures and Collection Methods*

A positive urine culture is required to make the diagnosis of a UTI. The culture should be taken before antimicrobial therapy is initiated. A urine culture may be obtained by a variety of techniques. Because the distal urethra is commonly colonized with the same pathogens that cause UTIs, the number of colony-forming units (CFU) necessary to estimate infection probability depends on the method used to collect the urine sample (References 4, 12).

Suprapubic aspiration (SPA) is considered the gold standard for accurate UTI diagnosis. However, because SPA is an invasive technique, it is not routinely performed. Suprapubic aspiration involves the advancing of a 2- to 4-cm needle above the symphysis pubis through the bladder wall until urine flows into the syringe. Any number of gram-negative bacilli or greater than  $10^3$  gram-positive cocci is associated with a greater than 99% probability of infection (References 1, 4, 8).

Even though transurethral catheterization also represents an invasive technique, it is a commonly used method of obtaining a reliable urine sample (particularly in young children), provided the initial aliquot of the sample is discarded to reduce the potential for culturing organisms introduced into the bladder upon catheterization. For urine samples collected by transurethral catheterization, the probability of infection is 95% if  $10^5$  CFU of bacteria are recovered. A catheterized urine culture is considered suggestive of infection if  $10^4$ – $10^5$  CFU are quantified, and repeating a culture may be warranted to establish the diagnosis (References 1, 4, 8).

In 2011, the American Academy of Pediatrics (AAP) revised its clinical practice guidelines for initial UTI in febrile children 2–24 months of age to recognize SPA and transurethral catheterization as the most reliable collection methods for diagnosing a UTI. To establish a UTI diagnosis, these guidelines recommend urinalysis results suggestive of a UTI (i.e., pyuria and/or bacteriuria) plus the presence of 50,000 CFU/mL or more of uropathogen collected by SPA or catheterization (Reference 11).

Clean void urine samples are simple to perform and are noninvasive. A clean void urine sample is obtained using the clean-catch midstream technique and is commonly used in older children and adolescents. After appropriate topical disinfection of the genitalia, the patient urinates the first aliquot of the sample into the toilet, after which the collection cup is placed under the

urine stream to collect the laboratory sample. Periurethral and preputial organisms contaminate clean-catch specimens in a significant percentage of samples, making interpretation of positive results challenging. In females,  $10^5$  CFU or greater of bacteria confers a high probability of infection (i.e., 80% to 95%, depending on whether one, two, or three positive urine specimens were recovered). In males, greater than  $10^4$  CFU of bacteria makes infection likely (References 1, 4, 8).

A bagged specimen is an alternative method of urine collection that involves attaching a plastic bag to the perineum to collect the urine specimen; the bagged urine technique may be used to collect a sample from infants and smaller children. Bagged urine samples are associated with high rates of false-positive results and are generally not reliable to establish the diagnosis of a UTI. However, a negative result on a bagged urine sample is helpful in ruling out a UTI (References 8, 11).

### *Imaging Studies*

Urinary tract infections in infants and young children may serve as an indicator of urinary tract abnormalities; therefore, imaging studies have traditionally been recommended after a first UTI to identify potential urinary tract anomalies that may predispose the young child to renal disease. Imaging studies performed in pediatric patients include renal and bladder ultrasonography (US), intravenous pyelography, voiding cystourethrography (VCUG), radionuclide cystography, renal cortical scan, computed tomography, and/or magnetic resonance imaging (MRI) (References 6, 8, 11).

Ultrasonography offers a noninvasive method to evaluate anatomy (e.g., renal size and various aspects of the parenchyma); it may also reveal obstructive lesions. Ultrasonography identifies hydronephrosis, dilation of distal ureters, bladder wall hypertrophy, and presence of ureteroceles. Intravenous pyelography, which requires parenteral administration of iodinated contrast dye, was previously used to detect such anomalies; however, US is currently preferred to intravenous pyelography for anatomic evaluation of the urinary tract because it effectively reveals these abnormalities but is safer, less invasive, and more cost-effective. Ultrasonography does not reliably detect VUR (References 6, 8, 11).

Voiding cystourethrography or radionuclide cystography is effective in diagnosing and grading VUR. Both of these imaging studies involve radiation exposure and catheterization. Radionuclide cystography, however, does not reveal male urethral or bladder abnormalities, whereas VCUG does (Reference 5).

Renal cortical scans, also known as scintigraphy, require injection of the radioisotope DMSA ( $^{99m}\text{Tc}$ -dimercaptosuccinic acid) or  $^{99m}\text{Tc}$ -glucoheptonate. It is a sensitive test for assessing renal

scarring or identifying acute changes associated with pyelonephritis. Renal cortical scans are also useful in diagnosing mass lesions such as neoplasms and abscesses (References 8, 11).

Computed tomography and MRI studies best visualize renal abscesses. Computed tomography is more commonly used because it is readily available. Magnetic resonance imaging may yield better soft tissue resolution and diagnostic sensitivity (Reference 8). There is some evidence to support the use of MRI for the evaluation of renal scarring (References 15, 16).

Guidelines for follow-up imaging studies vary. A published algorithm for imaging decisions in children with UTI recommends US plus VCUG for girls 36 months or younger, girls between 3 and 7 years of age with a temperature of 101.3°F (38.5°C) or higher, and for all boys regardless of age. The algorithm recommends observation without imaging for girls 3–7 years of age with a temperature less than 101.3°F (38.5°C) and girls older than 7 (Reference 5). Alternatively, the 2011 AAP clinical practice guideline for febrile infants and children 2–24 months of age recommends US after the initial UTI but not VCUG routinely, reserving the latter for a recurrent episode of febrile UTI (Reference 11). More conservative use of US has been proposed. Some authors advocate reviewing the US from the third trimester of pregnancy (if available) after the first uncomplicated febrile UTI in children younger than 3 years. If the US is unavailable or considered unreliable, it should be performed on the child. Children with atypical UTI presentations also benefit from ultrasonography (Reference 17).

### **Other Laboratory Tests**

Depending on the clinical presentation, a complete blood cell count, C-reactive protein, and blood culture may provide valuable data when treating an acutely ill child. A basic metabolic panel may expose electrolyte abnormalities if the child is dehydrated or renally compromised (References 4, 12, 18).

## **TREATMENT**

Antibiotic therapy is initiated empirically on the basis of local (or regional) susceptibility patterns of the selected antibiotic against the targeted organism(s). After reviewing the patient's allergy history, newer-generation cephalosporins, trimethoprim/sulfamethoxazole, or  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination are commonly selected for empiric UTI treatment. Once culture and susceptibility results are available, antibiotic therapy is adjusted accordingly. Patients with a history of anatomic or functional urinary tract abnormalities, recurrent UTIs, uncommon pathogens, catheter use, or immunodeficiency states may require more individualized antibiotic coverage (References 11, 12).

## **Parenteral Antibiotics**

Children, particularly those younger than 2 years, may require administration of parenteral antibiotic therapy. Criteria for parenteral antibiotic administration include acutely ill (“toxic”) children, infants younger than 2 months, immunocompromised patients, children who are unable to retain oral intake or who are dehydrated, and cases in which adherence to, obtaining, and/or administering oral antibiotics is uncertain (References 1, 11, 17).

Table 2 lists the most commonly used parenteral antibiotics prescribed for the treatment of pediatric UTIs, together with pediatric dosing recommendations and common and/or severe adverse drug events reported. The cephalosporins, aminoglycosides, and fluoroquinolone listed in Table 2 are generally active against uropathogens in the *Enterobacteriaceae* family (e.g., *E. coli*, *Klebsiella* spp., *Citrobacter* spp., *Enterobacter* spp., *M. morgani*, *P. mirabilis*, *P. stuartii*, and *Serratia* spp.). The newer-generation cephalosporins are more  $\beta$ -lactamase stable than the earlier generations and thus are more active against  $\beta$ -lactamase-producing pathogens and suitable for empiric therapy. Cefotaxime and ceftriaxone have comparable antimicrobial spectra of activity and may be used interchangeably in most instances; however, ceftriaxone is not routinely recommended for neonates. The drug is highly protein bound (more than 90% bound to albumin), and in hyperbilirubinemic neonates, bilirubin displacement from its albumin binding sites increases the risk of kernicterus. In addition, ceftriaxone is contraindicated in neonates receiving (or who may require) calcium-containing intravenous solutions; crystalline material has been recovered at autopsy from the lungs and kidneys of a limited number of neonates administered this combination. If an anti-pseudomonal antibiotic is indicated, aminoglycosides, ciprofloxacin, ceftazidime, and cefepime are active against *P. aeruginosa*, an organism recovered in 13.1% of nosocomial UTIs (Reference 4). Most gram-negative uropathogens produce  $\beta$ -lactamases; consequently, a significant percentage of these organisms are resistant to ampicillin. Ampicillin monotherapy is not a preferred empiric antibiotic selection for UTI. Ampicillin may be used empirically in combination with an aminoglycoside or a latter-generation cephalosporin. Unlike cephalosporins, ampicillin is microbiologically active against enterococci, particularly *Enterococcus faecalis* (References 1, 11, 19).

Duration of parenteral therapy depends on the patient's clinical response to therapy. Parenteral antibiotics are continued until the patient is afebrile and clinically stable, after which the antibiotic is switched to an appropriate oral agent (Reference 1). A study of infants younger than 6 months reported no difference in

readmission rate at 30 days after discharge for patients administered antibiotics intravenously for 3 days or less versus 4 days or more, provided the infants completed a 10- to 14-day total antibiotic course (Reference 20).

### Oral Antibiotics

An oral antibiotic is typically prescribed to pediatric patients with UTIs for one of the following indications: (1) to complete a UTI treatment course in a patient initiated on parenteral antibiotics or (2) as initial treatment of the UTI in a child presenting to an emergency department or physician's office who does not meet criteria for parenteral antibiotics. Advantages of oral antibiotic therapy include ease of administration and overall lower cost. Studies of children 1 month and older treated for pyelonephritis showed similar efficacy between oral and intravenous/oral sequential therapy. There was no statistical difference in renal scarring between oral and intravenous/oral treatment groups. The oral antibiotics used in these trials were amoxicillin/clavulanate, cefixime, and ceftibuten (References 21–23).

Table 3 identifies common oral antibiotics used for the empiric treatment of pediatric UTIs; the table includes the pediatric dosing recommendations and select adverse drug events reported. Documented safety and efficacy are the primary considerations when selecting an oral antibiotic for the treatment of UTIs. If a liquid formulation is indicated, an important consideration is palatability because that influences patient adherence to the prescribed regimen. Studies evaluating the taste of pediatric antibiotic oral formulations report substantial variability in palatability for the products tested. One study rates the palatability of some of the antibiotic suspensions included in Table 3. The rankings in decreasing order of palatability are as follows: cefixime, ceftibuten, trimethoprim/sulfamethoxazole, amoxicillin/clavulanate, and cefpodoxime (Reference 24). Cost and formulary status are additional considerations when selecting an oral antibiotic (Reference 24). Another factor to consider when selecting an antibiotic empirically is the *E. coli* local resistance pattern. Avoid selecting an antibiotic for empiric use if the local

**Table 2.** Parenteral Antibiotics Commonly Used for Pediatric UTIs (References 1, 11, 19)

Antibiotic	Pediatric Dosage <sup>a,b</sup>	Adverse Drug Events
Ampicillin	100–200 mg/kg/day divided every 4–6 hours	Hypersensitivity, hematologic toxicity, N/V/D, increased LFTs, interstitial nephritis
Cefazolin (Ancef, Kefzol)	50 mg/kg/day divided every 6–8 hours	Hypersensitivity, hematologic toxicity, N/V/D, increased LFTs, increased serum creatinine
Cefotaxime (Claforan)	100–150 mg/kg/day divided every 6–8 hours	Similar to cefazolin
Ceftriaxone (Rocephin)	50–75 mg/kg/day divided every 12–24 hours	Similar to cefazolin plus biliary sludging, cholelithiasis
Ceftazidime (Fortaz)	100–150 mg/kg/day divided every 8 hours	Similar to cefazolin
Cefepime (Maxipime)	100 mg/kg/day divided every 12 hours	Similar to cefazolin
Ciprofloxacin <sup>c</sup> (Cipro)	18–30 mg/kg/day divided every 8 hours	Tendon rupture, Achilles tendonitis, N/V/D, increased LFTs, increased serum creatinine
Gentamicin (Garamycin)	5–7.5 mg/kg/day divided every 8–24 hours	Nephrotoxicity, ototoxicity, neuromuscular blockade
Tobramycin (Nebcin)	5–7.5 mg/kg/day divided every 8–24 hours	Similar to gentamicin

<sup>a</sup>Doses referenced assume normal renal function and are consistent with dosing recommendations for children outside the neonatal period. For neonatal dosing recommendations, consult appropriate reference.

<sup>b</sup>Doses for larger children and adolescents are typically capped to the adult dose when weight-based dosing results in a higher value than the standard adult dose for the indication.

<sup>c</sup>Ciprofloxacin is approved by the U.S. Food and Drug Administration (FDA) for complicated UTIs and pyelonephritis in children 1–17 years of age.

D = diarrhea; LFT = liver function test; N = nausea; UTI = urinary tract infection; V = vomiting.

resistance rate against the targeted organism is 20% or higher (References 12, 25). Once the organism is identified in culture, deescalating to narrower-spectrum agents should be considered on the basis of susceptibility results and the patient's clinical condition.

Drug-specific properties are another important consideration. Use of trimethoprim/sulfamethoxazole should be avoided in children younger than 2 months because sulfonamides are highly protein bound and, in hyperbilirubinemic patients, may displace bilirubin and potentially cause kernicterus. Nitrofurantoin should be avoided in patients with glucose-6-dehydrogenase deficiency (G-6-PD) because of the risk of precipitating hemolytic anemia. Nitrofurantoin is contraindicated if creatinine clearance is less than 60 mL/minute because therapeutic urine concentrations are not attained in renal insufficiency (Reference 19). Nitrofurantoin should also be avoided in the treatment of febrile infants with UTIs; parenchymal and serum concentrations attained may be insufficient to treat pyelonephritis or urosepsis (Reference 11).

The AAP recommends a 7- to 14-day treatment course for children between 2 months and 2 years of age (Reference 11). Antibiotic courses of 10–14 days are commonly prescribed for children and adolescents with a diagnosis of pyelonephritis; courses of 3–7 days are generally used for the treatment of cystitis (Reference 9). For uncomplicated lower UTIs, even shorter treatment courses (2–4 days) with oral antibiotics have been reported as effective (References 26, 27).

### UTI Prophylaxis

The rationale for antibiotic prophylaxis after active UTI treatment is maintaining sterilization of the urine. The goal is to prevent irreversible renal parenchymal damage (renal scarring) and its sequelae. The antibiotic selected for prophylaxis is administered at a reduced dose, achieving therapeutic urine concentrations while delivering low antibiotic levels to the bowel to minimize its effect on normal intestinal flora. Traditionally, the following subgroups have been considered for antibiotic prophylaxis: neonates or infants being evaluated for anatomic

**Table 3.** Oral Antibiotics Commonly Used for Empiric Treatment of Pediatric UTIs (References 1, 19, 21–23)

Antibiotic	Pediatric Dosage <sup>a,b</sup>	Adverse Drug Events
Amoxicillin/clavulanate (Augmentin)	40–50 mg/kg/day divided every 8–12 hours	N/V/D, abdominal pain, hypersensitivity
Cefixime (Suprax)	8 mg/kg/dose every 12 hours × 1 day; then 8 mg/kg once daily	N/V/D, abdominal pain, hypersensitivity
Cefpodoxime (Vantin)	10 mg/kg/day divided every 12 hours	Similar to cefixime
Ceftibuten (Cedax)	9 mg/kg/dose every 12 hours × 1 day; then 9 mg/kg once daily	Similar to cefixime plus serum sickness-like reaction
Cephalexin (Keflex)	50 mg/kg/day divided every 6 hours	Similar to cefixime
Ciprofloxacin <sup>c</sup> (Cipro)	20–40 mg/kg/day divided every 12 hours	N/V/D, dizziness, photosensitivity, tendon rupture, Achilles tendonitis
Nitrofurantoin <sup>d</sup> (Furadantin, Macrochantin)	5–7 mg/kg/day divided every 6 hours	N/V, anorexia, hypersensitivity, hematologic toxicity, urine discoloration
Trimethoprim/sulfamethoxazole (Bactrim, Septra)	8–12 mg/kg/day trimethoprim divided every 12 hours	Hypersensitivity, N/V/D, hematologic toxicity, interstitial nephritis

<sup>a</sup>Doses referenced assume normal renal function and are consistent with dosing recommendations for children outside the neonatal period. For neonatal dosing recommendations, consult appropriate reference.

<sup>b</sup>Doses for larger children and adolescents are typically capped to the adult dose when weight-based dosing results in a higher value than the standard adult dose for the indication.

<sup>c</sup>Ciprofloxacin is approved by the U.S. Food and Drug Administration (FDA) for complicated UTIs and pyelonephritis in children 1–17 years of age.

<sup>d</sup>Nitrofurantoin should only be used for cystitis in patients with a creatinine clearance of 60 mL/min or greater.

D = diarrhea; N = nausea; UTI = urinary tract infection; V = vomiting.

**Table 4.** Oral Antibiotics Commonly Used for UTI Prophylaxis in Children (References 8, 19)

Antibiotic	Pediatric Dosage <sup>a,b</sup>	Adverse Drug Events
Amoxicillin (Amoxil)	10–15 mg/kg once daily at bedtime	N/V/D, abdominal pain, hypersensitivity
Cephalexin (Keflex)	12–15 mg/kg once daily at bedtime	N/V/D, abdominal pain, hypersensitivity
Nitrofurantoin (Furadantin, Macrochantin)	1–2 mg/kg once daily at bedtime	N/V, anorexia, flatulence, headache, hypersensitivity, urine discoloration
Trimethoprim/ sulfamethoxazole (Bactrim, Septra)	Trimethoprim 2 mg/kg at bedtime OR Trimethoprim 5 mg/kg twice weekly at bedtime	Hypersensitivity, N/V/D, hematologic toxicity, interstitial nephritis

<sup>a</sup>Doses referenced assume normal renal function and are consistent with dosing recommendations for children outside the neonatal period. For neonatal dosing recommendations, consult appropriate reference.

<sup>b</sup>Doses for larger children and adolescents are typically capped to the adult dose when weight-based dosing results in a higher value than the standard adult dose for the indication.

D = diarrhea; N = nausea; UTI = urinary tract infection; V = vomiting.

or functional urinary tract abnormalities; children with a history of VUR, dysfunctional voiding, or partial urinary obstruction; immunosuppressed patients; and children with recurrent UTIs despite normal urinary anatomy and function. In general, prophylactic antibiotics are continued until resolution of the underlying condition(s) predisposing the patient to UTIs (References 1, 6).

The antibiotics listed in Table 4 are commonly used for UTI prophylaxis in children. Typically, they yield comparable outcomes, provided the selected antimicrobial agent is active against the targeted organisms (References 1, 8). In patients with recurrent infections, careful evaluation of previous culture and susceptibility results serves as a valuable guide in antibiotic selection. The use of prophylactic cephalosporins for patients with VUR may result in untoward consequences. In a study of breakthrough UTIs in pediatric patients with VUR, there was a greater likelihood of culturing extended-spectrum  $\beta$ -lactamase-producing organisms or non-*E. coli* multidrug-resistant uropathogens in the cephalosporin prophylaxis groups than in the trimethoprim/sulfamethoxazole arm of the study (Reference 28).

The routine use of UTI prophylaxis is the subject of considerable debate. The 2011 AAP clinical practice guidelines do not recommend prophylactic antibiotics to prevent UTI recurrences. After the initial UTI, the clinician instructs the parents or guardians to seek prompt medical attention (i.e., within 48 hours) for any future febrile illness because early treatment is preferred to limit potential renal damage (Reference 11). A Cochrane review of the pediatric literature concludes that prophylactic antibiotics reduce the risk of recurrent symptomatic UTIs; however, their benefit is limited,

and the increased risk of bacterial resistance needs to be considered (Reference 29). Another meta-analysis recommends against the routine use of antibiotic prophylaxis in children at risk of developing UTIs, citing lack of evidence supporting a positive benefit (Reference 30). One study reports an increased risk of resistant infections but no decrease in risk of recurrent UTIs associated with antibiotic prophylaxis (Reference 31).

Initiation of prophylaxis should be considered if the benefits are expected to outweigh the risks after a thorough evaluation of the patient's clinical condition and risk factors for adverse UTI sequelae. Family involvement is imperative in the decision of whether to initiate prophylactic antibiotics.

## CONCLUSIONS

Urinary tract infections are a common disease state in children. Children with UTIs are at increased risk of long-term morbidity, including irreversible renal damage and its sequelae. Signs and symptoms in the young child may be nonspecific, making diagnosis more challenging on presentation. Specific rapid urine tests are useful in the initial patient workup to support a presumptive diagnosis pending culture results. A positive urine culture is required to make the diagnosis of UTI. The predominant pathogen isolated is *E. coli*. Follow-up imaging studies may be necessary to identify anatomic or functional abnormalities, particularly in the young infant or child with recurrent UTIs. Prompt and effective antimicrobial treatment is indicated in acute infection to reduce the risk of subsequent complications.

# CHAPTER 40

## BONE AND JOINT INFECTIONS

Kalen Manasco, Pharm.D., BCPS, AE-C

### LEARNING OBJECTIVES

1. Distinguish between the clinical presentation of osteomyelitis and infectious arthritis.
2. List the common etiologic organisms associated with osteomyelitis and infectious arthritis.
3. List appropriate antibiotic treatments for osteomyelitis and infectious arthritis.
4. Discuss monitoring parameters in patients with osteomyelitis and infectious arthritis.

### ABBREVIATIONS IN THIS CHAPTER

CA-MRSA	Community-associated methicillin-resistant <i>Staphylococcus aureus</i>
CRP	C-reactive protein
ESR	Erythrocyte sedimentation rate
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
PVL	Panton-Valentine leukocidin
WBC	White blood cell count

### INTRODUCTION

Bone and joint infections are classified as osteomyelitis or infectious arthritis. These infections are usually associated with long treatment courses of antimicrobial agents and can lead to significant morbidity in some cases (Reference 1). Bone and joint infections can affect patients of all ages, including children. The following sections will discuss osteomyelitis and infectious arthritis in detail.

### OSTEOMYELITIS

#### Definition

Osteomyelitis is defined as inflammation of the bone and/or bone marrow, usually accompanied by a microbial infection (References 2, 3). Although infection can occur with any bone throughout the body, the long bones are often affected in infants and children. Infections can be caused by bacteria, fungi, and mycobacteria. The infection is typically acute in origin, but all bone infections can progress to chronic osteomyelitis with a risk of necrosis of the bone.

### Epidemiology and Classification

The incidence of osteomyelitis has been reported as around 1 in 5000 children (Reference 4). It accounts for about 1% of all pediatric hospitalizations. One-half of the occurrences are in children younger than 5 years. Males are more commonly affected than females, with a ratio of about 2:1, respectively. Most infections involve one site, but up to 20% of children can present with multifocal osteomyelitis (References 1, 5). Neonatal osteomyelitis occurs in around 1–3 infants per 1000 neonatal intensive care admissions and is associated with a higher incidence of multifocal osteomyelitis compared with older children (Reference 6).

The overall incidence of osteomyelitis has been decreasing during the past several decades (Reference 7). However, there are an increasing number of osteomyelitis cases because of resistant gram-positive organisms. In addition, more virulent strains of bacteria have emerged as causative organisms. In particular, Panton-Valentine leukocidin (PVL)-positive community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) strains are of concern. Evidence has shown infections caused by these strains are associated with more severe disease and increased complications.

Historically, osteomyelitis has been classified by symptom onset and duration. Patients were identified as having acute, subacute, or chronic osteomyelitis. Acute infections occur within 1–2 weeks of disease onset, subacute infections last for a few weeks but less than 1 month, and chronic infections last more than 1 month with the presence of bone necrosis (References 8, 9). Acute osteomyelitis accounts for 50% of infections and is more common in children (References 1, 8). Subacute and chronic osteomyelitis typically occur in adult patients.

### Waldvogel Classification

In 1970, Waldvogel developed a classification system using both the pathogenesis and duration of the infection (References 10–12). The Waldvogel system classifies osteomyelitis as hematogenous, contiguous, or chronic. Hematogenous osteomyelitis is spread through the bloodstream and is commonly seen in neonates, infants, and children. Contiguous osteomyelitis is spread through an adjacent soft tissue infection or by direct inoculation into the bone (e.g., trauma, puncture wounds, and surgery). Most contiguous infections in pediatric patients are associated with puncture wounds of the foot or patella

(Reference 8). Osteomyelitis of the foot after a puncture wound occurs in about 1.5% of cases (Reference 13). Chronic osteomyelitis develops when the bone becomes necrotic because of the loss of blood supply. The disadvantage of the Waldvogel classification system is that it was not designed to guide surgical or antimicrobial therapy.

### **Cierny-Mader Staging System**

Cierny-Mader staging is another classification system for osteomyelitis that is based on anatomic location and physiologic status of the patient (Reference 14). Initially established for adults, it can also be used to stage osteomyelitis in children. The staging, developed to allow guidance for treatment and/or surgical management, is particularly useful for infections involving long bones. There are four stages that describe the anatomic location and three host classifications (A, B, or C). Stage 1 (medullary) is an infection entirely within the bone marrow from hematogenous spread. Stage 2 (superficial) involves the surface of the bone, usually from a contiguous focus or direct inoculation. Stage 3 (localized) involves both the surface of the bone and the bone marrow. Stage 4 (diffuse) involves the entire thickness of the bone. The physiologic status is defined by the host's ability to mount an immune response (i.e., immunocompetent vs. immunocompromised). Patients are classified into the following categories: healthy (C), presence of local host compromise (BL), presence of systemic host compromise (BS), presence of both local and systemic compromise (BLS), and presence of severe compromise that results in the treatment being worse than the disease (C). Systemic host factors include malnutrition, renal or hepatic failure, diabetes, and immunosuppression. The most common local host factors are venous stasis, major vessel compromise, arteritis, scarring, and neuropathy.

### **Pathophysiology**

Microorganisms can enter the bone through the bloodstream secondary to bacteremia, by direct inoculation (e.g., trauma, surgery), or from an adjacent soft tissue infection. Hematogenous spread to the bone occurs most commonly in pediatric patients because of the rich vascular supply and slow blood flow that is present in the metaphysis, particularly of long bones. The infecting organism initially affects the capillary loop near the epiphyseal growth plate to form a microabscess and localized inflammation. The organism then continues to travel through large venous sinusoids to areas of slow blood flow, where there is continued recruitment of inflammatory mediators, phagocytic cells, and toxins. Prostaglandins are produced in response to bone destruction and can decrease the amount of bacteria needed to cause infection (Reference 2). Reactive bone formation occurs around the area of infection. The

infection leads to edema and increased vascular permeability, which allows elevation of the periosteum. Eventually, the bacteria can enter the subperiosteal space and continue to form abscesses that become isolated from the blood supply within the bone. Once the blood supply is diminished, dead bone, or sequestra, are formed. *S. aureus* is of concern because it can express bacterial adhesion proteins, which promote attachment to the bone matrix (collagen, fibronectin, laminin) and cartilage (Reference 15). In addition, *S. aureus* strains produce endotoxins capable of suppressing the local inflammatory response. If the infection spreads into the adjacent growth plate and epiphysis, joint damage and concomitant infectious arthritis can occur.

The most common cause of osteomyelitis in children is acute hematogenous osteomyelitis. Although the metaphysis of the long bones is most commonly affected, the bones of the hip, knee, and shoulder can also be involved, especially with a concomitant joint infection (Reference 16). Osteomyelitis of the lower extremities has been reported in up to 72% of patients (Reference 17). In neonatal osteomyelitis, there is a higher frequency of concomitant septic arthritis (up to 75% of cases), particularly in the hip, shoulder, and knee (Reference 13). In children older than 1 month, adjacent infectious arthritis of the joint has been reported in up to 40% of patients (Reference 18). Adjacent infectious arthritis of the joint is most common in patients younger than 18 months.

### **Microorganisms**

There is usually only one infecting organism involved in acute hematogenous osteomyelitis. The most common organism is *S. aureus*, which accounts for about 80% of cases. The percentage of infections caused by methicillin-resistant *S. aureus* (MRSA) strains varies greatly by region, but it may approach 50% in some areas (Reference 1). Group A *Streptococcus* (*Streptococcus pyogenes*), *Streptococcus pneumoniae*, and *Kingella kingae* are also common causes in infants and children (References 19-21). *S. aureus*, *S. pyogenes*, and *S. pneumoniae* are gram-positive organisms found on the skin and in the oropharynx. *K. kingae* is a fastidious gram-negative coccobacillus that is part of the normal respiratory flora. *Haemophilus influenzae* type b (Hib) is becoming rare because of universal childhood immunization against this pathogen. After 4 years of age, the incidence of *H. influenzae* is dramatically decreased (Reference 22). Table 1 and Table 2 list the most common organisms seen in osteomyelitis by patient age and clinical condition.

Other organisms that cause osteomyelitis infrequently include *Mycobacterium* spp., *Bartonella henselae*, *Borrelia burgdorferi*, fungi (e.g., *Histoplasma*, *Cryptococcus*, *Blastomyces*, *Actinomyces*, *Coxiella*), *Pasteurella multocida*,

and anaerobic bacteria (e.g., *Bacteroides*, *Clostridium*, *Fusobacterium*, *Peptostreptococcus*) (References 25, 26). In particular, *Mycobacterium*, *Bartonella*, and fungi are usually found in immunocompromised patients.

Contiguous osteomyelitis in children most often occurs after direct inoculation of bacteria from a traumatic wound. Anaerobic bacteria should be considered additional causative organisms in these cases. It is uncommon for children to develop osteomyelitis secondary to a contiguous infection. However, these cases usually involve a primary infection in the oromaxillary cavity (e.g., sinus, tooth, mastoid bone) (Reference 1).

The most common cause of chronic osteomyelitis in children is inadequate treatment of a hematogenous bone infection (Reference 26). The presence of an orthopedic implant can also be associated with the development of chronic osteomyelitis.

**Table 1.** Common Pathogens in Pediatric Osteomyelitis Based on Patient Age

Age	Organism
Neonate ( $< 1$ month)	<i>Staphylococcus aureus</i> Group B streptococci ( <i>Streptococcus agalactiae</i> ) Gram-negative enteric organisms ( <i>Escherichia coli</i> , <i>Klebsiella oxytoca</i> ) Candida spp.
1 month to 5 years	<i>Staphylococcus aureus</i> <i>Streptococcus pyogenes</i> <i>Streptococcus pneumoniae</i> <i>Kingella kingae</i>
$> 5$ years	<i>Staphylococcus aureus</i> <i>Streptococcus pyogenes</i>

**Table 2.** Common Pathogens in Pediatric Osteomyelitis Based on Comorbid Conditions

Organism	Clinical Condition
<i>Salmonella</i> <sup>a</sup>	Sickle cell disease
<i>Staphylococcus epidermidis</i>	Foreign body
<i>Pseudomonas aeruginosa</i> <sup>b</sup>	Puncture wounds to the feet Immunocompromised
<i>Bartonella henselae</i>	Human immunodeficiency virus Kitten exposure
Fungi	Immunocompromised
Anaerobic bacteria	Dental abscess
<i>Pasteurella multocida</i>	Human or animal bite

## Risk Factors

Risk factors for the development of hematogenous osteomyelitis include bacteremia, nonpenetrating trauma, and long-term, indwelling intravenous catheters. Pediatric patients are at increased risk of acute hematogenous osteomyelitis because the metaphyseal plate has a rich blood supply, and infectious spread from bacteremia is more likely. Additional risk factors specific for neonates include placement of an umbilical catheter and frequent heel stick blood draws. Risk factors for developing contiguous osteomyelitis include penetrating trauma, animal bites, puncture wounds, and adjacent soft tissue infections.

## Clinical Presentation and Diagnosis

### Signs and Symptoms

The clinical presentation usually involves local inflammation, pain and swelling, and systemic symptoms such as fever, irritability, and lethargy. Clinical presentation also depends on the origin of the infection and can vary with age. Pseudoparalysis is the cardinal sign in neonates and young children, although irritability is the most common symptom in this age group (Reference 27). Pseudoparalysis occurs when the infant appears unable to move the affected arm or leg but has no true paralysis. In older children, the pain is usually more localized, and a common presentation is refusal to bear weight or presence of a limp. Fever is usually absent in most children with a diagnosis of osteomyelitis. Infections caused by *K. kingae* are usually preceded by an upper respiratory tract infection.

Clinically, patients with a PVL-positive strain of CA-MRSA present differently from those without the presence of PVL. Typical clinical manifestations associated with a PVL-positive strain include multiple infection sites, myositis, subperiosteal abscess, and severe life-threatening co-infections (Reference 28). In addition, chronic osteomyelitis is more likely to be diagnosed on admission or to develop in patients with PVL-positive isolates compared with patients having PVL-negative strains (Reference 29).

### Diagnostic Criteria

Diagnosis of osteomyelitis is based on clinical presentation, presence of certain laboratory markers, and imaging studies to detect infection in the bone. Laboratory data indicative of osteomyelitis include an elevated white blood cell count (WBC); increased inflammatory markers, such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP); presence of bacteria from a blood culture or biopsy of the bone of adjacent infected soft tissue; and abnormal physical examination, such as pain or tenderness. Blood cultures are only positive in about 50% of cases; thus, the presence of a negative

blood culture cannot rule out osteomyelitis (Reference 30). Polymerase chain reaction analyses have been useful in detecting *K. kingae* because it is difficult to culture using standard laboratory methods (Reference 31).

The CRP, a nonspecific, acute inflammatory marker, is useful early in the disease process. It typically peaks a few days after an acute infection and normalizes once treatment has begun. The ESR is a marker of chronic inflammation and can be used to guide long-term treatment and disease management. The CRP has been shown to predict recovery better than WBC or ESR (Reference 32). A normal WBC and CRP do not exclude a diagnosis of osteomyelitis. Patients with osteomyelitis caused by PVL-producing *S. aureus* have been found to have a higher mean ESR, CRP, and absolute neutrophil count compared with patients who do not have a PVL-producing strain (Reference 33).

If a biopsy of the infected bone is performed, histopathologic and microbiologic examinations of the bone are helpful diagnostic tools. The procedure is usually performed with guided computed tomography (CT) or ultrasonography. The presence of bacteria from a bone biopsy is diagnostic for osteomyelitis.

#### Imaging Procedures

Imaging studies are helpful in diagnosing osteomyelitis. Common studies include standard radiography, radionuclide imaging or scintigraphy, magnetic resonance imaging (MRI), CT scan, and positron emission tomography. Standard radiographs can detect soft tissue swelling but are usually normal during the first 2–3 weeks of the infection (see Figure 1). Standard radiographs are useful in detecting fractures or malignancies and thus in ruling out osteomyelitis. Radionuclide imaging (i.e., bone scan) is performed with an intravenous radiopharmaceutical (e.g., technetium-99m) administration. Radiography will show increased uptake of the technetium-99m in areas with inflammation. The sensitivity of radionuclide imaging is between 80% and 100%, but the specificity is low because it cannot distinguish infection from trauma or malignancy (Reference 1). This test is most useful when the exact infection site cannot be determined or when multifocal sites are suspected.

Magnetic resonance imaging has the best results for imaging, with 97% sensitivity and 92% specificity (References 34, 35). In fact, MRI is preferred to scintigraphy because of its ability to detect extrasosseous complications such as subperiosteal abscesses, septic arthritis, and deep venous thrombosis (see Figure 2) (Reference 36). Disadvantages of MRI compared with scintigraphy include high cost, inability to distinguish postsurgical inflammation from osteomyelitis, and patient sedation requirement. Computed tomography scans can also be performed to visualize bony structures, but they are less specific than MRI studies. Positron emission tomography

**Figure 1.** Radiographic image depicting long-bone regions (left labels) and bony changes (right labels) caused by *Staphylococcus aureus* osteomyelitis occurring in the distal right humerus of a 12-month-old infant (Reference 16).

is an imaging study that uses a nonspecific tracer that accumulates at infection or inflammation sites. In the management of osteomyelitis, it has been shown useful in diagnosing chronic osteomyelitis and as a follow-up study to assess response to therapy (Reference 37).

#### Course and Prognosis

Acute hematogenous osteomyelitis is associated with a favorable prognosis once bacteremia has cleared. Recurrence is reported in up to 5% of cases overall and in up to 50% of neonatal cases (Reference 1). Relapse has been reported in 30% to 60% of children who did not have abscess drainage, if present, despite adequate antimicrobial therapy (Reference 38). In one study, monitoring serial CRP values was helpful in identifying patients who might have a complicated course as well as in predicting outcomes (Reference 39). If CRP

## Treatment

### Goals of Therapy

The goals of antimicrobial therapy are eradication of the organism, resolution of infection, and prevention of long-term sequelae. Because clinical practice guidelines for the management of osteomyelitis do not presently exist, the infection is best managed with a multidisciplinary team of clinicians. Recommendations for the diagnosis and treatment of pediatric osteomyelitis are based on expert opinion, case series, and small clinical trials. Early initiation of appropriate empiric antimicrobial therapy is crucial to prevent complications from osteomyelitis. Table 3 and Table 4 list treatment options and dosing information for specific organisms associated with osteomyelitis. Important considerations when selecting an antibiotic for presumed osteomyelitis include infection type, etiologic organisms, availability of culture and sensitivity results, host factors, and antibiotic characteristics. The key antibiotic characteristics to consider include local resistance patterns, penetration into the bone, and potential for systemic toxicities.

### Pharmacologic Therapy

Specific considerations are necessary for both empiric and bacteria-specific treatment. Currently, there is no consensus on the appropriate duration of intravenous therapy or total duration of therapy for osteomyelitis. Clinicians must select treatment duration on the basis of clinical presentation, risk factors, infection site, and patient age. Therapy duration for acute osteomyelitis is typically 4–6 weeks. Chronic osteomyelitis requires treatment with both surgical and medical intervention. Patients may require antimicrobial therapy for up to 6–12 months.

Initial therapy typically includes intravenous antibiotics, which may be used for up to 2 weeks before switching to oral therapy. Recent evidence has shown that an earlier transition from intravenous to oral therapy results in clinical outcomes and treatment failures similar to those in prolonged intravenous therapy (References 41–43). A systematic review of 12 studies found that patients receiving 7 days of intravenous therapy followed by oral therapy had similar cure rates at 6 months compared with patients receiving greater than 1 week of intravenous therapy (95.0% vs. 98.8%) (Reference 41). A study of 29 pediatric patients who were treated for acute osteomyelitis with a median of 4 days of intravenous therapy followed by 28 days of oral therapy showed no complications or treatment failures at the 6-month follow-up (Reference 42). Another study of 131 pediatric patients with culture-positive acute hematogenous osteomyelitis showed a favorable outcome in patients who received 2–4 days of intravenous therapy followed by oral therapy for 20–30 days (Reference 43). Furthermore, patients with prolonged

**Figure 2.** Magnetic resonance image depicting long-bone regions (left femur) and extensive marrow edema and significant enhancement of the periosteum and adjacent soft tissues (right femur) caused by *Staphylococcus aureus* osteomyelitis occurring in the distal right femur of a 26-month-old infant (Reference 16).

values remained high on day 3 of treatment, the patient was more likely to have a complicated clinical course (determined at a follow-up visit 1–2 months after discharge). However, if CRP values fell to normal levels by day 5, patients were more likely to be asymptomatic at follow-up.

Complications of osteomyelitis include persistent bacteremia, subperiosteal abscesses, venous thromboembolism, and progression to chronic osteomyelitis (Reference 35). Furthermore, permanent abnormalities of bone growth are possible. Chronic osteomyelitis, which may persist for several months, is usually managed with a combination of prolonged courses of antimicrobial therapy and surgical management. The prognosis of contiguous osteomyelitis depends on early diagnosis and aggressive therapy to avoid progression to chronic osteomyelitis.

**Table 3. Directed Antibiotic Therapy for the Management of Bone and Joint Infections**

Microorganism	Preferred Therapy	Alternative Therapies
<i>Staphylococcus aureus</i> Methicillin-susceptible (MSSA)	Nafcillin or oxacillin	Cefazolin Oral alternatives: dicloxacillin or cephalexin
<i>Staphylococcus aureus</i> Methicillin-resistant (MRSA)	Vancomycin	Linezolid or daptomycin
Community-associated MRSA	Vancomycin or clindamycin	Linezolid or daptomycin
<i>Streptococcus agalactiae</i>	Penicillin G or ampicillin	Cefotaxime or ceftriaxone
<i>Staphylococcus epidermidis</i>	Vancomycin	Daptomycin
<i>Streptococcus pyogenes</i>	Penicillin G	Clindamycin
<i>Streptococcus pneumoniae</i>		
Penicillin-sensitive (MIC < 0.1 mg/L)	Penicillin G	Cefotaxime or ceftriaxone
Penicillin-intermediate (MIC 0.1–1 mg/L)	Cefotaxime or ceftriaxone	Fluoroquinolone, clindamycin
Penicillin-resistant (MIC ≥ 2 mg/L)	Vancomycin	Linezolid
<i>Kingella kingae</i>	Cefuroxime, cefotaxime, or ceftriaxone	Penicillin, ampicillin, macrolide, fluoroquinolone
<i>Salmonella</i> spp.	Ampicillin (if susceptible) If ampicillin resistant: cefotaxime or ceftriaxone	Ciprofloxacin
<i>Pseudomonas aeruginosa</i> or <i>Serratia marcescens</i>	Cefepime or piperacillin/tazobactam <b>AND</b> Gentamicin	Ceftazidime or meropenem <b>AND</b> Gentamicin
<i>Escherichia coli</i>	Cefotaxime or ceftriaxone	Meropenem
<i>Pasteurella multocida</i>	Penicillin G or ampicillin	Doxycycline Ampicillin/sulbactam
<i>Bacteroides fragilis</i>	Clindamycin	Metronidazole Ampicillin/sulbactam Ticarcillin/clavulanate
<i>Neisseria gonorrhoeae</i>	Ceftriaxone	Amoxicillin or doxycycline
<i>Bartonella henselae</i>	Azithromycin	Doxycycline

MIC = minimum inhibitory concentration; MRSA = methicillin-resistant *S. aureus*; MSSA = methicillin-susceptible *S. aureus*.

home intravenous therapy are more likely to develop central venous catheter-associated complications (e.g., thromboses, infections) (Reference 44).

Although there is no clear consensus on when to change from intravenous to oral therapy, most experts recommend a transition to oral therapy on the basis of clinical markers rather than number of days of intravenous therapy. When patients show normalizing temperature, improving physical examination, and decreasing inflammatory markers (ESR and CRP), they can be changed to oral therapy.

### **Empiric Antimicrobial Therapy**

Because the most common cause of osteomyelitis is *S. aureus*, initial empiric therapy should be targeted against this organism. Monotherapy with an antistaphylococcal

agent is appropriate for patients older than 5 years with no additional risk factors (e.g., immunocompromised, sickle cell disease). For patients at risk of other organisms (e.g., *Salmonella*, *Kingella*, or *Pseudomonas*) in addition to *S. aureus*, broad-spectrum antimicrobial therapy should be initiated with an antistaphylococcal agent plus a third-generation cephalosporin.

Intravenous penicillinase-resistant penicillins (e.g., nafcillin, oxacillin) or a first-generation cephalosporin (e.g., cefazolin) has historically been considered a first-line empiric agent because of its bactericidal activity against methicillin-susceptible *S. aureus* (MSSA). However, with an increasing prevalence of CA-MRSA, it is recommended to use vancomycin (60 mg/kg/day) or clindamycin (40 mg/kg/day), both intravenously, as first-line empiric therapy until culture and sensitivity

**Table 4. Antimicrobial Dosing (References 1, 15, 39, 40)**

Antimicrobial Agent	Neonates		Infants and Children	Comments
	≤ 7 days	> 7 days		
Ampicillin	75–150 mg/kg/day ÷ q8h	100–200 mg/kg/day ÷ q6h	150–200 mg/kg/day ÷ q6–8h	Max single dose 2000 mg
Cefazolin	40 mg/kg/day ÷ q12h	60 mg/kg/day ÷ q8h	100 mg/kg/day ÷ q6–8h	Max single dose 2000 mg
Cefepime	100 mg/kg/day ÷ q12h	100 mg/kg/day ÷ q12h	150 mg/kg/day ÷ q8h	Max single dose 2000 mg
Cefotaxime	150 mg/kg/day ÷ q8h	150–200 mg/kg/day ÷ q6–8h	150–200 mg/kg/day ÷ q6–8h	Max single dose 2000 mg
Ceftazidime	50 mg/kg/dose q8–12h	150 mg/kg/day ÷ q8h	150 mg/kg/day ÷ q8h	Max single dose 2000 mg Potential to induce β-lactamase production
Ceftriaxone	—	—	50 mg/kg/day q24h	Max single dose 2000 mg Avoid use in the first 28 days of life
Cephalexin	—	—	100 mg/kg/day ÷ q6–8h	Max single dose 1000 mg
Ciprofloxacin	—	—	20–30 mg/kg/day ÷ q12h	
Clindamycin	15 mg/kg/day ÷ q8h	20–30 mg/kg/day ÷ q6–8h	40 mg/kg/day ÷ q6–8h (IV) 30 mg/kg/day ÷ q8h (oral)	Only for cultures with negative D-test Max oral dose: 40 mg/kg/day or 600 mg q8h
Daptomycin	—	—	6–10 mg/kg/day	
Dicloxacillin	—	—	100 mg/kg/day ÷ q6h	
Doxycycline	—	—	2–4 mg/kg/day	Only for use in patients > 8 year
Gentamicin	5 mg/kg/day ÷ q12h	5–7.5 mg/kg/day ÷ q8h	7.5 mg/kg/day ÷ q8h	Monitor peak and trough concentrations
Linezolid	10 mg/kg/dose q12h	10 mg/kg/dose q8h	10 mg/kg/dose q8h	Max dose: 600 mg twice daily
Meropenem	40 mg/kg/day ÷ q12h	60 mg/kg/day ÷ q8h	60 mg/kg/day ÷ q8h	Max single dose 2000 mg
Nafcillin	75 mg/kg/day ÷ q8h	100–150 mg/kg/day ÷ q6h	150–200 mg/kg/day ÷ q6h	Max DAILY dose 12 g
Oxacillin	150 mg/kg/day ÷ q8h	200 mg/kg/day ÷ q6h	200 mg/kg/day ÷ q6h	Max DAILY dose 12 g
Penicillin G	75,000 units/kg/day ÷ q8h	200,000 units/kg/day ÷ q6h	250,000–400,000 units/kg/day ÷ q4–6h	Max DAILY dose 24 million units
Vancomycin	15 mg/kg/dose q12h	45–60 mg/kg/day ÷ q6–8h	60 mg/kg/day ÷ q6h	Target trough concentration: 10–15 mg/L (15–20 mg/L in severe disease)

h = hours; IV = intravenous; q = every.

results are available (Reference 35). In addition, these two agents provide coverage against *S. pyogenes* and *S. pneumoniae*. According to the latest Infectious Diseases Society of America (IDSA) guidelines for the management of MRSA infections, clindamycin should only be used empirically if local resistance patterns are low (usually defined as less than 10%) and there is no evidence of bacteremia (Reference 35). Otherwise, vancomycin is preferred. In patients with a severe clinical presentation, the addition of rifampin or gentamicin to vancomycin may also be considered (Reference 45). Furthermore, vancomycin should be used as empiric therapy when other resistant gram-positive organisms (e.g., coagulase-negative staphylococci) are suspected.

Empiric therapy for neonates should cover both *S. aureus* and *Escherichia coli*. Therapy should be initiated with nafcillin or oxacillin plus cefotaxime or gentamicin. A first-generation cephalosporin (e.g., cefazolin) or clindamycin can also be considered in place of nafcillin or oxacillin for neonates. Patients with sickle cell disease should receive a third-generation cephalosporin (e.g., ceftriaxone) for coverage against *Salmonella* spp. Empiric coverage against *K. kingae* is unnecessary in most patients unless there is a high clinical suspicion such as in patients 5 years and younger who present after an upper respiratory tract infection. Figure 3 describes the empiric management of osteomyelitis in pediatric patients.

### Definitive Antimicrobial Therapy

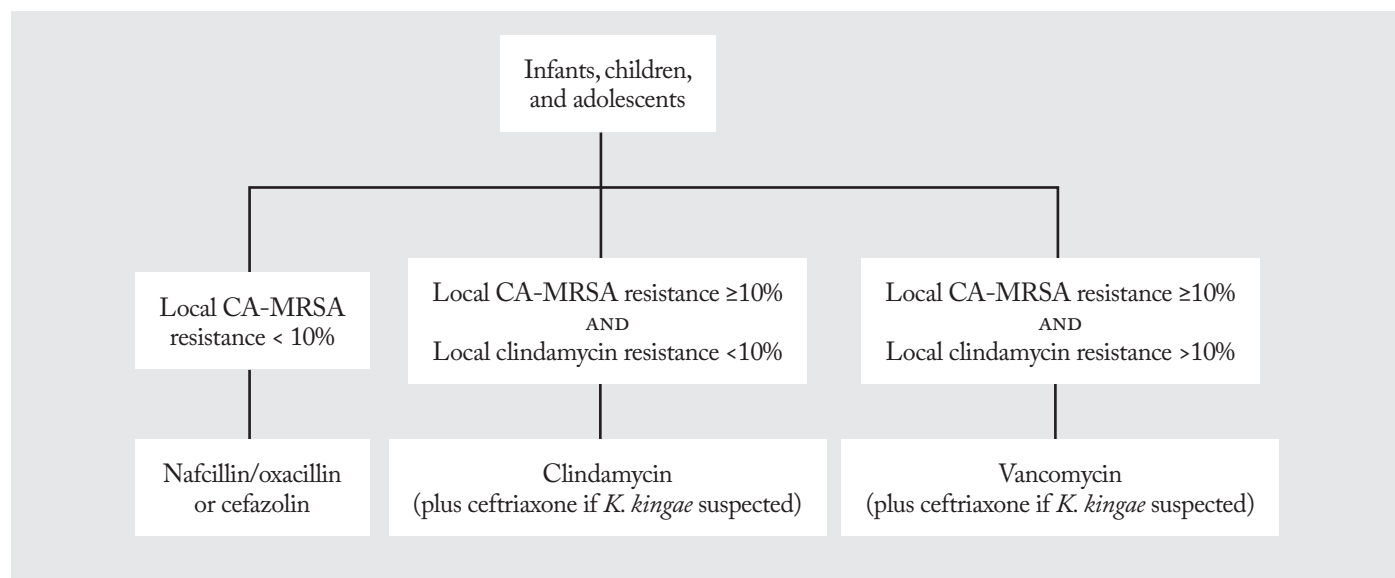

Once culture results and sensitivities are available, treatment should be directed to provide coverage against the specific organism isolated. If no organisms are identified,

empiric coverage should be continued if the patient is improving. For patients who do not improve and have negative cultures, alternative or additional therapies and evaluation should be considered.

### Gram-positive Organisms

Vancomycin is the treatment of choice for MRSA osteomyelitis, especially for strains that are not susceptible to clindamycin and in critically ill patients. However, dosing vancomycin at 40 mg/kg/day is inadequate to achieve the pharmacokinetic and pharmacodynamic targets recently proposed for adults. An area under the curve/minimum inhibitory concentration (AUC/MIC) ratio of 400 or more in adults with MRSA bacteremia or pneumonia correlates to positive treatment outcomes (Reference 35). Trough levels of 15–20 mg/L are recommended for invasive MRSA infections in adults, including osteomyelitis, because they correlate to an AUC/MIC ratio of 400 or more, increase tissue penetration, and minimize the selection of resistant strains of MRSA (Reference 35). Doses of at least 60 mg/kg/day should be initiated in children to attain these trough targets, particularly in severe cases (e.g., with concurrent bacteremia), even though data are limited on the efficacy and safety of these serum levels in children (References 38, 46). It is important to achieve adequate vancomycin serum concentrations early in therapy to ensure a faster transition to oral therapy (Reference 47).

Clindamycin is an attractive option for CA-MRSA osteomyelitis because of its high bone concentrations; its efficacy, which is close to 100% (in the absence of inducible resistance); and its availability in both intravenous

**Figure 3.** Empiric treatment algorithm for acute hematogenous osteomyelitis for infants, children, and adolescents.

CA-MRSA = community-associated methicillin-resistant *Staphylococcus aureus*.

and oral preparations (References 48–51). Clindamycin also has good activity against toxin-producing gram-positive organisms. The double-disk diffusion (D-test) is an important molecular test for the confirmation of inducible-resistant CA-MRSA strains (Reference 52) (Figure 4). This test identifies inducible clindamycin resistance among strains that initially show susceptibility to clindamycin. Clindamycin is a lincosamide antibiotic similar to the macrolide class of antibiotics. The practitioner should be aware of the potential for inducible resistance when a MRSA isolate shows clindamycin susceptibility and erythromycin resistance. The D-test is performed by creating a lawn of bacteria on an agar plate and placing a clindamycin and erythromycin disk 15 mm apart on the plate. If there is a uniform zone of inhibition around the clindamycin disk, then the test is negative (i.e., no inducible resistance). If there is blunting of the zone of inhibition on the side closest to the erythromycin disk that produced a D shape, then the test is positive (i.e., inducible resistance). For a positive D-test, the potential for treatment failure is increased, and clindamycin therapy should not be used. In an era of increasingly resistant gram-positive organisms, including vancomycin-intermediate and vancomycin-resistant staphylococci, clinical evidence is limited for the use of daptomycin and linezolid in pediatric osteomyelitis. These agents are not typically used for empiric therapy. Once culture results are known, they should be considered alternative therapy for MRSA osteomyelitis in patients who cannot receive vancomycin or clindamycin (Reference 35).

**Figure 4.** The D-test. A negative D-test is shown on the left, and a positive D-test is shown on the right. The erythromycin disk is located on the left of each agar plate, and the clindamycin disk is located on the right.

D-test = double-disk diffusion.

Daptomycin is a lipopeptide antibiotic with bactericidal activity against sensitive and resistant gram-positive organisms. It is an option for osteomyelitis treatment as a parenteral alternative to vancomycin (Reference 35). Evidence in children is limited; however, it has been found to be about 90% effective in adults for the treatment of osteomyelitis (References 53, 54). Daptomycin may have a role in the management of chronic osteomyelitis because of its ability to penetrate biofilm (Reference 26). Daptomycin should not be used in the setting of osteomyelitis with concomitant pneumonia because it is inactivated by alveolar surfactants.

Linezolid is an oxazolidinone antibiotic with activity against MRSA and other resistant gram-positive organisms. Linezolid achieves high bone concentrations and inhibits toxins produced by gram-positive bacteria (References 55, 56). Linezolid is approved for use in pediatric patients, including neonates, and is available in intravenous and oral formulations with around 100% oral bioavailability. Therefore, transitioning patients to oral therapy can be considered early in the treatment course. Linezolid was reported to be effective (85% complete recovery) and safe for pediatric patients with osteomyelitis in a case series and one large clinical trial (References 57, 58).

If MSSA is identified, patients who were empirically initiated on vancomycin or clindamycin should change to a penicillinase-resistant penicillin or cefazolin. There is greater bactericidal activity against MSSA with the penicillinase-resistant penicillins than with vancomycin (Reference 59). Cefazolin can be administered less frequently (every 8 hours) than either nafcillin or oxacillin (every 6 hours), which can be advantageous for outpatient use. In addition, there is a potential for thrombophlebitis with intravenous nafcillin administration. In patients with a serious hypersensitivity reaction to penicillin and a positive MSSA culture, clindamycin is the treatment of choice. Penicillin, clindamycin, or vancomycin may be used, depending on patient characteristics and microbial sensitivities to these agents, for the treatment of streptococcal species (e.g., *S. pyogenes* and *S. pneumoniae*).

#### Gram-negative Organisms

*K. kingae*, if identified, can be treated with a  $\beta$ -lactam antibiotic such as a second- or third-generation cephalosporin. Alternative agents include penicillin, ampicillin, macrolides, or ciprofloxacin. Clindamycin should not be used if the organism is inherently resistant. If *E. coli* is identified as the cause of osteomyelitis, therapy should be guided by the susceptibility results, with the empiric agent continued (e.g., cefotaxime) if clinical improvement has been documented and the bacterial strain is susceptible. A complete list of bacteria-specific therapy is provided in Table 3.

First-line treatment of *Salmonella* is ampicillin if the organism is susceptible. For resistant strains, a third-generation cephalosporin (e.g., cefotaxime, ceftriaxone) should be used. Fluoroquinolones (e.g., ciprofloxacin) are an alternative in patients with *Salmonella* osteomyelitis but are usually reserved for patients allergic to  $\beta$ -lactam antibiotics and as oral step-down therapy.

*Pseudomonas aeruginosa* is not a common organism in pediatric osteomyelitis, but if identified, therapy should include an antipseudomonal cephalosporin (e.g., ceftazidime, cefepime), antipseudomonal penicillin (e.g., piperacillin/tazobactam), or carbapenem (e.g., meropenem). Combination therapy with an antipseudomonal penicillin, carbapenem, or cephalosporin and an aminoglycoside may be considered in severe cases or with multidrug-resistant strains. The current American Academy of Pediatrics guidelines on the use of systemic fluoroquinolones in pediatric patients state that these agents can be used for definitive cases of acute or chronic osteomyelitis caused by *P. aeruginosa* (Reference 60).

For an anaerobic infection, therapy can be continued with clindamycin if it was initiated as an empiric agent. Metronidazole, ampicillin/sulbactam, and ticarcillin/clavulanate are alternative agents with anaerobic activity.

### **Role of Oral Antimicrobial Therapy**

Oral antibiotics play a very important role in the medical management of pediatric patients with osteomyelitis. Oral therapy is usually initiated after adequate treatment of intravenous therapy, depending on the severity of the infection and the clinical response of the patient. Oral antibiotics can also be used as first-line agents in mild infections, but this is less common. Important considerations when initiating oral antibiotic therapy for the treatment of osteomyelitis in children include palatability, cost, availability of appropriate dosage forms, and ease of administration (Reference 47). All of these characteristics are crucial in ensuring medication adherence for the treatment duration.

The most frequently used oral antibiotics in pediatric patients with osteomyelitis include clindamycin, linezolid, cephalexin, and dicloxacillin. Trimethoprim/sulfamethoxazole, doxycycline, or minocycline—alone or in combination with rifampin—and fluoroquinolones may also be considered, although data are limited. Trimethoprim/sulfamethoxazole has excellent activity against CA-MRSA and good oral palatability. Because of the risk of dental staining in younger children, tetracyclines can be used for CA-MRSA infections in patients after 8 years of age. Table 3 lists oral alternatives for the most common intravenous therapies. Patients should be initiated on oral therapy before discharge to ensure adherence to the selected therapy. Both clindamycin and linezolid have excellent oral bioavailability but poor

palatability (Reference 61). Oral  $\beta$ -lactam antibiotics must be given at high doses to achieve adequate bone penetration. Dosing is typically 2–3 times higher than recommended for other infections.

### **Outpatient Parenteral Antimicrobial Therapy**

Although sequential intravenous to oral therapy is the preferred treatment of osteomyelitis, intravenous therapy must sometimes be continued for an extended period. Candidates for home parenteral therapy include the following: neonates, patients with infections caused by organisms when there is no oral alternative, patients who cannot tolerate oral therapy, patients with chronic osteomyelitis, immunocompromised patients, patients with sickle cell anemia who have poor blood flow to the local area of infection, and patients in whom poor adherence to oral therapy is suspected (Reference 62). In these cases, patients must have an indwelling central venous catheter inserted to continue intravenous therapy as an outpatient. Coordination for home parenteral therapy requires an interprofessional approach using the physician, caregiver, pharmacist, and nurse. Educating the caregiver is essential to preventing possible complications from home intravenous therapy, including catheter-related bacteremia and line malfunction.

Outpatient parenteral antimicrobial therapy for osteomyelitis can decrease health care costs associated with this infection by reducing the number of hospital days and possible exposure to additional hospital pathogens. However, this approach may affect patient and family quality of life because it may be associated with increased cost to the family and considerably affect the child's ability to attend school or perform daily activities. Both the benefits and possible risks and disadvantages need to be considered when selecting patients for outpatient parenteral therapy.

### **Localized Antibiotic Therapy**

Localized antibiotic delivery directly to the infected bone provides the advantage of high local concentrations of the antibiotic with limited systemic toxicity. Cement beads made of polymethylmethacrylate (PMMA) are impregnated with antibiotics to allow drug release over several weeks to months (Reference 63). These beads must be surgically placed at initiation and removed upon therapy completion. Antibiotic-impregnated cement beads can be used in patients with difficult-to-treat infections and those with chronic osteomyelitis. They can be used in combination with systemic antibiotics or as an alternative. Antibiotics that have been used in this capacity include gentamicin,

vancomycin, penicillins, and cephalosporins. There is *in vitro* evidence with daptomycin in PMMA beads and in calcium sulfate, which is another localized delivery matrix (Reference 64).

### Nonpharmacologic Therapy

Nonpharmacologic therapy includes surgical debridement and the use of hyperbaric oxygen. Surgical debridement of the infected bone and drainage of adjacent soft tissue abscesses is a first-line treatment in addition to appropriate empiric antimicrobial therapy. Surgical drainage allows direct examination of the infected area and, if debridement of bone occurs, direct histopathologic examination of the bone. This can help guide decisions about appropriate antimicrobial therapy. Some patients with CA-MRSA may require several incision and drainage procedures during the course of therapy.

### Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy is used as an adjunctive treatment to surgery and antibiotics in patients with chronic osteomyelitis that is refractory to standard therapy. The procedure requires placement of the patient in an enclosed chamber where oxygen pressure is greater than sea level. The increased oxygen pressure enhances oxygen delivery to the infection site, leading to the formation of new capillaries, increased transport of antibiotics to the infected area, formation of a collagen matrix, suppression of anaerobic bacteria, and increased ability of phagocytes to target bacteria (Reference 65). Disadvantages of this treatment approach include limited clinical experience in pediatric patients, increased cost, and adverse effects, such as barotraumas and reversible myopia.

### Monitoring Parameters

Because patients with osteomyelitis will require prolonged antibiotic therapy, it is very important that they be closely monitored throughout the treatment. Once the initial antimicrobial therapy is started, improvements in clinical signs and symptoms should occur within 48–72 hours. Patients should be monitored for clinical and laboratory response to therapy, especially when no organism is identified and for the presence of adverse drug reactions and adherence to outpatient therapy. Laboratory parameters important for monitoring therapeutic response include culture and sensitivity results, improvement in markers of inflammation (e.g., CRP, ESR), and decrease in WBC. In patients with positive blood cultures, repeat cultures should be obtained to ensure eradication of the bacteremia. Patients receiving outpatient therapy should be monitored weekly for normalization of CRP and to ensure

no toxicity is associated with the treatment. After 4–6 weeks of appropriate antimicrobial therapy, success can be defined by the resolution of clinical signs and symptoms and normalization of all laboratory tests.

Common adverse reactions in patients receiving  $\beta$ -lactam antibiotics include diarrhea and gastrointestinal upset. Patients receiving  $\beta$ -lactam antibiotics should be monitored closely for the development of a rash or other allergic reaction (e.g., urticaria). Clindamycin causes gastrointestinal upset, diarrhea (that may develop into pseudomembranous colitis), and nausea. Patients and their caregivers should be counseled on contacting their provider if diarrhea becomes severe or if bloody stools develop. Renal function should be monitored weekly in patients receiving vancomycin, and patients should be monitored for the development of red man syndrome on initiation of therapy. If red man syndrome occurs, the infusion can be extended for a longer period (2 hours vs. 1 hour), and diphenhydramine can be administered before the infusion. Creatinine phosphokinase levels should be monitored routinely in patients receiving daptomycin because rhabdomyolysis is associated with increased drug serum levels. Caution is advised with the use of linezolid for more than 2 weeks because of treatment duration–related adverse effects (e.g., thrombocytopenia, peripheral neuropathies, optic neuritis) (References 35, 66). It is recommended to obtain weekly complete blood cell counts in patients receiving linezolid longer than 2 weeks and an ophthalmologic evaluation if therapy is continued for greater than 4 weeks. However, some data suggest that the hematologic effects of linezolid occur less frequently in children than in adults, especially in the first 2 weeks of therapy (Reference 67).

## INFECTIOUS ARTHRITIS

Infectious arthritis, commonly referred to as pyogenic or septic arthritis, is defined as an infection of the joint. It is much more common in pediatric patients than osteomyelitis. The infection usually begins in a monoarticular joint with inflammation of the joint space, synovium, synovial fluid, and surrounding cartilage. Prompt diagnosis and treatment is crucial in any patient with suspected infectious arthritis to prevent joint damage or spread of the infection to surrounding tissue or bone. In rare cases, if left untreated, the disease can be fatal. Many of the concepts previously introduced for osteomyelitis (most common organisms, treatments) also apply to infectious arthritis.

### Epidemiology

The incidence of infectious arthritis is between 5 and 12 cases per 100,000 children; however, the incidence varies by age (Reference 68). Children younger than 3 years and adolescents have the highest incidence (Reference

1). Males are affected twice as often as females, perhaps because males have more traumatic injuries during childhood. Infectious arthritis in children is almost exclusively from hematogenous spread and typically involves only one joint. The most common sites of infectious arthritis are the hip and knee, followed by the ankle (Reference 68). The hip is most commonly affected in neonates and infants. Infections of the upper extremities are less common, with the elbow and shoulder being reported in less than 10% of cases (References 69).

Although most cases of infectious arthritis are acute in nature, both chronic monoarticular arthritis and polyarticular arthritis can also occur. Mycobacteria, *B. burgdorferi*, and fungi typically present as chronic monoarticular arthritis. Polyarticular arthritis is most common after a viral infection.

### Pathophysiology

Infectious arthritis occurs secondarily to hematogenous seeding of an organism within the joint space. The synovial membrane is infected first. Edema and hypertrophy in the adjacent joint space lead to accumulation of exudative fluid in the synovium. Neutrophils, cytokines, and proteolytic enzymes are then recruited to the infection site. Pus accumulates in the joint space and leads to destruction of cartilage. Children younger than 18 months can develop infectious arthritis secondary to a bone infection because of the presence of transphyseal blood vessels that extend from the metaphysis to the epiphysis and growth plate (Reference 1).

### Microorganisms

Bacteria are the most common cause of infectious arthritis, whereas fungi and mycobacteria are rarer. Bacterial infectious arthritis is commonly classified into nongonococcal or gonococcal etiologies. Gram-positive organisms are most commonly identified in nongonococcal cases. Pediatric patients can also develop reactive arthritis in a joint after infection at a distant site in the body.

*S. aureus* is the most common bacterial cause of infectious arthritis in all age groups, followed by *S. pyogenes* and *K. kingae*. Similar to osteomyelitis, CA-MRSA strains have emerged as a common pathogen isolated from patients with infectious arthritis, but rates vary geographically. One small study of 45 patients in Texas found that one-third of isolates were positive for MRSA (Reference 70). Strains of *S. aureus* associated with the PVL gene are associated with more severe disease (e.g., CRP of 10 mg/dL or greater, longer duration of fever), the presence of concomitant abscess or cellulitis, and the possibility of a more difficult-to-treat infection (Reference 71).

In neonates and infants younger than 2 months, common causes also include group B streptococci, *Neisseria gonorrhoeae*, gram-negative enteric bacteria (e.g.,

*E. coli*), and, rarely, *Candida*. *S. aureus*, *S. pneumoniae*, *S. pyogenes*, and *K. kingae* are the most common organisms seen in children 2 months to 5 years of age. Because of the increase in Hib immunization rates during the past decade, this organism is now a rare cause of septic arthritis in an immunized child.

The most common cause of infectious arthritis in sexually active adolescents is *N. gonorrhoeae*. Other rare causes include *B. burgdorferi* (i.e., patients with tick exposure while in endemic areas), *Mycobacterium tuberculosis*, viruses (e.g., parvovirus B19, varicella, hepatitis B), and fungi.

Reactive arthritis is commonly seen in patients with gastrointestinal tract infections caused by *Salmonella*, *Shigella*, *Campylobacter*, or *Yersinia enterocolitidis* or with genitourinary tract infections caused by *Chlamydia trachomatis* or *N. gonorrhoeae*. It may also occur after a group A streptococcal infection.

### Risk Factors

Risk factors are associated with either systemic or host factors, such as age (younger than 3 years), preexisting joint disease, or immunosuppression. Local risk factors include recent joint trauma or surgery, presence of prosthetic joints, puncture wounds, recent administration of intra-articular corticosteroids, and rheumatoid arthritis. Although less common in the general pediatric population, intravenous drug abusers are also at increased risk of developing infectious arthritis.

### Clinical Presentation and Diagnosis

#### Signs and Symptoms

Patients with infectious arthritis typically present with an acute systemic infection. Fever, chills, and malaise are common symptoms. The joint is painful, hot, and edematous. It is important to distinguish patients with infectious causes of arthritis from those who have other causes. Transient synovitis is the most common cause of hip pain in children 5–10 years of age. Although no exact cause is known, transient synovitis has been associated with trauma, preceding viral infections, and vaccine-mediated reactions (Reference 1). The most common clinical presentation in these patients is unilateral pain and decreased range of motion. The patient may be afebrile or present with a low-grade fever. Other causes of joint pain (e.g., juvenile idiopathic arthritis, trauma, malignancy) should be considered if an infectious source cannot be identified.

#### Diagnostic Criteria

Clinical presentation is considered the gold standard diagnostic tool for infectious arthritis (Reference 72). Other diagnostic approaches include aspiration of the synovial fluid, radiography, ultrasonography, and MRI. The synovial fluid should be collected for culture and

sensitivity in any patient with a clinical presentation consistent with infectious arthritis. Typical findings suggestive of infectious arthritis upon analysis of joint fluid include isolation of bacteria on the Gram stain, leukocytosis (50,000/mm<sup>3</sup> or greater), decreased glucose (less than 50% of serum glucose), and increased lactate dehydrogenase, protein, or lactic acid. In addition, blood cultures should be performed to determine the presence of bacteremia. Additional laboratory findings that may suggest infectious arthritis include an increased WBC or increased inflammatory markers (e.g., ESR and CRP). Studies have shown the ESR and CRP to be elevated during septic arthritis in around 95% and 90% of patients, respectively (Reference 73). About 30% to 40% of patients will also have a positive blood culture (Reference 68).

Radiography is performed to rule out trauma or malignancy. A radiograph is useful in identifying whether there are significant abnormalities on the adjacent bones to suggest the presence of a concomitant osteomyelitis. Ultrasonography is used to determine the presence of fluid within the joint space and can guide in joint aspiration. However, ultrasonography cannot discern whether fluid within the joint space is infected. An MRI should be considered for patients with suspected concomitant osteomyelitis.

### **Course and Prognosis**

The overall prognosis is favorable for infectious arthritis with prompt initiation of antimicrobial therapy and adequate drainage. Infections of the hip are associated with the highest rates of long-term sequelae. Complications of infectious arthritis include abnormal bone growth, bony deformities at the femoral or humeral head, and local cartilage destruction. These occur more commonly in neonatal patients, patients with adjacent osteomyelitis, patients who do not seek immediate medical care after initiation of symptoms, and patients with *S. aureus*, including both MSSA and MRSA. If diagnosis is made promptly, the incidence of long-term sequelae after infectious arthritis is much lower.

### **Treatment**

The goals of therapy for infectious arthritis include eradicating the infecting organism, resolving the infection and inflammation, and preventing long-term sequelae. Treatment of infectious arthritis is very similar to that of osteomyelitis because of the similarity of causative organisms. However, considerations should be made for patient-specific age, risk factors, and other disease-related issues. Once culture and sensitivity results are available, therapy can be tailored to the specific organism.

The recommended duration of antibiotic therapy for septic arthritis is 3–4 weeks (Reference 35). A sequential intravenous to oral therapy approach is similar to that for osteomyelitis. Studies have shown similar outcomes in patients treated with shorter courses of intravenous therapy (7 days or less) compared with prolonged courses (more than 10 days) for the treatment of infectious arthritis. Patients may be changed to oral therapy once they have been afebrile for at least 24 hours, the joint swelling has improved to allow better range of motion, and the CRP is decreasing (References 74, 75). Once oral therapy is initiated, the highest recommended weight-based doses per day are required to achieve adequate joint tissue concentrations (Reference 76).

### **Pharmacologic Therapy**

Empiric therapy should target *S. aureus* and usually includes vancomycin or intravenous clindamycin to provide coverage against MRSA. If *K. kingae* is strongly suggested (age younger than 5 years, preceding upper respiratory infection), a  $\beta$ -lactam antibiotic (e.g., penicillin or cephalosporin) should be added to vancomycin or clindamycin (Reference 77). Therapy for sexually active adolescents should include ceftriaxone to cover *N. gonorrhoeae* in addition to staphylococcal coverage. When culture and sensitivity results are available, treatment should be directed at the specific bacteria isolated from the joint fluid. Table 4 lists the most common organisms and corresponding antimicrobial therapy for infectious arthritis. Intra-articular antibiotics are not indicated for the management of infectious arthritis. One small study showed benefit in reducing long-term complications with the addition of dexamethasone to standard antibiotic therapy (Reference 78). More research is required before this approach can be routinely recommended.

### **Nonpharmacologic Therapy**

First-line therapy in the management of infectious arthritis is joint aspiration. This strategy is even more crucial than antimicrobial therapy to provide positive clinical outcomes. Closed-needle aspiration of the joint is indicated for all joints except the hip and shoulder, which require open drainage. Joint drainage can be repeated daily for 5–7 days. An alternative to needle aspiration is arthroscopy with placement of a drainage tube. Joint aspiration and drainage should always be performed in conjunction with antibiotic therapy. Aspiration not only aids in diagnosis but also helps in the therapeutic management of these patients. Antimicrobial therapy should be initiated, if possible, after joint aspiration. Parameters to monitor after joint drainage include the volume of synovial fluid and the presence of WBCs, which should decrease with each subsequent drainage.

## Monitoring Parameters

The key monitoring parameters in the management of infectious arthritis include laboratory and inflammatory markers and clinical signs and symptoms, particularly improvement in joint movement, and adherence to antimicrobial therapy. Routine monitoring of CRP is suggested to follow response to therapy. Patients may be safely transitioned to oral therapy once the CRP normalizes, even in the presence of continued fever. If CRP has not decreased after adequate microbial coverage for 72 hours, further studies are warranted to ensure appropriate drainage has occurred.

## CONCLUSIONS

Bone and joint infections are common causes of invasive infections in the pediatric population. *S. aureus* remains the most common causative organism in both osteomyelitis and infectious arthritis, with an increasing incidence of CA-MRSA seen in recent years. Prompt identification of bone or joint infection and prompt initiation of appropriate empiric antimicrobial therapy are keys in the management of these infections. Treatment courses are typically prolonged, 3–4 weeks for infectious arthritis and 4–6 weeks for osteomyelitis, with an early transition to oral antibiotic therapy becoming the standard of care. The management of these infections requires a multidisciplinary approach including infectious disease physicians, nurses, physical therapists, pharmacists, and surgeons. Pharmacists play a crucial role in assisting with determining cost-effective therapies, transitioning patients to appropriate oral therapy, ensuring adherence to outpatient therapy, monitoring for medication toxicities and adverse drug reactions, and assisting with discharge planning.

# CHAPTER 41

## SKIN AND SOFT TISSUE INFECTIONS OF BACTERIAL AND VIRAL ETIOLOGY

Grace J. Lee, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. Recognize common bacterial and viral skin and soft tissue infections (SSTIs) of childhood through an understanding of their definitions, epidemiology, and clinical presentation.
2. Select empiric and definitive antimicrobial therapy on the basis of the etiologic agent, antimicrobial resistance patterns, severity of illness, and clinical evidence.
3. Recommend supportive treatment to aid in the recovery from active illness, and preventive strategies for avoiding disease transmission and outbreaks.
4. Recognize the increasing prevalence of community-associated methicillin-resistant *Staphylococcus aureus* as a pathogen in pediatric SSTIs and its impact on antibiotic selection.
5. Monitor antimicrobial therapy to maximize effectiveness and safety.

### ABBREVIATIONS IN THIS CHAPTER

BI	Bullous impetigo
CA-MRSA	Community-associated methicillin-resistant <i>Staphylococcus aureus</i>
GAS	Group A $\beta$ -hemolytic <i>Streptococcus</i>
HA-MRSA	Hospital-acquired methicillin-resistant <i>Staphylococcus aureus</i>
HFMD	Hand, foot, and mouth disease
HHV	Human herpes virus
HSV	Herpes simplex virus
IC	Impetigo contagiosa
IVIG	Intravenous immunoglobulin
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
MSSA	Methicillin-sensitive <i>Staphylococcus aureus</i>
NF	Necrotizing fasciitis
OC	Orbital cellulitis
PC	Periorbital cellulitis
SSSS	Staphylococcal scalded skin syndrome
SSTI	Skin and soft tissue infection
TMP/SMX	Trimethoprim/sulfamethoxazole
VZV	Varicella zoster virus

### INTRODUCTION

Skin and soft tissue infections (SSTIs), a common reason for children to seek medical attention, can range from a localized, superficial folliculitis, easily managed as an outpatient, to a life-threatening necrotizing fasciitis (NF), requiring immediate surgical intervention (Figure 1). Failure to quickly control a localized infection or identify symptoms suggestive of a deep tissue source can result in disseminated disease and significant morbidity. Therefore, pharmacists should be familiar with the clinical presentation of common skin lesions so that they can refer patients to seek further treatment when necessary. Diagnosing superficial skin infections in an ambulatory setting can be difficult because of their clinical similarities to other inflammatory diseases and challenges in histologic or microbiologic analysis (e.g., turnaround time, difficulty obtaining good-quality samples). A detailed history, time course, and physical examination are essential in making the proper diagnosis. Pharmacologic treatment is often empiric, requiring a general knowledge of common pathogens and local resistance patterns to antibiotics.

This chapter aims to provide an overview of the diagnosis and management of common bacterial and viral SSTIs encountered in children. A discussion of fungal dermatologic conditions is beyond the scope of this chapter; thus, the reader is referred elsewhere in this book.

### SUPERFICIAL BACTERIAL SKIN INFECTIONS

Historically, the most common pathogens responsible for SSTIs are *Staphylococcus aureus* and group A  $\beta$ -hemolytic *Streptococcus* (*Streptococcus pyogenes*) (GAS). In recent years, an increasing prevalence of community-associated methicillin-resistant *S. aureus* (CA-MRSA) has been observed in SSTIs. Community-associated methicillin-resistant *S. aureus* differs from hospital-acquired MRSA (HA-MRSA) in several ways. First, CA-MRSA affects populations not historically at risk of nosocomial infections (e.g., previously healthy children). Second, *S. aureus* resistance to methicillin is conferred by an alteration in the penicillin-binding protein PBP2, which is encoded on the *mecA* gene complex of the staphylococcal cassette chromosome *mec* (SCC*mec*). Shorter-length SCC*mec* subtypes carried by CA-MRSA compared with HA-MRSA encode

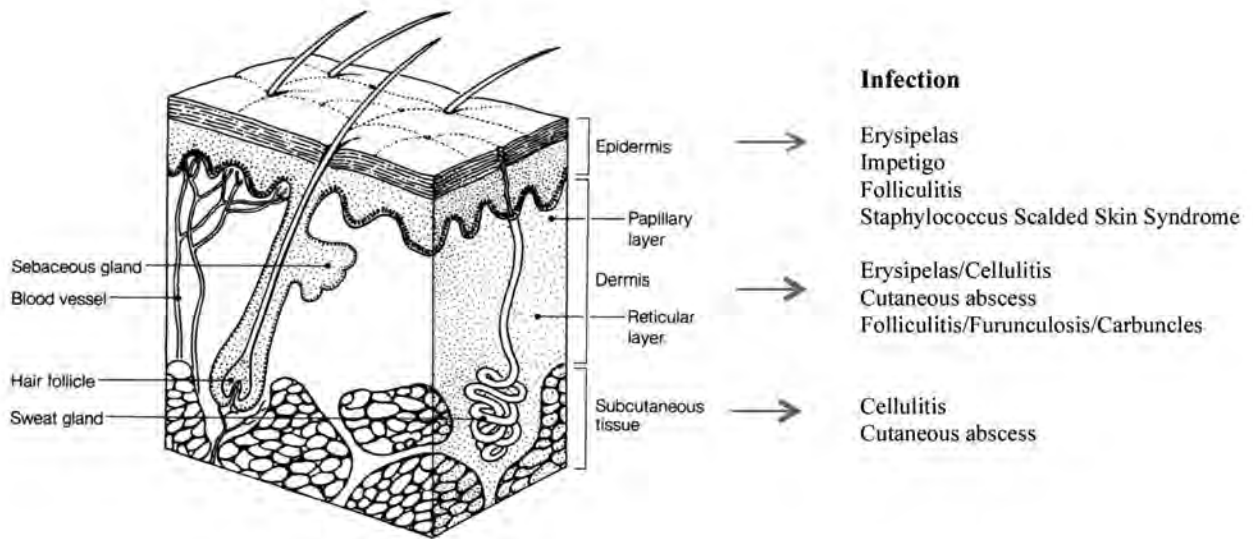

Figure 1. Schematic of skin structure and sites of superficial bacterial infections.

fewer proteins that produce antibiotic resistance, making CA-MRSA isolates less prone to developing multidrug resistance. Another unique molecular feature of CA-MRSA is the expression of a virulence factor, Panton-Valentine leukocidin (PVL), which can cause tissue necrosis and leukocyte destruction. This may partly explain the high association of CA-MRSA with pustular SSTIs such as furuncles, purulent cellulitis, and cutaneous abscesses.

### Folliculitis, Furuncles, and Carbuncles

Folliculitis, furuncles, and carbuncles are a family of pyodermic infections that originate around a hair follicle. Folliculitis is the most superficial and least extensive of the three, resulting in the formation of a small follicular abscess in the epidermis. Furuncles (or boils) are characterized by a more widespread inflammatory response of adjacent follicles extending into the dermis and subcutaneous tissue. These suppurative lesions are painful, erythematous, fluctuant, and may cause cellulitis in the surrounding areas. Carbuncles represent a confluence of furuncles with still-wider infiltration that can spontaneously drain from multiple sites (References 1–3).

Children of all age groups can develop folliculitis. Furunculosis tends to occur in adolescents, whereas carbuncles are generally seen in adulthood (Reference 2). Risk factors include hyperhidrosis, obesity, diabetes, seborrhea, anemia, malnutrition, and immunodeficiency. Clusters of infections may occur in people who interact in close quarters, especially in settings where skin injury is common, or in those who share household items that can transfer infectious material (Reference 1).

### Microbiologic Etiology

*S. aureus* is the most common causative agent of all three infections, and CA-MRSA now accounts for 3% to 25% of folliculitis (Reference 4). Genes for the virulence factor PVL have been detected in 42% of furuncles caused by *S. aureus*, specifically those associated with epidemic disease (Reference 5). Colonization with *S. aureus* is likely a risk factor for recurrent infection because nasal carriage rates are twice as high in patients with recurrent infection as in the general population (Reference 5). Gram-negative folliculitis with *Klebsiella* spp., *Enterobacter* spp., and *Proteus* spp. typically presents on the faces of patients with a history of antibiotic therapy for acne (Reference 1). “Hot tub” folliculitis is contracted through exposure to *Pseudomonas aeruginosa* from a contaminated hot tub or whirlpool.

### Clinical Presentation

Folliculitis occurs in hair-bearing areas and typically arises with no preexisting trauma to the skin. Inflammation along the hair shaft causes swelling and erythema that is accompanied by the formation of small dome-shaped pustules. Sites commonly affected include the scalp, extremities, buttocks, and areas of skin prone to moisture and friction (Figure 2). Furuncles and carbuncles can present as fluctuant masses that drain spontaneously, and often, they are accompanied by constitutional symptoms, such as fever and malaise. These infections are most often seen on the neck, breasts, face, buttocks, axillae, and groin (Reference 2).

**Figure 2.** Staphylococcal folliculitis on the buttocks where the lesions have been excoriated. Images reprinted with permission from Medscape.com, 2011.

### Diagnosis

The diagnosis of these conditions is largely based on clinical appearance. Cultures are not routinely obtained, but drainage from a lesion or abscess may undergo Gram staining and analysis when it is necessary to identify the causative organism.

### Treatment

Most folliculitis cases will resolve spontaneously, but complicated follicular infections should be treated with a short course of oral antibiotics targeting *S. aureus*. Cephalexin and dicloxacillin are recommended for methicillin-sensitive *S. aureus* (MSSA) coverage. Empiric coverage for CA-MRSA is recommended in communities where the local prevalence exceeds 10% (Reference 6); treatment options include trimethoprim/sulfamethoxazole (TMP/SMX) (in children at least 2 months of age to minimize the potential for bilirubin displacement from albumin and hence increase the risk of kernicterus), doxycycline (in children at least 8 years of age to minimize potential interference with tooth and bone formation), or clindamycin. Inducible resistance to clindamycin should be ruled out with a D-test before it is initiated. If local resistance patterns are greater than 10% to 15%, clindamycin should be avoided (References 6, 7).

Prompt therapy for furuncles and carbuncles is important to prevent dissemination into deep tissues or other organs. Warm, moist compresses can be applied to lesions to encourage wound drainage, and loculations within connective masses should be gently incised to ensure the complete evacuation of purulent material. Parenteral antibiotics are rarely indicated; however, patients presenting with severe systemic symptoms should

be treated initially with a parenteral penicillinase-resistant penicillin (e.g., oxacillin, nafcillin) or a first-generation cephalosporin and then converted to oral therapy for 7–10 days. Empiric vancomycin should be considered in all critically ill patients, especially those living in communities where CA-MRSA prevalence is high.

Treatments of chronic dermatologic conditions that predispose a patient to secondary bacterial infections and improvements in daily hygiene (e.g., antiseptic body washes, one-time use of washcloths, frequent dressing changes of draining lesions) are essential for preventing outbreaks. Topical anti-infectives such as chlorhexidine are most effective when used in conjunction with other strategies; however, the risk of adverse neurologic effects should preclude the use of hexachlorophene in children younger than 2 months (Reference 7). Dilute bleach baths given twice daily for 15 minutes may eradicate skin colonization of methicillin-resistant *S. aureus* (MRSA), but they should only be administered with clear instructions. Decolonization strategies with nasal mupirocin and oral rifampin can help reduce *S. aureus* nasal colonization, although their efficacy in preventing disease recurrence and impact on antimicrobial resistance is unclear (Reference 7). Current recommendations of the Infectious Diseases Society of America (IDSA) include the use of mupirocin alone for 5–10 days or in combination with a topical antiseptic for topical decolonization. In severe recurrent infection, rifampin together with TMP/SMX or doxycycline for 5–10 days is recommended.

### Erysipelas and Cellulitis

Erysipelas and cellulitis are diffuse, spreading skin infections without a suppurative focus. Erysipelas infection involves the epidermis, dermis, and occasionally lymphatic system. Because of its proximity to the skin surface, erysipelas is characterized by intense erythema and sharply demarcated, palpable borders. The disease can affect individuals across all racial and socioeconomic groups; it is commonly seen among the very young and very elderly. Neonates and young children are particularly at risk in the pediatric age group. Immunosuppression is a risk factor for disease.

In contrast, cellulitis predominantly affects deep layers of the skin such as the dermis and cutaneous tissue. It is manifested by generalized areas of edema, erythema, warmth, and tenderness without distinct margins (References 1, 3, 8). Cellulitis is a common reason for clinic visits in the United States, accounting in one study for 2.2% of all office visits to general practitioners (Reference 9). Infection can occur through the inoculation of a pathogen at a site of minor skin trauma or secondary

to conditions such as a compromised cutaneous barrier, recent surgical procedure, penetrating trauma from intravenous drug use or animal bites, impaired lymphatic drainage, or immunosuppression (Reference 7).

### **Microbiologic Etiology**

Group A  $\beta$ -hemolytic *Streptococcus*, or *S. pyogenes*, is the most common cause of erysipelas, though groups B, C, and G have also been implicated. Other rare etiologies such as *S. aureus*, *Klebsiella pneumoniae*, *Yersinia enterocolitica*, and *Haemophilus influenzae* should be considered, especially in immunocompromised patients or those not responding to empiric anti-streptococcal therapy (Reference 8).

Historically, most cellulitis cases have been caused by GAS and *S. aureus*. A recent systematic review of patients presenting with uncomplicated, nonpurulent cellulitis who underwent confirmatory tests (e.g., needle aspiration or punch biopsy) confirmed this observation (Reference 10). The proportion of staphylococcal isolates that were MRSA was not quantified in this study. The contribution of MRSA relative to GAS and MSSA in nonpurulent cellulitis remains unknown; however, in cellulitis cases complicated by abscess formation, CA-MRSA should be strongly suspected, given its high prevalence as reported in epidemiologic studies of purulent SSTIs (Reference 7).

### **Clinical Presentation**

Erysipelas usually originates from a minor skin trauma that becomes inoculated with a pathogen. A small red patch may rapidly develop streaking and induration as the lymphatic system becomes involved. The affected area, which is exquisitely tender and sharply demarcated, can advance rapidly and further progress to bullae formation with severe necrosis. In general, patients are not toxic appearing, and they lack systemic symptoms such as fever. The most common infection sites are the face (in a butterfly distribution) and lower extremities (legs and feet), though in neonates, the periumbilical area is often the primary infection site (References 1, 11).

Bacterial cellulitis represents an inflammatory process in solid tissues, with typical findings of redness, warmth, pain, and swelling, but without suppuration or necrosis (Reference 2). Although most patients show no signs of systemic illness, severe cases of cellulitis can be accompanied by fever, hemodynamic instability, and regional lymphadenopathy, together with eruptions of petechiae, vesicles, and bullae. Common infection sites in children are the lower extremities, face, periorbital area, and perineum (References 2, 12). Complications from deeply disseminated cellulitis may result in osteomyelitis and septic arthritis (Reference 1).

### **Diagnosis**

The diagnosis of erysipelas is largely based on the clinical appearance of the skin. Laboratory assessment may show an elevated leukocyte count with polymorphonuclear predominance, though blood cultures are only positive in 5% of cases (Reference 13). Needle aspirations of the lesion should be performed at the advancing margin or at the initiating wound if an abscess is present (Reference 1).

Cellulitis is often diagnosed by clinical findings. A key difference between cellulitis and other erythematous skin lesions is its unifocality. Cellulitis rarely presents bilaterally or in a disseminated distribution unless in an immunocompromised host (Reference 12). Blood cultures do not aid in diagnosis because they are positive less than 5% of the time. Invasive diagnostic procedures such as needle aspiration and skin biopsies are seldom performed because of their variable yield; however, they may be useful when it is necessary to identify the causative organism in patients with underlying comorbidities (References 13, 14).

### **Treatment**

Initial treatment of erysipelas should include oral antibiotics with streptococcal coverage. Most GAS remains susceptible to  $\beta$ -lactams (including penicillins and cephalosporins). In patients with severe penicillin allergies, clindamycin and macrolides are reasonable alternatives, assuming that local resistance rates are low (Reference 15). Patients presenting with systemic symptoms should be treated aggressively with parenteral antibiotics, followed by oral antibiotics once fever subsides and the cutaneous progression of the infection is halted. A 10- to 14-day treatment course is typically recommended.

Empiric antibiotic regimens for uncomplicated, nonpurulent cellulitis should cover GAS and MSSA. Because most patients can be treated with oral antibiotics, appropriate medications may include cephalexin, dicloxacillin, clindamycin, or macrolides. Patients presenting with suppurative cellulitis should receive oral antibiotics against CA-MRSA such as TMP/SMX, clindamycin (if local resistance rates are less than 10%), or a tetracycline, pending culture results.

In hospitalized patients with suspected cellulitis, parenteral options include a penicillinase-resistant penicillin (e.g., oxacillin, nafcillin), a first-generation cephalosporin (e.g., cefazolin), a combination  $\beta$ -lactam/ $\beta$ -lactamase inhibitor (e.g., ampicillin/sulbactam), clindamycin, or vancomycin (Reference 3). The IDSA practice guidelines recommend broadening the scope of antibiotics to cover CA-MRSA in patients with complicated SSTIs (e.g., deep soft tissue infections, surgical/traumatic wound infection, major abscesses, infected ulcers, and burns), those who do not respond to initial therapy, or those who

present with systemic toxicity. In addition to surgical debridement, antibiotic options specific to pediatrics include vancomycin (with a targeted trough of 10–15 mg/dL), clindamycin, and linezolid (Reference 7).

Treatment duration in uncomplicated cellulitis is typically 5–10 days. Longer therapy durations may be necessary for complicated cases and should be individualized on the basis of patient response. Elevation of the infected area promotes gravity drainage of edema and inflammatory substances. Underlying conditions that may predispose a patient to secondary cellulitis (e.g., immunosuppression, trauma, primary skin conditions such as eczema) should also be addressed.

### Impetigo

Impetigo is an infection of the superficial dermis that results in purulent lesions. The infected vesicle can easily rupture, causing the contents to form a honey-colored crust. Primary impetigo can be further classified as non-bullous or bullous. Non-bullous impetigo (also known as impetigo contagiosa [IC]) is characterized by the aforementioned crusted appearance. Bullous impetigo (BI), by contrast, is characterized by friable, fluid-filled vesicles or blisters (Reference 16).

Impetigo is the third most common type of skin infection in children, typically affecting children 2–5 years of age (Reference 17). Seventy percent of all impetigo cases are non-bullous because of the high contagiousness of impetigo (Reference 18). Transmission occurs through direct contact; thus, conditions of crowding and poor hygiene, day care, and warm climates are risk factors for outbreaks. Predisposition to disease depends on host factors such as atopy, immunosuppression, renal impairment, and diabetes (Reference 16). Bullous impetigo occurs more commonly in children younger than 5 years; however, most cases are diagnosed in neonates, possibly because of their lack of immunity against and impaired clearance of staphylococcal toxins (Reference 16).

### Microbiologic Etiology

The most common causative organisms for IC are *S. aureus*, GAS, or a combination of the two (Reference 18). Bullous impetigo is almost exclusively caused by *S. aureus* (Reference 19). The incidence of MRSA in impetigo was less than 20% in a Japanese study conducted between 1994 and 2000, but its frequency is increasing (References 3, 19).

Colonization with *Streptococcus* or *Staphylococcus* is believed to precede the development of active impetigo (Reference 3). Exfoliative exotoxins produced by *S. aureus* are virulence factors in both forms of impetigo, but especially in BI. The same exotoxins are implicated in staphylococcal scalded skin syndrome (SSSS), which is thought to be a more systemic version of BI (Reference 16).

### Clinical Presentation

In IC, lesions usually begin as small red macules that quickly turn into vesicles surrounded by erythema. The vesicles become pustular and rupture to give a thick honey-colored crust. Satellite lesions may appear when autoinoculation, or host reinfection, occurs at open breaks in the skin. Pruritus and other systemic complications, such as peripheral erythema and local lymphadenopathy, may be present. Areas commonly affected include the face and extremities.

Most impetigo cases are self-limiting and resolve without scarring within weeks. However, acute post-streptococcal glomerulonephritis may affect 1% to 5% of patients with IC (Reference 20). This risk is not attenuated by appropriate antibiotic treatment. Complications of systemic staphylococcal disease include SSSS, sepsis, cellulitis, pneumonia, lymphangitis, and osteomyelitis (Reference 19).

Bullous impetigo typically evolves from rapidly enlarging vesicles to flaccid bullae over normal skin with limited erythema. The encased fluid turns turbid and often ruptures within 48 hours, resulting in thin brown to golden-yellow crusts. The formation of collarette scales in the periphery of a ruptured lesion is a pathognomonic finding of BI (Reference 21) (Figure 3). Trunks and extremities are commonly affected, as are areas around the nose, mouth, and moist intertriginous zones, such as the diaper area, neck folds, and axillae. Systemic complications are uncommon.

### Diagnosis

Diagnosis is often made on clinical appearance alone. Microbiologic analysis and skin biopsies are rarely indicated, except to clarify cases of extensive involvement or in patients who do not respond to initial antibiotics.

Figure 3. Bullous impetigo with circumscribed lesions and thin collarettes of scales. Images reprinted with permission from Medscape.com, 2011.

Bacteria may be cultured from the blister contents. Antistreptococcal antibody assays do not aid in diagnosing IC but provide supporting evidence of recent systemic streptococcal infection in patients with suspected post streptococcal glomerulonephritis.

### **Treatment**

Expert opinions recommend a 7-day course of topical treatment for localized, uncomplicated impetigo cases (References 3, 16). The basis of this recommendation is derived from meta-analyses examining the comparative efficacy of various outpatient regimens (References 22, 23). Topical antibiotics, such as mupirocin 2%, fusidic acid 2% (not available in the United States), and gentamicin 0.1%, were clinically superior compared with placebo (Reference 22). Among the topical antibiotics, comparisons of mupirocin and fusidic acid did not show a difference in clinical outcome (Reference 22).

In more recent literature, protein synthesis inhibitors called pleuromutilins have shown good in vitro activity against various streptococcal and staphylococcal species (Reference 24). Retapamulin is the first topical agent in this category licensed for impetigo caused by MSSA or *S. pyogenes* in patients 9 months or older (Reference 25). When applied twice daily for 5 days, retapamulin 1% ointment was found superior to placebo for the treatment of impetigo and non-inferior to fusidic acid (References 26, 27). Although clinical studies have suggested its efficacy against a few fusidic acid and mupirocin-resistant strains, this has not been shown on a large scale (Reference 27).

In two meta-analyses, topical treatment was favored over oral antibiotics for uncomplicated impetigo (References 22, 23). However, robust studies comparing topical and oral treatments remain deficient. In general, oral antibiotics should be reserved for cases of recalcitrant, extensive, or systemic disease. Because of the predominance of *S. aureus* in BI and IC, penicillinase-resistant penicillins,  $\beta$ -lactam/ $\beta$ -lactamase combinations, or first-generation cephalosporins are appropriate first-line oral antibiotic choices for the treatment of extensive impetigo. Macrolides may be substituted in patients with true penicillin allergies but only in regions with less than 10% macrolide resistance or confirmed macrolide susceptibility. When MRSA is suspected, clindamycin or TMP/SMX should be considered. Because no clinical trials have shown the superiority of one antibiotic over another, choice of an optimal regimen will depend on local susceptibility data and patient-specific factors, such as contraindications, allergies, and tolerance of adverse effects. Recommended length of therapy is 7 days (References 16, 19).

### **Staphylococcal Scalded Skin Syndrome**

Staphylococcal scalded skin syndrome, an infection caused by certain strains of *S. aureus*, results in the loss of keratinocyte cell adhesion and leads to blistering of the upper layer of the skin. These flaccid bullae rupture easily to reveal an erythematous base, giving rise to a moist, scalded appearance and widespread desquamation (Reference 28). Staphylococcal scalded skin syndrome is believed to be a generalized form of BI because of their shared virulence factor, the exfoliative toxin (ET), which compromises intercellular adhesion and gives rise to the pathognomonic histologic findings of mid-epidermal separation at the zona granulosa (Reference 29).

Staphylococcal scalded skin syndrome usually presents in children younger than 5 years. Disease transmission is likely through contact with asymptomatic carriers of *S. aureus*. Infants and young children may be especially susceptible because of waning immunity from maternal antibodies and impaired renal clearance of ET (Reference 29). Mortality in childhood SSSS is 5% but may exceed 60% in adults (Reference 30).

### **Microbiologic Etiology**

Staphylococcal scalded skin syndrome, by definition, is caused by *S. aureus*-bearing ET-encoding genes, which were detected in up to 10% of all *S. aureus* strains in a recent study from Europe (Reference 31). A greater percentage of MRSA strains express these genes than do MSSA strains, though the clinical significance of this is unknown. Currently, there are very few cases of MRSA causing SSSS reported in the literature (References 32–34). Most SSSS cases in the United States are caused by *S. aureus* phage type II, which is predominantly methicillin sensitive (References 29, 35).

### **Clinical Presentation**

Patients may present with a prodrome of sore throat and conjunctivitis, accompanied by constitutional symptoms of fever, malaise, and irritability. Within 48 hours, exquisitely tender erythematous patches, which rapidly erupt on the face, neck, axilla, and perineum, may develop into non-tense bullae that rupture to reveal a friable, erythematous base susceptible to denuding by simple rubbing (e.g., positive Nikolsky sign) (Figure 4). Large areas of the skin may be involved, particularly in flexural and perioral regions. Mucous membranes are spared (Figure 5). Complications include secondary infections, electrolyte disturbances, and difficulties in temperature regulation (References 29, 30, 36, 37).

**Figure 4.** Erythematous patches on the torso, arm, and neck characteristic of staphylococcal scalded skin syndrome. Photo credit: Dr. James Corb, Children's Hospital of Orange County.

**Figure 5.** Perioral peeling from staphylococcal scalded skin syndrome. Photo credit: Dr. James Corb, Children's Hospital of Orange County.

### **Diagnosis**

Generalized SSSS is a manifestation of the hematogenous spread of ET produced by bacteria from a focus of colonization (nares, eye, umbilicus, groin, or wound site) or active infection (pneumonia, osteomyelitis, or endocarditis). The yield of bacterial cultures from blister aspirates and blood is generally poor because symptoms are mediated through toxins released by organisms residing in extracutaneous reservoirs. However, isolation of *S. aureus* from a suspected focus of infection may be confirmatory (References 36, 37).

### **Treatment**

Although limited evidence exists to guide the optimal treatment of SSSS, a parenteral antibiotic with staphylococcal activity (i.e., penicillinase-resistant penicillin or a first- or second-generation cephalosporin) is recommended and should be initiated promptly. The addition of clindamycin as an adjunct to any regimen should be strongly considered because of its ability to attenuate toxin production (Reference 37). Because patients with extensive exfoliation are at high risk of secondary gram-negative infections or septicemia, some experts recommend adding gentamicin to an antistaphylococcal regimen or changing to a third-generation cephalosporin plus clindamycin (References 16, 29). Lack of symptomatic improvement within 48 hours should also prompt expanded coverage to include MRSA.

Eroded areas are best covered with bland emollients, such as petrolatum, to prevent moisture loss and protect against bacterial infections. Topical antibiotic ointments may be prescribed for conjunctivitis and mupirocin for nasal decolonization. Extensive skin involvement may necessitate additional treatment considerations, including aggressive pain management, fluid and nutritional support, temperature regulation, and prevention of pressure sores and secondary infections. In outbreaks, carriers should be immediately identified and treated with antistaphylococcal antibiotics.

Exfoliation may continue for 24–48 hours after the initiation of appropriate antibiotic therapy until toxin production ceases. Thereafter, skin lesions should heal rapidly in 7–10 days with minimal scarring because only the superficial layers are affected (Reference 29). Typical length of antibiotic treatment is at least 10 days.

### **Cutaneous Abscesses**

A cutaneous abscess is an encapsulated collection of pus within the dermis and deep skin tissues that is accompanied by swelling and an erythematous rim. It is among the leading causes of pediatric outpatient clinic visits. In an epidemiologic study of SSTIs in the United States between 2001 and 2003, pediatric patients represented 24% of an estimated 11.6 million SSTI-related visits in

an ambulatory care setting (Reference 38). The combined category of cutaneous abscesses and cellulitis accounted for 62% of all SSTI diagnoses and rose 15% in incidence compared with statistics from 1992 to 1994 (Reference 38). The disease burden also appeared to shift from the physician's office to the outpatient clinic and emergency department because the visit rates for the latter two settings increased by 59% and 31%, respectively, during these periods (Reference 38). The authors surmised that these trends, in part, coincided with the emergence of CA-MRSA as a pathogen during the late 1990s, which is associated with a rapidly progressive onset that would cause patients to seek treatment in urgent care settings.

In recent years, SSTIs (particularly abscesses) have continued to be the most common manifestation of CA-MRSA (Reference 4). Although nasal colonization with MRSA has been identified as a risk factor for recurring SSTIs, its predictive value for new infections within a community is not fully understood (Reference 39). Because MRSA can also reside in other sites including the pharynx, axillae, rectum, and perineum, one pediatric study suggests a stronger correlation between rectal MRSA colonization and abscess development than nasal MRSA colonization (Reference 40).

### **Microbiologic Etiology**

*S. aureus* is the most common bacteria isolated from cutaneous abscesses, accounting for 66% to 82% of all samples obtained through incision and drainage (I&D) in four recent pediatric studies (References 40–43). Of note, the incidence of CA-MRSA has increased significantly, now representing 49% to 100% of *S. aureus* cultures isolated from abscesses in pediatric patients (References 40–44). One study observed an increase in the incidence of MRSA by 80% between 2003 and 2006 (Reference 43).

Although most abscesses occurring above the trunk and extremities are caused by *S. aureus*, anaerobic organisms such as *Peptococcus* spp. and *Propionibacterium* spp. may also be involved. Abscesses in the perineal region are often polymicrobial, containing anaerobic and aerobic bacteria that constitute the normal flora of regional skin and mucous membranes (Reference 2).

### **Clinical Presentation**

Abscesses typically result from minor trauma to an area that becomes infected. The area may develop a nodule, which can become fluctuant or pustular and is surrounded by erythematous swelling (Figure 6). It is usually painful and tender. Accompanying features can include local cellulitis, lymphangitis, regional lymphadenopathy, fever, and leukocytosis (Reference 2).

One prospective study noted that most abscesses in children developed around the diaper area, namely the gluteus (43%), perineum/labia (5.4%), and inguinal (7.4%) areas; other locations included the upper leg (8.1%), lower leg (8.4%), axilla (13.4%), forearm (2.7%), abdomen (8.1%), and head (3.3%) (Reference 44).

### **Diagnosis**

The diagnosis of cutaneous abscesses should not be based on clinical examination alone because agreement among evaluators can be poor (Reference 45). Assessment methods that are more objective, such as bedside ultrasonography, can help determine the presence of a drainable fluid collection (Reference 46). Gram staining and culture may be especially useful in the presence of several lesions, surrounding cellulitis, systemic manifestations of infection, or an immunocompromised host (Reference 3).

### **Treatment**

Incision and drainage is the cornerstone of therapy for the treatment of cutaneous abscesses (Reference 7). There is a paucity of controlled comparative trials to guide the treatment of this disease state. A recent randomized, double-blind study comparing placebo with 10 days of TMP/SMX after I&D of skin abscesses in 149 children showed that both groups experienced similarly low rates of treatment failure when evaluated at 10 days (Reference 47). This finding was also true in the subset of patients infected with CA-MRSA who did not see a greater rate of clinical resolution while receiving appropriate antibiotics. Although the use of inappropriate antibiotics may not be associated with worse outcomes, an infected area greater than 5 cm in diameter may be (Reference 48).

The IDSA practice guidelines do not advocate continuing antibiotics after I&D for simple abscesses (Reference 7). However, antibiotic therapy should be

**Figure 6.** An erythematous, fluctuant abscess in the axilla. Photo credit: Dr. James Corb, Children's Hospital of Orange County.

considered in complicated disease or specific hosts (Table 1). If antibiotics are initiated, empiric coverage for CA-MRSA is recommended until culture and sensitivity results are known. Initial oral options may include TMP/SMX, clindamycin, and doxycycline. Linezolid, given its wide spectrum of activity against other drug-resistant organisms and comparatively expensive cost, should be reserved as a last resort for outpatient management. In hospitalized children, vancomycin is recommended with a trough goal of 10–15 mg/dL. Parenteral clindamycin and linezolid are other options if the patient is stable without ongoing bacteremia or intravascular infection (Reference 7).

### Animal and Human Bites

Animal and human bites are wounds that can result in infectious complications. The incidence of animal bites in the United States is estimated to be 2–5 million per year, with most cases occurring in children. Around 85% to 90% of bite injuries are caused by dogs, followed by cats (5% to 10%) and humans (2% to 3%) (Reference 49). About 1.3 in 1000 people with dog bites require medical treatment, with the highest incidence being among 5- to 9-year-old boys (6 in 1000 people) (Reference 50). There is much less epidemiologic information on cat bites specific to children. In one prospective study of patients presenting to the emergency department with cat bites, 58% of patients were younger than 21 years, among which the greatest portion were patients younger than 6 years (Reference 51). Human bites have been characterized by some as a “leisure time injury of the young single male” on the basis of an epidemiologic study showing a predominance of males between 16 and 20 years of age and a possible association with alcohol use (Reference 52). In this same study, children younger than 15 years accounted for 12% of human bite injuries presenting at an emergency department (Reference 52). Around 1% to 3% of human bites in children are from child abuse (Reference 49).

### Microbiologic Etiology

Sources of bacteria recovered from a bite wound are those that colonize the victim’s skin and those that derive from the oral cavity of the aggressor, as well as environmental organisms. In one study involving children who sustained injuries from animal bites (17 dogs, 4 cats), an average of 2.8 organisms were isolated from each specimen, more than 66% of which were a combination of aerobic and anaerobic bacteria (Reference 53). In an adult study that analyzed the bacteriology of wounds associated with clinical signs of infection, *Pasteurella* spp. was the most frequent isolate, followed by *Streptococcus* spp., *Staphylococcus* spp., *Moraxella* spp.,

**Table 1.** Patients for Whom Antibiotic Therapy Is Recommended After I&D of Simple Abscess (Reference 7)

- Severe or extensive disease (e.g., involving many infection sites)
- Rapid progression in the presence of associated cellulitis, signs and symptoms of systemic illness
- Associated comorbidities or immunosuppression (diabetes mellitus, human immunodeficiency virus infection/AIDS, neoplasm)
- Extremes of age
- Abscess in area difficult to drain
- Associated septic phlebitis
- Lack of response to I&D alone

AIDS = acquired immunodeficiency syndrome; I&D = incision and drainage.

Information from Liu C, Bayer A, Cosgrove S, Daum R, Fridkin S, Gorwitz R, et al. Clinical practice guidelines by the Infectious Diseases Society of America for the treatment of methicillin-resistant *Staphylococcus aureus* infections in adults and children. Clin Infect Dis 2011;52:1–38.

and *Neisseria* spp. Anaerobes included *Fusobacterium* spp., *Bacteroides* spp., *Porphyromonas* spp., and *Prevotella* spp. (Reference 54). Dogs and cats, as well as other feral animals, may be carriers of rabies. *Bartonella henselae*, which is associated with a febrile illness known as “cat scratch disease,” is a pathogen unique to cat bites. Common aerobic microbes isolated from human bite injuries include *Streptococcus anginosus*, *S. aureus*, coagulase-negative *Staphylococcus*, *Enterococcus* spp., *Corynebacterium* spp., and *Eikenella corrodens*. *Prevotella* spp., *Porphyromonas* spp., *Bacteroides* spp., *Fusobacterium* spp., and *Peptostreptococcus* spp. are typical anaerobic pathogens (Reference 55). Moreover, hepatitis B and C, as well as human immunodeficiency virus (HIV), can rarely be transmitted from the aggressor to the victim through bite injuries (Reference 56).

### Clinical Presentation

Anatomic differences in the tooth shapes of cats and dogs result in wound profiles unique to each animal. Cat teeth are long and slender, which are more likely to inflict small but deep puncture wounds. Most cat bites do not penetrate beyond the dermis; however, in one study, 25% of wounds damaged the subcutaneous layer, and 4% affected muscle, tendon, or bone (Reference 51). In contrast, dog bites are predominantly crush injuries, lacerations, or abrasions that result in partial skin penetration (Reference 57). In children, the hands and arms are the most common wound sites for cat bites,

compared with head and neck injuries with dog bites (References 51, 58). Around 4% of wounds associated with dog and cat bites result in hospitalization (References 50, 51). Human bites are typically located on the face, upper extremity, or trunk and can range in presentation depending on the mechanism of injury. Two types of bite wounds are common: (1) an occlusional injury, which is a direct penetration trauma to the skin tissue caused by the biter's teeth, and (2) a clenched-fist injury, in which bacteria inoculated through the broken skin of a fist in a flexed position travel caudally to tendons and joints when the hand is relaxed to cause deeper infections. Because the intercanine distance of an adult is typically 2.5–4 cm, the presentation of a lesion with said dimensions on a child may be suggestive of abuse (Reference 49).

It is estimated that 3% to 18% of dog bites and 28% to 80% of cat bites become infected (Reference 54). Patients presenting 12 hours after the inciting event likely have established infection (Reference 3). The wound site may appear edematous, erythematous, and bruised, and it may drain serosanguineous fluid. Pain is a common finding. Lymphadenopathy, streaking, and fever can signify more systemic complications such as cellulitis, subcutaneous abscesses, osteomyelitis, tendonitis, and, rarely, bacteremia (Reference 3).

Several studies have sought to identify risk factors correlated with the development of wound infections. For cat bites, these included deep puncture or full-thickness wounds and injuries to the extremities. Of interest, facial wounds had lower absolute risks of infection, perhaps because of the increased blood supply to the area (Reference 51). The three strongest predictors of infection after a dog bite are wound depth, need for wound debridement, and female sex, though factors such as wound location or type and time between wound and debridement have been identified as secondary determinants (References 57, 59). Human bites can result in infection in 10% to 15% of cases (Reference 60). Clenched fist injuries are particularly prone to complications because relaxation of the hand brings the wound closer to tendons, metacarpal heads, and joint spaces, where the infection can spread.

### Diagnosis

Diagnosis is based on a positive history of interaction with an animal or individual who inflicted the wound, as well as a clinical examination. Cultures should only be obtained for wounds more than 8–12 hours old or those that appear infected. Radiography is indicated if there is concern about injury to deep structures or a need to assess foreign body inoculation (References 61, 62).

### Treatment

The goals of bite wound management are the treatment or prevention of infection and minimization of soft tissue damage. Many treatment algorithms, which are largely based on expert opinion, focus on timely wound cleaning, irrigation, debridement, and closure if appropriate. The wound should be cleansed with clean water and gentle soap to remove any visible dirt. Soaking the injury or using alcohol or peroxide is not recommended because of the potential for further tissue injury. Irrigation with a saline lavage can be administered with a 30-mL syringe and 18-gauge intravenous catheter. Debridement is indicated for the removal of any foreign body or devitalized tissue. Edematous wounds should be passively elevated to encourage lymphatic drainage and accelerate healing. The decision on whether to close a wound is controversial. Fresh, non-punctured wounds that are limited and thoroughly cleaned may be closed by primary intention. Surgical closure of bite wounds to the neck and face up to 24 hours after the injury, together with the administration of prophylactic antibiotics, is a reasonable treatment strategy because of good vascular supply to the area and cosmetic considerations (Reference 49). All wounds with established infection or at high risk of infection, including puncture wounds, crush injuries, wounds more than 12–24 hours old, hand or foot wounds, cat or human bites, or wounds in immunocompromised individuals, should not be sutured but kept well bandaged (References 49, 56). Immunoprophylaxis against tetanus, rabies, hepatitis, and HIV should be considered after a human bite on the basis of the aggressor's clinical history and the patient's immune status. The reader is referred to the Centers for Disease Control and Prevention Web site for current guidelines on postexposure prophylaxis for the aforementioned diseases.

Most uncomplicated bite injuries can be managed in the outpatient setting. Prophylactic antibiotics in low-risk wounds (early presenting, non-infected, non-puncturing) have limited benefit and are not routinely recommended (Reference 63). However, a 3- to 5-day oral course should be considered in selected cases (Table 2) (References 3, 49, 53, 56). Close follow-up is indicated in the next 48 hours to monitor for signs of developing infection.

Patients presenting with signs of established infection after an animal bite should be empirically treated with antibiotics, which will cover the typical pathogens including *S. aureus*, *Pasteurella multocida*, and other anaerobes. Empiric coverage for human bites should cover mixed flora, with special attention to *E. corrodens*, because it is not susceptible to first-generation cephalosporins. Outpatient management with oral amoxicillin/clavulanate is first line for all mammalian bites, with TMP/SMX or an extended-spectrum cephalosporin

**Table 2.** Indications for Prophylactic Antibiotics After a Mammalian Bite (References 3, 49, 56)

- Human bite wounds
- Puncture wounds beyond the epidermis
- Wounds with associated crush injury and edema
- Wounds on the hands/feet or in proximity to a bone or joint
- Facial bites
- Genital area bites
- Wounds present in complicated hosts (extremes of age, immunocompromised or asplenic, chronic disease)

Information from Stevens DL, Bisno AL, Chambers HF, Everett ED, Dellinger P, Goldstein EJ, et al. Practice guidelines for the diagnosis and management of skin and soft tissue infections. *Clin Infect Dis* 2005;41:1373–406; Kannikeswaran N, Kamat D. Mammalian bites. *Clin Pediatr* 2009;48:145–8; Thomas N, Brook I. Animal bite-associated infections: microbiology and treatment. *Expert Rev Anti Infect Ther* 2011;9:215–26.

(e.g., cefuroxime) in combination with clindamycin as alternatives in patients with penicillin allergies (References 56, 62). Other oral alternatives include doxycycline and the fluoroquinolones, which when dictated by cultures and sensitivities, may be used safely in children. Intravenous antimicrobials with activity against mixed flora such as  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combinations, TMP/SMX plus clindamycin, and second-generation cephalosporins with anaerobic activity (e.g., cefoxitin) are suitable empiric choices for severe infections (References 56, 62). Broad-spectrum carbapenems should be reserved for treatment failure or drug-resistant isolates. Therapy duration will vary by the severity of injury, but it can range from 7–14 days for soft tissue infections to 3–6 weeks for involvement of the joints or bones (References 3, 56, 62).

## DEEP BACTERIAL TISSUE INFECTIONS

### Periorbital and Orbital Cellulitis

The orbital septum is a fibrous tissue that arises from the periosteum of the skull and continues into the eyelids. This anatomic landmark serves as a barrier to prevent superficial infections from penetrating deep into the orbit. Infections occurring in the soft tissue anterior to the septum are called periorbital cellulitis (PC), whereas those occurring posterior to the septum are considered orbital cellulitis (OC). Periorbital cellulitis is a disease that occurs in young children, particularly those younger than 5 years. Males and females are equally affected. In comparison, OC is only one-third as common as PC and tends to affect children 5–7 years of age (References

64–70). Epidemiologic studies of OC describe a 2:1 male predominance (References 66, 68, 70, 71). Because of its association with upper respiratory tract infections, OC tends to occur more frequently in the winter (References 66, 71).

Predisposing factors for orbital infections include upper respiratory tract or sinus infections, extension of external ocular infections, dental abscesses, superficial breaks in the skin from underlying skin conditions, an insect bite, a penetrating injury to the orbit, periocular surgery, and hematogenous seeding (Reference 71).

### Microbiologic Etiology

The organisms responsible for PC and OC have historically been the same bacteria implicated in respiratory tract and sinus infections; however, widespread administration of childhood Haemophilus and streptococcal vaccines may shift the types of causative pathogens.

Periorbital cellulitis seeded from minor trauma to the skin is often caused by staphylococcal and streptococcal species, which account for greater than 70% of positive cultures (e.g., orbital/sinus, conjunctiva, blood) obtained from infected children (References 66–69, 71). Orbital cellulitis is often a complication of acute sinusitis (specifically the ethmoid sinus); thus, respiratory organisms such as *Streptococcus pneumoniae*, GAS, other streptococcal species (*S. anginosus*), *S. aureus*, nontypeable *H. influenzae*, or *Moraxella catarrhalis* are common pathogens. Although *S. aureus* is often implicated in these disease states, the pervasiveness of MRSA appears to be highly regional, ranging from 13% to 73% (References 65, 70). Mixed or polymicrobial infections, sometimes involving anaerobic organisms, tend to occur more commonly in older children because of the greater constriction between the sinus and their drainage passages, which impedes aeration and leads to an overgrowth of microbial flora (Reference 64).

### Clinical Presentation

Both PC and OC can present with unilateral ocular erythema, edema, warmth, and tenderness (Figure 7). Fever and other systemic signs may also be seen. Other symptoms specific to OC, related to its invasiveness and potential to increase intraorbital pressure, include chemosis, blurred vision, impaired ocular movements, and proptosis (Figure 8). In general, markers for an inflammatory response are more robust in OC, manifested as higher fevers, greater elevation of C-reactive protein, and a more dramatic left shift (Reference 71).

Most patients recover from PC and OC without any long-term sequelae. Complications from PC include local abscess formation, development of OC, and intracranial extension of infection. Untreated OC can

**Figure 7.** Periorbital and orbital cellulitis can both present with fever, acute unilateral eyelid erythema, and limited extraocular motions. Photo credit: Dr. Thomas F. Sellers, Centers for Disease Control and Prevention.

**Figure 8.** Orbital cellulitis with proptosis, ophthalmoplegia, and edema and erythema of the eyelids. Images reprinted with permission from Medscape.com, 2011.

lead to significant morbidity from vision loss; intracranial infections such as meningitis, subdural empyemas, and abscesses; and cavernous sinus thrombosis (Reference 71).

### **Diagnosis**

Periorbital cellulitis and OC are diagnosed largely by physical examination. The use of computed tomography (CT) in differentiating between PC and OC is controversial because definitive diagnosis and staging are difficult. However, CT may be indicated when patients exhibit central nervous system involvement or deterioration in visual acuity (Reference 71). Positive radiographic evidence of sinusitis in the ethmoid and maxillary cavities, as well as subperiosteal or orbital abscesses and diffuse fat infiltration, is seen more often in cases of OC than PC.

Microbiologic confirmation of orbital infections is best obtained by surgical sampling, whereby yields in excess of 80% are reported (References 65, 70). Less invasive swabs obtained from the conjunctiva and sinus aperture also are more likely to be positive than blood cultures, which are usually of low yield (less than 7%) (References 64–66, 69, 70).

### **Treatment**

Literature regarding the management of PC and OC is largely retrospective and based on expert opinion. Simple PC without systemic involvement may be treated with empiric oral antibiotics that cover pathogens associated with the likely cause of infection. Local prevalence of MRSA should be considered when determining *S. aureus* coverage. A treatment course of 7–10 days is generally sufficient (Reference 71).

No clear consensus exists on which patients should be hospitalized for parenteral antibiotics, but some experts consider children high risk if they have suspected PC exhibiting signs of systemic illness, or any suspected cases of OC, especially in children younger than 12 months (Reference 69). Empiric parenteral antibiotics should cover *Streptococcus* spp., common respiratory pathogens, *S. aureus* (including MRSA when appropriate), and anaerobes. A  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination is a reasonable initial choice. If sinus involvement with respiratory pathogens is suspected, a second- or third-generation cephalosporin plus clindamycin can be tried. Vancomycin may be substituted for clindamycin for enhanced MRSA coverage; however, anaerobic coverage may need to be bolstered with metronidazole. Parenteral antibiotics should be narrowed on the basis of susceptibility data and continued until systemic symptoms have resolved and significant improvement is seen in the eye, at which point an oral agent may be substituted to complete a 10- to

14-day course. Medical management alone may be adequate for treating OC, especially in children younger than 9 years or those presenting with no or only small subperiosteal abscesses (References 69, 72). Evaluation for surgical intervention is indicated in patients with significant visual impairment; frontal sinus or pansinusitis; defined abscesses; prominent mass effect; gas in the orbit; ophthalmoplegia; or lack of clinical improvement despite adequate parenteral therapy (References 69, 73).

### Necrotizing Fasciitis

Necrotizing fasciitis is a potentially life-threatening infection of the subcutaneous tissues comprising the superficial fascial plane, characterized by rapid and widespread inflammation and necrosis. The incidence of NF in adults has been reported to be 0.40 cases per 100,000, and the incidence in children is 0.08 cases per 100,000 (References 74, 75). Infections can be polymicrobial or monomicrobial, with most of the latter caused by GAS. In a prospective surveillance study of all Canadian children younger than 16 years, non-GAS-related NF and GAS-related NF accounted for 0.81 and 2.12 cases per 1 million children, respectively (Reference 76). Most children were younger than 5 years (Reference 76).

General risk factors for NF include conditions that compromise skin integrity, such as recent trauma or skin lesions. Non-GAS-related NF is associated with chronic illnesses, malnutrition, obesity, immunosuppression, and intravenous drug use. In neonates, non-GAS-related NF can develop secondary to surgery, procedures, or necrotizing enterocolitis (Reference 77).

In contrast, GAS-related NF generally affects healthy children. A strong correlation has been noted between GAS-related NF and varicella infection. Fifty-eight percent of patients from the Canadian study were recently given a diagnosis of varicella (Reference 76). Although an association between nonsteroidal anti-inflammatory drugs (NSAIDs) and GAS-related NF has been reported in many case reports, a causal relationship has not been proved (Reference 78).

### Microbial Etiology

Group A  $\beta$ -hemolytic *Streptococcus* is the most common cause of monomicrobial NF, though other bacteria have been implicated, such as *S. aureus*, *Vibrio vulnificus*, *Aeromonas hydrophila*, and *Peptostreptococcus* spp. Invasive GAS infections can occur from the translocation of colonized GAS in the pharynx through systemic spread to the site of minor trauma; however, more often than not, the infection occurs spontaneously with no preceding prodrome. The pathogenesis of GAS is

facilitated by several important cell surface proteins that help it evade phagocytosis: proteases, which can precipitate intravascular occlusion; and pyrogenic exotoxins, which can act as superantigens (Reference 79).

In contrast, polymicrobial NF is a mixed infection involving anaerobic bacteria, such as *Bacteroides* and *Peptostreptococcus* spp., and bowel flora, including coliforms and anaerobic bacteria (Reference 3). Critically ill neonates are especially vulnerable to polymicrobial NF involving *S. aureus* because of the variety of monitoring and surgical procedures they undergo (Reference 77).

### Clinical Presentation

Patients with early stages of NF present with mild swelling and erythema over an affected site, but they may report pain seemingly out of proportion to the infection. High temperatures, tachycardia, altered mental status, and systemic toxicity are common. In children and neonates, the most common infection sites are the trunk, followed by the head and neck, limbs, lower extremities, and perineum (References 76, 77, 80). Eventually, necrosis of the soft tissue, skin ischemia, and gangrene of the overlying skin ensue and can give rise to blister or bulla formation and skin ulceration. Damage to superficial nerves can lead to the loss of sensation. Rapidly advancing erythema without margins, lack of response to appropriate antibiotics, and progression to systemic signs of sepsis should suggest NF. Symptoms generally progress for 2–4 days, but GAS-related NF tends to spread very quickly and can culminate in multisystem organ failure early in the disease process (References 74, 81). In two pediatric case series, complications occurred in 78% to 85% of patients, and mortality ranged from 5.4% to 18% (References 76, 82). Immunocompromised status was an independent risk factor for mortality (References 82, 83).

### Diagnosis

Laboratory evaluation of patients with suspected NF is nonspecific but reflects evidence of systemic inflammation and organ dysfunction. One adult study found that a composite scoring system based on elevations in C-reactive protein, white blood cell count, hemoglobin, serum sodium, creatinine, and glucose was correlated with an increased likelihood of NF (Reference 84). This has not been validated prospectively in children.

Evidence of NF on ultrasonography may include the presence of fluid accumulation within thickened fascia or loculated abscesses. Gas in the soft tissue is a positive finding by plain radiography in 24% to 73% of patients, especially in patients with non-GAS-related NF (Reference 81). Magnetic resonance imaging and CT can be useful in distinguishing cellulitis from necrotizing infections.

Samples from the blood and surgically obtained deep tissue should be cultured to identify the pathogen and tailor antibiotic treatment. For rapid microbiologic evaluation, Gram staining can be performed on any discharge from the wound, blisters, or histologic samples. Frozen section biopsy can provide confirmation of the diagnosis (Reference 3).

### **Treatment**

Surgical management is the first line of treatment in NF. Aggressive debridement of the wound up to the first margins of pink, viable tissues is required to control disease morbidity because NF can invade areas beyond the extent of visibly involved skin. Often, multiple, sequential debridement is necessary until signs of disease progression have stopped. Occasionally, amputation may be necessary. Meticulous wound management after surgery is critical, given the often extensive area involved and risk of secondary infections.

Empiric antibiotics should be continued until debridement is no longer needed, clinical improvement has been seen, and fever has subsided for at least 72 hours. If GAS is suspected, the combination of clindamycin and penicillin has shown superior clinical efficacy to penicillins alone (Reference 85). Pharmacologically, clindamycin may suppress toxin production, modulate cytokine production, and sustain bacterial killing during slow phases of growth when penicillins are ineffective. Empiric coverage for polymicrobial infections should include agents with an expanded spectrum of activities against gram-negative organisms and anaerobes. Regimens recommended by the IDSA include a  $\beta$ -lactam/ $\beta$ -lactamase combination and clindamycin plus ciprofloxacin, a combination of metronidazole or clindamycin with a third-generation cephalosporin, or monotherapy with a penicillin/penicillinase combination or carbapenem (Reference 3). Although the IDSA makes no recommendations specific to the treatment of NF in children, the combination of clindamycin and a third-generation cephalosporin or monotherapy with a  $\beta$ -lactam/ $\beta$ -lactamase combination are reasonable empiric regimens that would cover both monomicrobial and polymicrobial NF (Reference 15). Additional gram-negative and anaerobic coverage may be required in children at risk of polymicrobial NF because of underlying medical conditions and immunocompromised states. When antimicrobial options are limited because of pathogen susceptibility and need for tissue penetration, the benefit of fluoroquinolone use in children is believed to outweigh the minimal risks of musculoskeletal adverse effects, which is endorsed by the American Academy of Pediatrics (AAP) (Reference 86).

Given the suggested role of superantigens in the pathogenesis of GAS-related NF, intravenous immunoglobulin (IVIG) may help attenuate the untoward

host inflammatory effect by neutralizing superantigens. Despite in vitro data and smaller case series that suggest benefit, this has not been reproduced in larger-scale studies (Reference 87). In the only multicenter, placebo-controlled trial of adults with streptococcal toxic shock syndrome, adjunctive therapy with IVIG showed a trend toward benefit (Reference 88); however, a recent retrospective review of IVIG use in children with streptococcal toxic shock syndrome showed no difference in clinical outcomes compared with patients who did not receive IVIG (Reference 89). The routine use of IVIG remains controversial in the absence of substantial clinical benefits, high cost, and scarcity. Intravenous immunoglobulin has not been studied in polymicrobial NF and should not be recommended.

Other critical supportive measures in the treatment of NF include adequate nutritional support, fluid management, and pain control. Total parenteral therapy should be instituted soon after surgery for adequate provision of caloric substrates and close management of fluid status. Although a causative effect between NSAIDs and NF has not been definitively proved, their use should be limited during NF. Tetanus prophylaxis with a toxoid vaccine and immunoglobulin may be indicated in patients who are not up to date with their immunizations to prevent potential complications from *Clostridium tetani*.

Because of the potential morbidity of invasive streptococcal disease, chemoprophylaxis with penicillin, a first-generation cephalosporin, clindamycin, or erythromycin should be considered in close household contacts with the following risk factors: those younger than 2 years, the elderly, the immunosuppressed (e.g., asplenia, corticosteroid use), those with malignancy, and those with chronic diseases (e.g., diabetes, peripheral vascular disease) (References 79, 90). Immunization with the varicella vaccine is an important method of eliminating risk factors for GAS-related NF in children.

## **VIRAL SKIN INFECTIONS**

### **Herpes Simplex Virus**

Herpes simplex viruses (HSVs) belong to the family of human herpes viruses (HHVs), all of which cause a primary infection and remain capable of reactivation later in life. Types 1 and 2 are the most pathogenic, and the two can be distinguished by the dermatologic areas they typically infect. Herpes simplex virus-1 infections tend to occur “above the waist,” involving the skin, oral cavity, lips, and face. Herpes labialis is the most common HSV-1 disease (also known as orolabial HSV-1 or gingivostomatitis). Herpes simplex virus-2 infections typically occur in the genital region (“below the waist”) in teenagers and adults who are sexually active

(Reference 91). Despite these generalizations, both viruses can cause disease in either area, as evidenced by the increasing incidence of orolabial HSV-2 and genital herpes caused by HSV-1 (Reference 92).

Herpes simplex virus-1 is ubiquitous among humans. Almost 60% to 90% of adults worldwide are infected with HSV-1 and are largely asymptomatic because of long latency periods in healthy individuals (Reference 92). Unlike other childhood viral illnesses, which are acquired during day care or school outbreaks, primary HSV-1 infections occur early in life, between 1 and 3 years of age, likely through close contact with family members who are contagious or on the verge of developing recurrent disease (Reference 92). By preschool age, the prevalence of HSV-1 in children around the world is estimated to be between 17% and 55% (Reference 93).

The prevalence of genital herpes among adults aged 14–69 years is 16.2% (Reference 94). A woman who experiences a primary genital herpes outbreak or recurrence can pass the virus on to her newborn. The incidence of neonatal herpes infection is about 1 in every 3500–20,000 births (Reference 92). The disease carries high morbidity and mortality. Even with treatment, 15% of infants with encephalitis and 57% with disseminated disease die (Reference 95).

### ***Microbiologic Etiology***

Herpes simplex virus-1 and -2 are large DNA viruses with genomes that code for a variety of glycoproteins and polypeptides involved in viral replication. After multiplying in the epithelial cells, the virus invades local nerve endings and travels up to the neural cell bodies in the regional sensory ganglia, where it remains dormant until reactivation. The trigeminal ganglion is the most common reservoir for oral-facial HSV-1 infection. Exposure to triggers such as trauma, ultraviolet light, fever, physical and emotional stress, radiotherapy, and organ transplants may result in disease reactivation (Reference 96). Herpes simplex virus shedding from the oral cavity is observed in 2% to 9% of asymptomatic subjects (Reference 93). Transmission of HSV-2 infections can occur through skin contact or bodily fluids, including semen, cervical fluid, or vesicular fluid from active lesions. A person may be contagious even when clinically asymptomatic (Reference 91). The incubation period is typically from 2 days to 2 weeks after exposure (Reference 92).

### ***Clinical Presentation***

Primary HSV infection may result in (1) an asymptomatic course, resulting in antibody production; (2) a localized or general eruption; or (3) a serious systemic disease (Reference 97). Most healthy children who

contract the herpes virus will present with a prodrome and develop lesions on the skin and mucous membranes in a variety of distributions, including the digits, knees, ear and face, mouth, and genital area (Figure 9 and Figure 10). Symptoms associated with primary infections will always be more severe than those associated with a recurrence. Immunocompromised patients most commonly present with severe local lesions, though disseminated disease with generalized vesicular skin lesions and visceral involvement can also occur (Reference 92). Despite proper treatment, HSV infection acquired during the neonatal period is associated with significant morbidity and mortality because it can disseminate to the liver, lungs, and central nervous system. Skin lesions are present in 60% of cases with disseminated disease and in 85% of localized infection to the skin, eyes, and mouth (Reference 92).

### ***Diagnosis***

Most HSV-1 cases may be diagnosed by history and physical examination. Although a positive viral culture obtained from mucous membranes or lesions is considered confirmatory, this is rarely performed. Immunologic assays are better at differentiating between different subtypes and confirming exposure (Reference 92).

### ***Treatment***

The cornerstone of therapy is the purine nucleoside analog acyclovir, which limits viral replication but cannot eradicate cells that are already infected. Clinically, this translates into decreases in viral shedding, healing time, and disease severity. Acyclovir is available in oral and intravenous dosage forms, but the oral formulation requires frequent dosing because of its short half-life and poor bioavailability. Oral acyclovir is effective for primary and recurrent genital herpes and orolabial herpes in immunocompetent hosts (References 98, 99). Parenteral acyclovir should be reserved for systemic disease requiring hospitalization, as well as for neonates or immunocompromised patients. Failure to respond to acyclovir may necessitate treatment with intravenous foscarnet, which can cause significant renal toxicity (Reference 91).

Valacyclovir and famciclovir are oral prodrugs to acyclovir and penciclovir, respectively. Their enhanced bioavailability permits less frequent dosing compared with acyclovir. They have efficacy comparable to acyclovir for mucocutaneous herpetic disease but not for systemic infections. In adolescents and adults, these drugs are indicated for primary and recurrent genital herpes and recurrent orolabial herpes (Reference 98). Their use in primary, moderate to severe orolabial herpes is extrapolated from their overwhelming clinical success in treating recurrent disease. Chronic suppressive therapy

**Figure 9.** Primary herpes simplex virus (HSV) gingivostomatitis in an infant. Images reprinted with permission from Medscape.com, 2011.

**Figure 10.** Herpes gladiatorum behind the ear. Images reprinted with permission from Medscape.com, 2011.

with these agents for up to 1 year is safe and effective in preventing recurrences and asymptomatic viral shedding in patients prone to frequent outbreaks (Reference 98). Recent studies delineating their pharmacokinetic profiles and dosing recommendations in younger children may potentially allow their use in lieu of acyclovir in orolabial herpes (References 100, 101).

Topical formulations of acyclovir and penciclovir can be used in localized HSV disease to lessen disease severity, viral shedding, and associated discomfort. Topical antivirals are not as consistently effective as oral regimens for genital and orolabial herpes and should not be routinely recommended (Reference 98). Docosanol is a biphenyl alcohol that is available over the counter as a topical cream. When applied early during the prodromal phase, docosanol can help reduce healing time and shorten the duration of painful symptoms in orolabial herpes. Other over-the-counter anesthetics containing benzocaine, lidocaine, tetracaine, benzyl alcohol, camphor, or phenol may provide symptomatic pain relief when applied at the first sign of tingling and burning before orolabial lesion development, but they do not alter the underlying disease course.

### Varicella

Chickenpox is a ubiquitous childhood vesicular exanthema caused by the varicella zoster virus (VZV) (Figure 11 and Figure 12). Presentation and prevention with immunization are discussed in the Pediatric Vaccines chapter. Discussion of varicella in this chapter is limited to diagnostic and treatment strategies in children infected with chickenpox.

### Diagnosis

Diagnosis of varicella in healthy hosts is based on the appearance of the lesion, confirmed by a history of exposure. Laboratory analysis is not necessary but may reveal an initially depressed white blood cell count, decreased platelet count, and mildly elevated liver function tests. If central nervous system involvement is suspected, cerebrospinal fluid analysis may show mild lymphocytosis, slight elevation of protein, and near-normal glucose levels (Reference 102).

In high-risk patients, rapid confirmation of varicella is important to determine appropriate antiviral therapy. This is best accomplished with immunofluorescence or immunoperoxidase staining for VZV-infected cells obtained from lesion scrapings or an enzyme immunoassay sensitive to VZV antigens present in vesicular fluids. Polymerase chain reaction assays, which can also be performed on vesicular fluid, have a faster, higher yield than viral cultures (Reference 103).

### **Treatment**

In healthy children, supportive care is the primary treatment of varicella. Local therapy with drying agents, such as calamine lotion, oatmeal soaks, or Burow solution, can be used on weeping lesions. Topical agents containing antihistamines should be avoided because of the increased risk of percutaneous absorption from loss of skin integrity. Daily baths with soap and water are recommended to destroy the virus's lipid envelope. Acetaminophen should be used for fever and analgesia because antipyretics such as aspirin and NSAIDs have been associated with an increased risk of Reye syndrome and invasive GAS disease, respectively.

Acyclovir is the antiviral drug of choice for treating primary VZV infection. When initiated within 24 hours of the onset of rash, oral acyclovir at 20 mg/kg/dose (maximum 800 mg/dose) four times/day for 5 days was safe and modestly effective in decreasing markers of VZV disease severity (Reference 104). In particular, the clinical benefit seemed more pronounced in children older than 12 years and in secondary household cases that tended to exhibit more serious dermatologic and constitutional symptoms (Reference 102). Because of these observations and the self-limiting nature of VZV, the AAP does not recommend the routine use of antivirals for postexposure prophylaxis or treatment in otherwise young, healthy children; however, acyclovir may be useful for children with complicated disease (pneumonia, encephalitis, or hepatitis) or comorbid conditions (Table 3). Parenteral acyclovir should be initiated in any child who develops severe complications or in any high-risk patient with VZV. Acyclovir doses of 500 mg/m<sup>2</sup> (or a 10-mg/kg/dose in older children) administered every 8 hours for at least 7 days reduce the dissemination of varicella and hasten cutaneous healing in immunosuppressed patients (Reference 102).

Although the efficacy and safety of oral acyclovir is well established in uncomplicated VZV, frequent administration is required because of poor bioavailability. Recent pharmacokinetic data on agents with improved bioavailability such as valacyclovir and famciclovir should greatly simplify dosing regimens and improve adherence (References 100, 101).

### **OTHER VIRAL EXANTHEMS (HAND, FOOT, AND MOUTH DISEASE; FIFTH DISEASE; AND SIXTH DISEASE)**

Other common pediatric SSTIs include hand, foot, and mouth disease (HFMD), fifth disease, and sixth disease. These childhood exanthems are typified by a prodrome of fever and constitutional symptoms for several days, followed by the appearance of a characteristic rash in a specific distribution. Diagnosis is largely based on clinical presentation because serology may not always

permit a distinction between previous and recent exposure. Polymerase chain reaction may be useful for confirming primary infection except in sixth disease, where the herpes virus may remain dormant intracellularly. Treatment in otherwise healthy patients consists of supportive management and the occasional use of IVIG or other systemic antivirals in severe systemic disease.

### Hand, Foot, and Mouth Disease

Hand, foot, and mouth disease is a highly contagious infection that presents with painful ulcerative lesions in the mouth and rhomboid vesicles (“square blisters”) on the palms, soles, and sides of fingers and toes. In the United States, outbreaks of HFMD are typically caused by coxsackievirus A16 or enterovirus 71 (Reference 105). Hand, foot, and mouth disease often occurs as an outbreak among collections of children in a school or child care setting. Incidence is highest during the summer and fall months, with epidemics occurring in 3-year cycles in the United States (Reference 105).

Enteroviruses spread primarily through contact with respiratory droplets or infectious fecal material, though vertical transmission from mother to child is also possible. Because of their resistance to environmental insults, enteroviruses can survive on fomites,

adding to their contagiousness (Reference 106). Once infected, patients are contagious until the blisters have resolved (Reference 107).

After the prodrome, patients develop large, painful oral lesions on the palate, tongue, and buccal mucosa in 1–2 days, followed by the presentation of peripheral skin lesions; however, not all patients will express both mucosal and dermatologic symptoms (Reference 106) (Figure 13 and Figure 14). Skin lesions are more commonly found on the dorsal surfaces and may present on the palms, fingers, toes, soles, buttocks, genitals, and limbs. The exanthem begins with red macules that evolve into gray vesicles surrounded by an erythematous halo, but they are not typically pruritic. Cutaneous lesions generally heal without scabbing in 1 week (Reference 108). Complications from coxsackievirus infection include myocarditis, pneumonia, and meningoencephalitis. Recent outbreaks of enterovirus 71 HFMD in Asia have been associated with central nervous system manifestations, particularly encephalitis (Reference 109). In a small case series, treatment with oral acyclovir provided symptomatic relief and improvement in lesions within 24 hours (Reference 110). A trial of acyclovir may be considered in high-risk patients (e.g., immunocompromised hosts or neonates) or outbreaks. Intravenous immunoglobulin has been used

in patients hospitalized with systemic disease with some beneficial effects, but it should not be used routinely for HFMD (Reference 106).

### **Erythema Infectiosum (Fifth Disease)**

Fifth disease, or erythema infectiosum, is a ubiquitous, benign childhood viral exanthema caused by parvovirus B19, typically affecting children 4–10 years of age. Infection peaks during late winter to early spring, and secondary spread within a household occurs in up to 50% of susceptible individuals (Reference 111). Spread of the virus is primarily through infected respiratory droplets, although transmission by blood products or vertical transmission can occur. The end of the incubation period, ranging from 4 to 14 days, is marked by the

formation of immunoglobulin G (IgG) and clearance of viremia, which precedes the characteristic rash. Thus, a patient who exhibits the diagnostic eruptions is not considered contagious (Reference 105).

The rash associated with fifth disease typically develops on the cheeks and appears as if the patient was slapped (Figure 15). The pattern may turn lacy or maculopapular and spread to the proximal extremities or on the trunk. The exanthem may fade and recur when triggered by local irritation, high temperatures, or emotional stress, but this does not represent recrudescence of disease. Arthralgias involving the small joints of the hands, wrists, knees, or ankles can occur in 10% of patients (Reference 111). Transient anemia is a complication that may develop in patients with limited red blood cell reserves, resulting in an aplastic crisis. Parvovirus B19 infection contracted during pregnancy can lead to non-immune hydrops fetalis, a fetal complication resulting in profound anemia, heart failure, and occasionally the death of the fetus in utero (Reference 112). Intravenous immunoglobulins may be considered in chronically immunosuppressed patients with signs of anemia, but they may precipitate the rash and joint symptoms of erythema infectiosum (Reference 105). When symptomatic anemia is present, patients may be supported by blood transfusions.

### **Roseola (Sixth Disease/Exanthema Subitum)**

Roseola, also known as sixth disease or exanthema subitum, is a benign childhood exanthema caused by the 6th and 7th variants of the human herpes virus (HHV). It is one of the most common childhood exanthemas, affecting children between 6 and 18 months of age (Reference 105). Little is known about how the viruses are transmitted, and there seems to be no seasonal predilection for primary infections (Reference 113). Because herpes viruses may remain latent in bodily reservoirs years after the primary infection, the leading hypothesis is that young infants acquire disease through exposure to the saliva or oral secretions of an asymptomatic caretaker who is shedding virus. Vertical transmission of the virus from mother to baby is possible (Reference 114). In addition, HHV-6 can insert its genome into human chromosomes, enabling it to be passed on congenitally (Reference 105).

The classic presentation permitting a clinical diagnosis of primary roseola is fever for 3–5 days that rapidly subsides, followed by the development of a rose-pink maculopapular rash on the neck and trunk that spreads to the extremities and face. Central nervous system complications, including febrile seizures, can occur in up to 15% of primary infections (Reference 112). Examination of the oropharynx may reveal red papules on the soft palate and uvula (Nagayama spots), exudative tonsillar lesions, or herpangina. Other physical findings include mild upper respiratory congestion, otitis media,

**Figure 15.** Erythematous rash resembling a slapped cheek associated with erythema infectiosum (fifth disease). Photo credit: Centers for Disease Control and Prevention.

nausea, vomiting, cervical and post-occipital lymphadenopathy, and hepatosplenomegaly (References 105, 108). Reactivation from latent disease or reinfection may occur later in life, particularly in immunocompromised individuals such as transplant recipients. Serious manifestations of reactivated HHV-6 include bone marrow suppression, pneumonitis, encephalitis, hepatitis, and organ rejection. Reserved for only severe systemic infection, antivirals such as ganciclovir, foscarnet, and cidofovir show in vitro activity against HHV-6 and have resulted in viral clearance among immunocompromised patients with systemic disease (References 115–117).

## CONCLUSIONS

Bacterial and viral infections of the skin and soft tissue are common childhood illnesses that are well tolerated by most healthy hosts, but they can develop into severe systemic complications without timely treatment, especially in an immunocompromised patient. The selection of antibiotics for treating bacterial infections must ensure adequate coverage of the most likely organisms based on a patient's risk factors and show favorable absorption and penetration to the infected site. An understanding of local susceptibility patterns is crucial in light of the ever-increasing prevalence of resistant pathogens, such as CA-MRSA. Outpatient regimens with the greatest likelihood of patient acceptance are those that are palatable with simple administration schedules. Parents should be instructed to seek further medical attention if dermatologic and systemic symptoms do not improve within 48 hours. Although parenteral antibiotics should always be administered in a child exhibiting systemic complications from an SSTI, surgical drainage and intervention often plays an

integral role in the overall treatment plan of a loculated soft tissue infection or NF. Empiric antibiotics should be narrowed once microbial susceptibilities are available to prevent the evolution of a drug-resistant organism.

Viral skin illnesses are ubiquitous and often acquired early in childhood without significant sequelae. Although the management of viral skin infections is largely supportive, aspirin and NSAIDs should be strictly avoided as antipyretics because of the risk of Reye syndrome and invasive GAS disease, respectively. Antivirals may be indicated in select cases of severe primary or recurrent infections in high-risk populations. Recent pediatric pharmacokinetic data and new drug formulations will allow the use of highly bioavailable antivirals that were previously unavailable to children. A thorough understanding of infectious-related complications and risk factors for more severe disease is important to ensure care is escalated when needed.

## APPENDIX 1: PEDIATRIC ANTIBIOTIC THERAPY FOR SUPERFICIAL BACTERIAL SKIN INFECTIONS

Infection	Pathogen	Daily Oral Dose (Maximal Daily Dose)	Daily Parenteral Dose (Maximal Daily Dose)	Notes
Folliculitis Furuncle Carbuncle	<i>S. aureus</i> (CA-MRSA)	Cephalexin 25 mg/kg/d divided q6h (2 g)	Cefazolin 75 mg/kg/d divided q8h (6 g)	For frequent recurrences, reduce <i>Staphylococcus</i> colonization with nasal mupirocin 2% three times/day for 5–10 days.
		Dicloxacillin 12 mg/kg/d divided q6h (1 g)	Oxacillin or nafcillin 150 mg/kg/d divided q4h (12 g)	
		<u>CA-MRSA coverage:</u> Clindamycin 30 mg/kg/d divided q8h (1.35 g)	<u>CA-MRSA coverage:</u> Vancomycin 45–60 mg/kg/d divided q6–8h <sup>c</sup>	For severe recurrent infections, rifampin 20 mg/kg/d divided q12h plus doxycycline or TMP/SMX for 5–10 days
		TMP/SMX 12 mg/kg/d of TMP divided q12h (640 mg TMP) <sup>a</sup> Doxycycline 2–4 mg/kg/d divided q12h (200 mg) <sup>b</sup>	Clindamycin 40 mg/kg/d divided q8h (1.8 g)	
Erysipelas	GAS	Cephalexin 25 mg/kg/d divided q6h (2 g) Penicillin 50 mg/kg/d divided q6h (2 g) Erythromycin 40 mg/kg/d divided q6h (1 g) Clindamycin 30 mg/kg/d divided q8h (1.35 g)	Cefazolin 75 mg/kg/d divided q8h (6 g) Penicillin 250,000 units/kg/d divided q4–6h (24 MU) Azithromycin 10 mg/kg/d divided q24h (500 mg) Clindamycin 40 mg/kg/d divided q8h (1.8 g)	If MSSA coverage desired, consider using first-generation cephalosporin or adding oxacillin in combination with other options
Cellulitis	<i>S. aureus</i> (CA-MRSA) GAS	Cephalexin 25 mg/kg/d divided q6h (2 g)	Cefazolin 75 mg/kg/d divided q8h (6 g)	Consider MRSA coverage if exhibiting systemic illness or no improvement on initial therapy
		Dicloxacillin 12 mg/kg/d divided q6h (2 g) Erythromycin 40 mg/kg/d divided q6h (1 g)	Oxacillin or nafcillin 150 mg/kg/d divided q4h (12 g) Ampicillin/sulbactam 200 mg/kg/d of ampicillin divided q6h (12 g of ampicillin)	
		<u>CA-MRSA coverage:</u> Clindamycin 30 mg/kg/d divided q8h (1.35 g) TMP/SMX 12 mg/kg/d of TMP divided q12h (640 mg TMP) <sup>a</sup> Doxycycline 2–4 mg/kg/d divided q12h (200 mg) <sup>b</sup>	<u>CA-MRSA coverage:</u> Vancomycin 45–60 mg/kg/d divided q6–8h <sup>c</sup> Clindamycin 40 mg/kg/d divided q8h (1.8 g) Linezolid 20–30 mg/kg/d divided q8–12 h (1.2 g) <sup>d</sup>	
Bullous impetigo	<i>S. aureus</i> (CA-MRSA)	Cephalexin 25 mg/kg/d divided q6h (2 g)		Topical mupirocin 2% three times/day and retapamulin 1% twice daily for 7 days; recommended for localized disease
		Dicloxacillin 12 mg/kg/d divided q6h (1 g)		
Impetigo contagiosa	<i>S. aureus</i> (CA-MRSA) GAS	Amoxicillin/clavulanate 30–45 mg/kg/day of amoxicillin divided q8–12h (1.75 g of amoxicillin)		
		Erythromycin 40 mg/kg/d divided q6h (1 g)		
		<u>CA-MRSA coverage:</u> Clindamycin 30 mg/kg/d divided q8h (1.35 g) TMP/SMX 12 mg/kg/d of TMP divided q12h (640 mg TMP) <sup>a</sup>		

<b><i>Staphylococcus</i></b> scalded skin syndrome	<i>S. aureus</i>	Clindamycin 40 mg/kg/d divided q8h (1.8 g) plus: Oxacillin or nafcillin 150 mg/kg/d divided q4h (12 g) or Cefazolin 75 mg/kg/d divided q8h (6 g)	For secondary bacterial infection, consider adding age-appropriate gentamicin. Alternatively, Clindamycin plus ceftriaxone IV 100 mg/kg/d divided q12h or cefotaxime IV 150 mg/kg/d divided q8h may be used.
Cutaneous abscess	CA-MRSA	Clindamycin 30 mg/kg/d divided q8h (1.35 g) TMP/SMX 12 mg/kg/d of TMP divided q12h (640 mg TMP) <sup>a</sup> Doxycycline 2–4 mg/kg/d divided q12h (200 mg) <sup>b</sup> Linezolid 20–30 mg/kg/d divided q8–12 h (1.2 g) <sup>d</sup>	Vancomycin 45–60 mg/kg/d divided q6–8h <sup>c</sup> Clindamycin 40 mg/kg/d divided q8h (1.8 g) Linezolid 20–30 mg/kg/d divided q8–12 h (1.2 g) <sup>d</sup>
Animal and human bites	<i>Pasteurella</i> spp. <i>Staphylococcus</i> spp. <i>Streptococcus</i> spp. <i>E. corrodens</i> , anaerobes	Amoxicillin/clavulanate 45 mg/kg/d of amoxicillin divided q8–12h (1.75 g of amoxicillin)  Clindamycin 30 mg/kg/d divided q8h (1.35 g) plus: TMP/SMX 12 mg/kg/d of TMP divided q12h (640 mg TMP) <sup>a</sup> or Cefuroxime 30 mg/kg/d divided q12h (1 g)  Doxycycline 2–4 mg/kg/d divided q12h (200 mg) <sup>b</sup> Ciprofloxacin 30 mg/kg/d divided q12h (1 g) <sup>c</sup>	Reserve carbapenems for treatment failure or multidrug resistance.  Ampicillin/sulbactam 200 mg/kg/d of ampicillin divided q6h (12 g of ampicillin)  Clindamycin 40 mg/kg/d divided q8h (1.8 g) plus TMP/SMX 12 mg/kg/d of TMP divided q6h (640 mg TMP)  Cefoxitin 100 mg/kg/d divided q4–6h (12 g) Meropenem 60 mg/kg/d divided q8h (3 g)

**Bold face** signifies first line regimens.

CA-MRSA = community-associated *Staphylococcus aureus*; d = day; GAS = group A  $\beta$ -hemolytic *Streptococcus*; h = hour(s); IV = intravenous(ly); MRSA = methicillin-resistant *Staphylococcus aureus*; MSSA = methicillin-sensitive *Staphylococcus aureus*; mu = million units; q = every; TMP/SMX = trimethoprim/sulfamethoxazole.

<sup>a</sup>TMP/SMX contraindicated in children < 2 months old.

<sup>b</sup>Doxycycline contraindicated in children < 8 years old.

<sup>c</sup>Titrate vancomycin to trough levels of 10–15 mcg/mL for superficial infections.

<sup>d</sup>Linezolid 10 mg/kg/dose q8h in children < 5 years old, 10 mg/kg/dose q12 in children > 5 years

<sup>e</sup>Fluoroquinolones may be used in children if clinically indicated with close monitoring of musculoskeletal adverse effects.

## APPENDIX 2: PEDIATRIC ANTIBIOTIC THERAPY FOR DEEP BACTERIAL SKIN INFECTIONS

Infection	Pathogen	Daily Regimen (Maximal Daily Dose)	Notes
<i>Stye, insect bite, impetigo, eczema</i>	<i>S. aureus</i> (especially <i>stye</i> ), <i>S. pyogenes</i>	Cephalexin PO 50 mg/kg/d divided q6–8h (2 g) Dicloxacillin PO 12 mg/kg/d divided q6h (2 g)	If MRSA suspected, Clindamycin PO 30 mg/kg/d divided q8h (1.35 g) or TMP/SMX PO 12 mg/kg/d (TMP component) divided q12h (640 mg TMP) <sup>a</sup> For severe infection, vancomycin PO 60 mg/kg/d divided q6h (3 g), targeting trough of 15–20 mg/dL
<b>Complicated rhinosinusitis</b>	<i>S. pneumoniae</i> , <i>H. influenzae</i> <i>M. catarrhalis</i>	Amoxicillin/clavulanate PO 90 mg/kg/d of amoxicillin divided q12h (1.75 g of amoxicillin) Cefuroxime PO 30 mg/kg/d divided q12h (1 g) Cefdinir PO 14 mg/kg/d divided q12h (600 mg)	Consider Ceftriaxone IV 100 mg/kg/d divided q12 (4 g) if no improvement
<b>Dental abscess</b>	Mixed aerobic and anaerobic bacteria	Clindamycin PO 30 mg/kg/day divided q8h (1.35 g) Amoxicillin/clavulanate PO 90 mg/kg/d of amoxicillin divided q12h (1.75 g of amoxicillin) Ampicillin/sulbactam IV 200 mg/kg/d of ampicillin divided q6h (12 g of ampicillin)	
<b>Hematogenous spread with preceding viral upper respiratory infection</b>	<i>S. pneumoniae</i> , <i>H. influenzae</i> <i>S. pyogenes</i> , <i>S. aureus</i>	Cefotaxime IV 200 mg/kg/d divided q8h (12 g) or Ceftriaxone IV 100 mg/kg/d divided q12h (4 g) plus Clindamycin IV 40 mg/kg/d divided q8h (4.8 g)	
<b>Orbital cellulitis</b>	<i>Streptococcus</i> spp., <i>H. influenzae</i> <i>S. aureus</i> , anaerobes	Ampicillin/sulbactam IV 200 mg/kg/d of ampicillin divided q6h (12 g of ampicillin) or Piperacillin/tazobactam IV 300 mg/kg/d of Piperacillin divided q6h (12 g of ampicillin) Cefotaxime IV 200 mg/kg/d divided q8h (12 g) or Ceftriaxone IV 100 mg/kg/d divided q12h (4 g) plus Clindamycin IV 40 mg/kg/d divided q8h (4.8 g)	If MRSA suspected, consider vancomycin IV 45–60 mg/kg/day divided q6–8h (3 g), targeting trough 15–20 mg/dL plus Metronidazole IV 30 mg/kg/d divided q8h (4 g) for anaerobic coverage
<b>Necrotizing fasciitis</b>	Monomicrobial: GAS Polymicrobial: <i>S. aureus</i> Enterics and anaerobes	Penicillin G IV 400,000 units/kg/d divided q4h plus Clindamycin IV 40 mg/kg/d divided q8h (4.8 g) Cefotaxime IV 200 mg/kg/d divided q8h (12 g) or ceftazidime IV 150 mg/kg/d divided q8h (6 g) plus Clindamycin IV 40 mg/kg/d divided q8h (4.8 g) or Metronidazole IV 30 mg/kg/d divided q8h (4 g) Ampicillin/sulbactam IV 200 mg/kg/d of ampicillin divided q6h (12 g of ampicillin) or Piperacillin/tazobactam IV 300 mg/kg/d of Piperacillin divided q6h (12 g of piperacillin) plus Clindamycin IV 40 mg/kg/d divided q8h (4.8 g) plus Ciprofloxacin IV 30 mg/kg/d divided q12h (800 mg) <sup>b</sup> Oxacillin or nafcillin IV 150 mg/kg/d divided q4h (12 g) Meropenem IV 60 mg/kg/d divided q8h (6 g)	Aminoglycosides can be considered if additional gram-negative coverage required. Pseudomonal coverage should be considered in immunosuppressed patients.

Bold face signifies first line regimens.

CA-MRSA = community-associated MRSA; d = day; GAS = group A  $\beta$ -hemolytic *Streptococcus*; h = hours; IV = intravenous; MRSA = methicillin-resistant *Staphylococcus aureus*; PO = orally; q = every; TMP/SMX = trimethoprim/sulfamethoxazole.

<sup>a</sup>TMP/SMX contraindicated in children < 2 months old.

<sup>b</sup>Fluoroquinolones may be used in children if clinically indicated with close monitoring of musculoskeletal adverse effects.

References: Stevens DL, Bisno AL, Chambers HF, Everett ED, Dellinger P, Goldstein EJ, et al. Practice guidelines for the diagnosis and management of skin and soft tissue infections. Periorbital and orbital cellulitis. Pediatr Rev 2010;31 242–9.

### APPENDIX 3: PEDIATRIC ANTIVIRAL THERAPY FOR COMMON SKIN INFECTIONS

Drug	Daily Oral Dosing (Maximal Daily Dose)	Daily Parenteral Dosing	Notes
<b>Acyclovir</b>	HSV (orolabial and genital, initial) - Children: 15 mg/kg/dose five times/day up to 80 mg/kg/day for 7 days (1 g) HSV (orolabial and genital, episodic/suppressive) - Children: 15 mg/kg/dose two to five times/day up to 80 mg/kg/day for 5 days (1 g) VZV- Children: 20 mg/kg/dose four times/day for 5 days (3.2 g)	HSV - Neonates: 20 mg/kg/dose q8h HSV - Children: 5-10 mg/kg/dose q8h or 250-500 mg/m <sup>2</sup> /dose q8h <sup>a</sup> VZV - Children: 10 mg/kg/dose or 500 mg/m <sup>2</sup> /dose q8h	Dose obese patients by ideal body weight. Maintain good hydration status to avoid renal toxicity. Dose adjust for renal impairment.
<b>Valacyclovir</b>	Genital herpes (initial) - Adolescents: 1 g/dose twice daily for 7 days Genital herpes (episodic/suppressive) - Adolescents: 1 g/dose daily for 5 days VZV- Children: 20 mg/kg/dose three times/day for 7 days (3 g)		Prodrug of acyclovir
<b>Famciclovir</b>	Genital herpes (initial) - Adolescents: 250 mg/dose three times/day for 7 days Genital herpes (episodic/suppressive) - Adolescents: 125-250 mg/dose twice daily for 5 days VZV - Adults: 500 mg/dose three times/day for 7 days <sup>b</sup>		Prodrug of penciclovir
<b>Foscarnet</b>		Children and adults: 40 mg/kg/dose q8-12h	For acyclovir-resistant HSV/VZV infection only. Maintain good hydration status to avoid renal toxicity. Dose adjust for renal impairment.

HSV = herpes simplex virus; VZV = varicella zoster virus.

<sup>a</sup>Children < 12 years old can receive 30 mg/kg/day, > 12 years old can receive 15 mg/kg/day.

<sup>b</sup>For weight-based pediatric dosing recommendations for famciclovir see Saez-Llorens X, Yogev R, Arguedas A, Rodriguez A, Spigarelli MG, De Leon Castrejon T, et al. # CHAPTER 42

## HUMAN IMMUNODEFICIENCY VIRUS

Rustin D. Crutchley, Pharm.D., AAHIVE;  
and Cara M. Felton, Pharm.D., AAHIVP

### LEARNING OBJECTIVES

1. Explain the routes of transmission for human immunodeficiency virus (HIV).
2. Describe the life cycle of HIV.
3. Identify signs and symptoms of acute and chronic HIV infection, including the most common opportunistic infections.
4. Recommend appropriate prophylaxis for common opportunistic infections.
5. Identify goals of therapy for children with HIV infection and recommend appropriate antiretroviral (ARV) therapy for treatment-naïve HIV-infected children.
6. Describe efficacy parameters and adverse effects of ARV therapy.
7. Describe the importance of adherence to ARV therapy and strategies to improve adherence for HIV-infected children.
8. Summarize important clinical caveats in pediatric HIV infection.

### ABBREVIATIONS IN THIS CHAPTER

AIDS	Acquired immunodeficiency syndrome
ARV	Antiretroviral
cART	Combination antiretroviral therapy
CMV	Cytomegalovirus
EIA	Enzyme immunoassay
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HIV	Human immunodeficiency virus
MAC	<i>Mycobacterium avium</i> complex
MTCT	Mother-to-child-transmission
NNRTI	Nonnucleoside reverse transcriptase inhibitor
NRTI	Nucleoside reverse transcriptase inhibitor
OI	Opportunistic infection
PCP	<i>Pneumocystis jirovecii</i> pneumonia
PCR	Polymerase chain reaction
PI	Protease inhibitor
TDM	Therapeutic drug monitoring

### INTRODUCTION

This chapter describes the current epidemiology of HIV, the genetic diversity of the virus, and the ways in which it affects the immune system, emphasizing

prominent reservoirs of latent viral infection. We will discuss common routes of transmission, identifying signs and symptoms of acute and chronic HIV infection. Pertinent surrogate markers for HIV and the ways in which they pertain to HIV disease progression and the importance of resistance testing will be explained. Because more than 20 ARVs are available, we will focus on the goals of treatment, including nonpharmacologic and pharmacologic approaches for treating HIV infection, with special attention on medication adherence. At the conclusion of this chapter, the reader will appreciate the complexity of the disease and have a clearer and more complete understanding of how to care for and optimize ARV treatment among HIV-infected children and adolescents.

### EPIDEMIOLOGY

Human immunodeficiency virus affects about 33.3 million people worldwide (Reference 1). About two-thirds of the global burden of disease exists in sub-Saharan Africa. According to the World Health Organization (WHO), in 2009 there was a reported 2.5 million children (younger than 15 years) living with HIV globally, with an incidence of 370,000 new HIV infections and 260,000 deaths secondary to AIDS (Reference 1). Almost 15% of these new HIV infections were in children younger than 15 years, and an additional 41% of these infections occurred among young people 15–24 years of age. In 2009, among 40 states with confidential name-based HIV infection reporting, the estimated number of diagnoses of HIV infection among children younger than 13 years was 166; by contrast, there were 21 cases in the 13- to 14-year-old group and 2036 cases in the 15- to 19-year-old group (Reference 2).

Human immunodeficiency virus exists as two different virus types: HIV-1 and HIV-2. Human immunodeficiency virus type 1 is much more common worldwide than HIV-2. The first cases of HIV-1 infection were reported in the United States in 1981 among homosexual men in San Francisco, California (Reference 3). Human immunodeficiency virus type 1 is extremely diverse in its genetic composition and is classified into three groups: M, N, and O. The M group, which is the most common, consists of 11 different subtypes or

clades designated by the letters A–K. The geographic distribution of these different subtypes varies; for example, subtype B is common in the United States, and subtype C is common in South Africa.

In 1986, HIV-2 was isolated from patients with AIDS in West Africa, where it is still predominantly found. Most of the world's remaining burden of HIV-2 infection is reported among countries with strong socioeconomic ties to West Africa such as France, Spain, Portugal, and former Portuguese colonies Brazil, Angola, Mozambique, and parts of India near Goa. Although HIV-2 has modes of transmission similar to HIV-1, it is less virulent than HIV-1, and disease progresses more slowly. Human immunodeficiency virus type 2 infections, compared with HIV-1, results in comparatively lower viral loads, less transmission, and fewer AIDS cases (Reference 4).

## ETIOLOGY

### Pathophysiology

Human immunodeficiency virus type 1 belongs to the lentivirus subfamily of retroviruses. It is a single-stranded RNA virus that uses reverse transcriptase to produce proviral DNA required for virus replication and persistent infection of CD4<sup>+</sup> cells. Human immunodeficiency virus type 1 consists of nine separate genes that are divided into three classes: structural proteins that encode for the viral core, enzymes for viral replication and integration and for the structure of the viral envelope; regulatory proteins involved with viral transcription and protein synthesis; and accessory proteins.

During acute infection, HIV specifically infects CD4<sup>+</sup> cells. Human immunodeficiency virus entry into the CD4<sup>+</sup> cells is a multistep process. First, gp120, a trimer envelope glycoprotein on the HIV virion, binds to the CD4<sup>+</sup> cell receptor. Once bound, a conformational change occurs in gp120, allowing additional binding to one of the co-receptors on the CD4<sup>+</sup> cell: CCR5 or CXCR4. The CCR5 co-receptor is associated with early infection, and the CXCR4 co-receptor is more commonly found in treatment-experienced patients or in those with advanced stages of HIV disease. CCR5 antagonists, such as maraviroc, bind to the CCR5 co-receptor, which thereby prevents HIV binding and subsequent fusion of the viral envelope and the cell membrane.

Once the HIV virion binds to one of the co-receptors, it enables the trimer gp41 to bind to the CD4<sup>+</sup> cell membrane, facilitating the fusion of the virion with the CD4<sup>+</sup> cell. The HIV entry inhibitor enfuvirtide is a fusion inhibitor that binds to gp41 and prevents fusion of the HIV virion with the CD4<sup>+</sup> cell membrane. Uncoating of the capsid releases single-stranded HIV RNA into the cytoplasm of the CD4<sup>+</sup> cell. This is then

transcribed into double-stranded HIV DNA by HIV reverse transcriptase. Human immunodeficiency virus reverse transcriptase is highly error prone with no proof-reading mechanism, permitting the evolution of several mutations in HIV RNA as viral replication continues, thus contributing to its genetic variation. Nucleoside reverse transcriptase inhibitors (NRTIs) are nucleoside analogs that must be triphosphorylated (except for tenofovir, which is a nucleotide and requires only two additional phosphorylations) before incorporation by reverse transcriptase into the HIV DNA chain. These NRTIs then act as DNA chain terminators, inhibiting further synthesis of HIV DNA. Nonnucleoside reverse transcriptase inhibitors (NNRTIs) also inhibit reverse transcriptase by binding directly to the enzyme, creating structural alterations that prevent the addition of nucleosides to the growing DNA chain.

Double-stranded HIV DNA is then transported to the nucleus and integrated into the genome of the CD4<sup>+</sup> cell as proviral HIV DNA virus by HIV integrase. Integrase strand transfer inhibitors such as raltegravir prevent HIV integrase from inserting HIV proviral DNA into the host cell's DNA. Human immunodeficiency virus proviral DNA virus is representative of latent HIV viral reservoirs. Common sites of latent reservoir infection primarily include lymphoid tissue, as well as peripheral blood dendritic cells and monocytes, resting CD4<sup>+</sup> lymphocytes, and microglial cells of the central nervous system, reproductive tract, and gastrointestinal tract. The establishment of these latent reservoirs of infection serves as one of the primary reasons for the difficulty in finding a cure for HIV (Reference 5).

Once the proviral HIV DNA is activated in the CD4<sup>+</sup> cell, it is transcribed and translated into a polyprotein, which is cleaved by HIV protease into several different smaller proteins or subunits that are responsible for assembling a new, mature HIV virion. Protease inhibitors (PIs) bind HIV protease, preventing the cleavage of the polyprotein into individual proteins, which makes the assembly of a mature and infectious HIV virion unlikely. This new HIV virion then buds off from the infected CD4<sup>+</sup> cell and infects another CD4<sup>+</sup> cell. The life cycle of HIV infection and replication described above is repeated 1–10 billion times/day.

### Genetic Basis

The CCR5 co-receptor is a common host factor important for HIV transmission and pathogenesis. Not only do CD4<sup>+</sup> cells have CCR5 co-receptors, but these co-receptors can also exist on macrophages. Therefore, HIV can also infect macrophages, which seem to act as one of the primary sources responsible for HIV transmission into the brain. About 3% to 5% of patients with HIV infection can remain asymptomatic, maintaining normal CD4<sup>+</sup> cell counts for several years without

ARV therapy; these are termed *long-term nonprogressors*. About 1% of HIV-infected patients will have undetectable viral loads with maintenance of high CD4<sup>+</sup> cell counts; these are termed *elite controllers* (References 6–8). Slow HIV disease progression in these patients may occur because of varying genotypes of the 32-bp deletion ( $\Delta$ 32) in the CCR5 co-receptor. Some patients who are homozygous for the CCR5  $\Delta$ 32-bp deletion do not express the co-receptor on CD4<sup>+</sup> cells and are consequently resistant to HIV infection (Reference 9). Those heterozygous for this CCR5 genetic mutation have slower disease progression than individuals without the mutation. Other genetic polymorphisms that may influence HIV infection and the rate of disease progression include *APOBEC3G*, *HLA-\*B27*, and *HLA-\*B57* (Reference 10).

### Risk Factors

One of the primary risk factors for HIV infection is the transmission of HIV from mother to child (also known as mother-to-child-transmission [MTCT]). In 2009, the estimated number of new diagnoses of HIV from MTCT in the United States was 131 (Reference 11). The transmission risk of passing HIV from an untreated

HIV-infected mother to the fetus is about 20%. In these cases, elective cesarian section may be a suitable option to significantly reduce the rates of MTCT. For those who are taking ARVs and have excellent virologic control (defined as an undetectable viral load of less than 20–75 copies/mL), the risk of MTCT is reduced to less than 1% to 2%. Refer to Table 1 for a comprehensive list of other risk factors (including more common and less common) for HIV transmission (References 12–16).

## CLINICAL PRESENTATION AND DIAGNOSIS

### Signs and Symptoms

Infants and children infected with HIV often show signs of developmental delay (late to develop motor skills and cognitive ability). Weight gain or growth during the first year of life (failure to thrive) is usually absent. Children with HIV may also develop opportunistic infections (OIs) or conditions that further affect growth and development. Human immunodeficiency virus encephalopathy can lead to microcephaly or brain atrophy. Motor impairments, such as gait abnormalities and ataxia, may also occur (Reference 17). *Candida* infections (such as mucosal oropharyngeal thrush, vaginitis, and invasive

**Table 1.** Risk Factors for HIV Transmission (References 12–16)

Risk Factor	Comment
<b>More Common</b>	
Breastfeeding	Can be as high as 42% risk, depending on the breastfeeding duration (Reference 12)
Injection drug use	Needle exchange programs and methadone maintenance programs have been shown to reduce the risk of HIV transmission (References 13, 14).
Unprotected vaginal or anal sex	Men who have sex with men who engage in unprotected receptive anal sex have the highest risk of transmission.
Multiple sex partners	Presence of other sexually transmitted infections (e.g., herpes simplex, syphilis) can increase the risk of HIV infection during sex.
Substance abuse	Alcohol, crack cocaine, crystal methamphetamine, and opioids can lead to high-risk sexual behavior.
<b>Less Common</b>	
Use of contaminated needles or sharps	Needlestick or sharp object injury to a health care worker
Receipt of contaminated blood products	Through blood transfusion, organ/tissue transplantation
Unprotected oral sex	Carries a lower risk than unprotected vaginal or anal sex
Receipt of pre-chewed food	Feeding infants with food that is pre-chewed by an HIV-infected person (Reference 15)
Being bitten by an HIV-infected person or deep or open-mouth kissing with an HIV-infected person whose mouth or gums are bleeding	HIV cannot reproduce outside the human body and is not spread by air or water; mosquitoes; saliva, tears, or sweat; shaking hands or sharing dishes; or closed-mouth or “social” kissing (Reference 16).

esophageal candidiasis), cytomegalovirus (CMV), and *Pneumocystis jirovecii* pneumonia (previously termed *P. carinii* pneumonia [PCP]) are common OIs and will be discussed below. Children with HIV infection are also prone to recurrent bacterial infections and to lymphoid interstitial pneumonia, which is rare in the adult population (References 18, 19).

Acute HIV infection in adolescents who are infected through high-risk behaviors, such as sharing needles or unprotected sexual contact, may present with nonspecific symptoms, including fever, headache, sore throat, joint and/or muscle pain, lymphadenopathy, and generalized rash (References 20–24). This acute retroviral syndrome typically occurs 2–4 weeks after infection. The persistence of these symptoms in the presence of ulcers on the mucosa of the mouth, anus, genitalia, or esophagus is suggestive of HIV infection. Gastrointestinal disturbances such as nausea, diarrhea, weight loss, and loss of appetite may also occur. Signs and symptoms of chronic HIV infection include continued weight loss, fatigue, recurrent yeast infections (vaginal or oral), and skin abnormalities (frequent rashes, psoriasis) (Reference 21).

### Opportunistic Infections

*P. jirovecii* pneumonia is one of the most common OIs diagnosed in HIV-infected children, with the highest rates of occurrence in infants up to 12 months old. The risk of PCP infection increases with a decrease in CD4<sup>+</sup> count and CD4<sup>+</sup> percentage. Distinguishing features of infection include fever, cough, dyspnea, and tachypnea. Pediatric patients typically also present with low oxygen saturation, a CD4<sup>+</sup> count below 200 cells/mm<sup>3</sup>, and/or a CD4<sup>+</sup> percentage less than 15% in children older than 5 years. Chest radiographs may be normal, show little infiltrate, or show bilateral parenchymal infiltrates. Although elevated lactate dehydrogenase and decreased serum albumin may also be present, they are not specific to PCP infection. To diagnose PCP, the organism must be identified in pulmonary tissue, preferably obtained by bronchoscopy with bronchoalveolar lavage. *Pneumocystis* organisms may be recognized through staining: methenamine-silver and toluidine blue stain the cyst wall, but immunofluorescent antibodies, which also stain the cyst wall, have higher specificity. Prophylaxis against PCP is highly recommended in children 1–12 months of age regardless of CD4<sup>+</sup> count, in children 1–5 years of age with CD4<sup>+</sup> counts less than 500 cells/mm<sup>3</sup> or CD4<sup>+</sup> percentage less than 15%, and in children 6 years or older with CD4<sup>+</sup> counts less than 200 cells/mm<sup>3</sup> and/or CD4<sup>+</sup> percentage less than 15%. Primary prophylaxis should not be discontinued in patients younger than 1 year, but it may be discontinued in older children after they have received ARV treatment for at least 6 months and have met the following CD4<sup>+</sup> count thresholds: children 1–5

years of age: CD4<sup>+</sup> count of 500 cells/mm<sup>3</sup> or greater for more than 3 consecutive months; children 6 years and older: CD4<sup>+</sup> count of 200 cells/mm<sup>3</sup> or greater for more than 3 consecutive months (Reference 25).

*Mycobacterium avium* complex (MAC) is another common OI among HIV-infected children. The risk of infection increases with varying levels of age-specific immunosuppression (see Table 2). *M. avium* complex colonizes the gastrointestinal and respiratory tracts; its presence in these locations can be predictive of DMAC (disseminated infection), which can involve the lungs, lymph nodes, liver, spleen, and bone marrow (Reference 26). Respiratory symptoms are rare, but cough may be present. Common signs and symptoms include fever, weight loss, muscle weakness, abdominal pain, diarrhea, chills, night sweats, fatigue, and hepatosplenomegaly. Laboratory findings reveal anemia, neutropenia, and thrombocytopenia and may include elevated lactate dehydrogenase or alkaline phosphatase values. A blood culture or bone marrow biopsy is required for a diagnosis of MAC. Although a positive acid-fast bacillus test may be indicative of MAC in a symptomatic patient, it cannot be distinguished from *Mycobacterium tuberculosis* without a culture or confirmation with a polymerase chain reaction (PCR) test. As with PCP, prophylaxis against MAC is highly recommended in patients meeting certain CD4<sup>+</sup> counts or CD4<sup>+</sup> percentage thresholds (Table 2). Prophylaxis is indicated in the following situations: in infants with CD4<sup>+</sup> counts less than 750 cells/mm<sup>3</sup>; in children 1–2 years of age with CD4<sup>+</sup> counts less than 500 cells/mm<sup>3</sup>; in children 2–5 years of age with CD4<sup>+</sup> counts less than 75 cells/mm<sup>3</sup>; and in children 6 years and older with CD4<sup>+</sup> counts less than 50 cells/mm<sup>3</sup>. Primary prophylaxis should not be discontinued in patients younger than 2 years, but it may be discontinued in older children after they have received ARV treatment for at least 6 months and have met the following CD4<sup>+</sup> count thresholds: children 2–5 years of age: CD4<sup>+</sup> count greater than 200 cells/mm<sup>3</sup> for more than 3 consecutive months; children 6 years and older: CD4<sup>+</sup> count greater than 100 cells/mm<sup>3</sup> for more than 3 consecutive months (Reference 25).

*Toxoplasma gondii* infection in infants and children is usually the result of maternal infection present before or at birth. In older children and adolescents, acquisition is typically through ingesting parasite-containing raw or undercooked meat or water or soil contaminated with sporulated oocysts. Because cats are confirmed hosts for *T. gondii* and may excrete sporulated oocysts in their feces after early infection, contact with their feces can also be a risk factor for infection. In patients with AIDS, *T. gondii* usually presents with central nervous system effects, including headache, confusion, neurologic deficiencies, and seizures. Fever may be present, and nausea or vomiting can occur with significant mental

status changes. Diagnosis is confirmed by enzyme immunoassay (EIA) testing for immunoglobulins specific to *Toxoplasma* (immunoglobulin A, E, or M up to 6 months of age or G after 1 year of age). Children older than 5 years with CD4<sup>+</sup> counts below 100 cells/mm<sup>3</sup> and positive antibody tests should receive prophylaxis for *T. gondii*; children 5 years and younger with positive antibody testing should receive prophylaxis if the CD4<sup>+</sup> percentage is below 15%. Primary prophylaxis should not be discontinued in patients younger than 1 year, but it may be discontinued in older children after they have received ARV treatment for at least 6 months if they meet the following CD4<sup>+</sup> count thresholds: children 1–5 years of age: CD4<sup>+</sup> percentage of 15% or greater

for more than 3 consecutive months; children 6 years and older: CD4<sup>+</sup> percentage of 15% or greater or CD4<sup>+</sup> count greater than 100–200 cells/mm<sup>3</sup> for more than 3 consecutive months (Reference 25).

Cytomegalovirus may be transmitted perinatally by ingesting CMV-containing bodily fluids (blood, breast milk, saliva, genital secretions) or through sexual contact. The risk of infection is highest during the first year of life. Symptoms of disease include microcephaly, hearing impairment, hepatosplenomegaly, and retinitis, which may be characterized by blurred vision or blind spots. Photopsia is highly associated with CMV retinitis in patients with AIDS (Reference 27). Many children with CMV at birth subsequently acquire developmental

**Table 2.** Primary Prophylactic Drug Regimens for Common Opportunistic Infections in HIV-Infected Children and Adolescents (Reference 25)

Pathogen	Indication for HIV-Infected Children	Preferred Prophylaxis Regimen(s): Children	Preferred Prophylaxis Regimen(s): Adolescents
<i>Pneumocystis jirovecii</i> pneumonia (PCP)	Age 1–12 months	Trimethoprim/sulfamethoxazole (TMP/SMX) <sup>a</sup> : 150/750 mg/m <sup>2</sup> of body surface area per day, given as: Two divided doses daily OR three times/week OR As a single dose three times/week on consecutive days MDD: 320/1600 mg	TMP/SMX: 160/800 mg once daily OR 160/800 mg three times/week OR 80/400 mg once daily
	Age 1–5 years with CD4 <sup>+</sup> < 500 cells/mm <sup>3</sup> or CD4% < 15%		
	Age 6–12 years with CD4 <sup>+</sup> < 200 cells/mm <sup>3</sup> or CD4% < 15%		
	Adolescents with CD4 <sup>+</sup> < 200 cells/mm <sup>3</sup> or CD4% < 14%		
<i>Mycobacterium avium</i> complex (MAC)	Age < 1 year with CD4 <sup>+</sup> < 750 cells/mm <sup>3</sup>	Clarithromycin: 7.5 mg/kg twice daily MDD: 1000 mg Azithromycin: 20 mg/kg once weekly Maximum weekly dose: 1200 mg	Azithromycin: 1200 mg once weekly OR 600 mg twice weekly Clarithromycin: 500 mg twice daily
	Age 1–2 years with CD4 <sup>+</sup> < 500 cells/mm <sup>3</sup>		
	Age 2–5 years with CD4 <sup>+</sup> < 75 cells/mm <sup>3</sup>		
	Age ≥ 6 years with CD4 <sup>+</sup> < 50 cells/mm <sup>3</sup>		
<i>Toxoplasma gondii</i>	<i>Toxoplasma</i> Antibody(+), PLUS: Age < 6 years with CD4% < 15%	TMP/SMX: 150/750 mg/m <sup>2</sup> body surface area per day, given as: Two divided doses daily OR three times/week OR As a single dose three times/week on consecutive days MDD: 320/1600 mg	TMP/SMX: 160/800 mg once daily
	OR Age ≥ 6 years with CD4 <sup>+</sup> < 100 cells/mm <sup>3</sup>		

<sup>a</sup>Patients who are allergic to sulfonamide antibiotics may take dapsone as an alternative to TMP/SMX for PCP prophylaxis; if so, they should be monitored for signs of cross-sensitivity. Additional alternatives to TMP/SMX include aerosolized pentamidine and atovaquone. MDD = maximum daily dose; TMP/SMX = trimethoprim/sulfamethoxazole.

delays, neurologic deficits, learning disabilities, ophthalmologic complications, or seizure disorders. Similar to HIV infection, CMV is difficult to diagnose in infants with antibody testing because maternal antibodies may be present throughout the first year of life. In children older than 12 months, a positive antibody test does not always indicate an active infection, but it is indicative of CMV exposure. Cytomegalovirus may be detected by culture or a polymerase chain reaction test. Primary prophylaxis for CMV is not routinely recommended; however, yearly screenings are recommended for children who tested negative at birth and for children whose CD4<sup>+</sup> counts are below 100 cells/mm<sup>3</sup> or who have a CD4<sup>+</sup> percentage below 10% (Reference 25).

*Candida* infections are common among HIV-infected children and are most often caused by *Candida albicans*. These infections are found in the mucosa of the oral cavity, esophagus, and oropharynx (thrush, angular cheilitis) and as dermatitis in the diaper area; they may also be found in the vulvovaginal area of adolescent girls. Infants and toddlers with *Candida* infection may present with discomfort in the diaper area or difficulty/pain on swallowing. *Candida* infection can be diagnosed with a biopsy of infected tissue (for staining or culture); invasive disease, although not typically a significantly high-risk issue in HIV-positive patients, may be diagnosed by blood culture. Although a low CD4<sup>+</sup> count, less than 100 cells/mm<sup>3</sup>, increases the risk of developing a *Candida* infection, primary prophylaxis is rarely recommended because active infections respond well to existing treatment measures. Initiating antifungal prophylaxis also increases both the risk of developing antifungal drug resistance and the potential for drug-drug interactions with ARV medications (Reference 25).

Table 2 provides a summary of recommended prophylaxis regimens for PCP, MAC, and toxoplasmosis. There are resources available that provide greater detailed information on alternative primary prophylaxis regimens, secondary prophylaxis, discontinuation of prophylaxis, and the treatment of active infection in HIV-positive children and adolescents (References 25, 28, 29).

## Diagnostic Criteria

### Laboratory Data

Human immunodeficiency virus infection is diagnosed by several methods, including detection of viral antibodies, the p24 antigen, or HIV genetic material. Standard antibody testing is performed using EIA. Because of their high sensitivity and somewhat low specificity, positive EIA results must be confirmed by a Western blot, which uses antibodies to identify specific proteins after they are separated by gel electrophoresis. A negative EIA is typically considered a true negative; however, a false-negative result is possible if the test is performed

in the “window period” of acute infection (i.e., the time it takes the body to produce antibodies to HIV). For indeterminate results, a repeat EIA is recommended as well as HIV RNA testing. Antibody testing may be performed by standard or rapid testing methods. Rapid tests offer the following advantages: the result can be read by a counselor/provider while the patient remains on-site (results can be available in 40 minutes or less); patients can receive an immediate offer of or referral to medical care and/or counseling services; and these tests are performed using blood, plasma, serum, or saliva samples (References 30, 31). The immediate results obtained from rapid testing have allowed more patients to be made aware of their infection status and expedited the care of patients with newly diagnosed HIV infection (References 32, 33). Many commercially available rapid tests can identify both HIV-1 and HIV-2. It is recommended to confirm a positive rapid test result with both the standard EIA and the Western blot tests. Criteria for interpreting a Western blot result have been offered by several national and international agencies, including the CDC and WHO. The CDC criteria for a positive result include reactivity to either the gp41 or the p24 antigen, in addition to the gp120/160 antigens.

A PCR test, a DNA test, or nucleic acid amplification can detect HIV antigens or isolate the virus. These methods are most useful to identify infection for those in the “window period” or for the diagnosis of HIV in infants. Virologic testing (for the presence of HIV RNA), rather than antibody testing, is recommended in infants because of the presence of maternal antibodies transferred by the placenta. Human immunodeficiency virus virologic testing should be performed in exposed infants within 14–21 days of birth, at 1–2 months old, and at 4–6 months old. Consideration may be given to performing the first round of testing at birth in infants who are at high risk of HIV infection, such as those born to mothers who did not receive antepartum ARV therapy for the prevention of MTCT or whose mothers did not have a viral load less than 1000 copies/mL at delivery. An infant with an initial negative virologic test should be retested at 1–2 months of age. Although infants should complete a 6-week course of zidovudine prophylaxis against HIV, this has not been shown to alter the time to detect HIV or alter the sensitivity of the testing method. A third virologic test is recommended at 4–6 months of age in infants who have two previously negative tests to ultimately rule out the presence of HIV infection. Although not recommended at birth, two sets of negative antibody tests performed at a minimum of 6 months of age may also rule out HIV infection in children in the absence of other clinical or virologic signs of infection. Antibody testing is also considered at 12–18 months of age in patients with previous negative virologic testing to confirm that maternal antibodies are no longer present. Human

immunodeficiency virus infection may be diagnosed by antibody testing and confirmatory Western blot in children 18 months and older (Reference 28).

### Course and Prognosis of Disease

The highest risk of disease progression is in children younger than 5 years, regardless of immunologic status; there is a 4-fold increased risk of progressing to AIDS and a 6-fold increased risk of death for a 1-year-old child than for a child 5 years or older at a similar CD4<sup>+</sup> percentage. Children who are at least 5 years old have a 12-month risk of death or progression to AIDS similar to that of young adults (around 20 years old), at CD4<sup>+</sup> counts less than 350 cells/mm<sup>3</sup> (References 28, 34). The difference in risk of disease progression and death between these age groups is likely multifactorial. High levels of HIV RNA can persist for a longer period in younger children, and although viral load levels may be low at birth, they can increase substantially by 2 months of age to more than 100,000 copies/mL. The risk of HIV progressing to AIDS increases when viral loads are above this threshold. In addition, a young child's developing immune system may not be robust enough to limit viral replication.

The virologic set point is the level of HIV RNA that is reached after a decline in viral load after acute infection; this level is typically set about 6–12 months after infection and shows a correlation with the risk of disease progression or death in adolescent patients. The application of this information to infants and young children is less clear because of the fluctuations in HIV viral load seen in this population. In infants, high viral loads (greater than 299,000 copies/mL) are associated with a greater risk of disease progression and death (References 35, 36). This increased risk is also present for adolescents with viral loads higher than 100,000 copies/mL (References 37, 38). The risk of progression to AIDS and death in children is greatest in the first year of life regardless of HIV RNA level, with the risk increasing at higher viral loads (Reference 39). Given the potential for fluctuating HIV RNA levels in very young children as mentioned previously, it is important to consider both the immunologic and virologic status of a child when determining his or her risk of disease progression (Reference 40).

## TREATMENT

### Goals of Therapy

Human immunodeficiency virus is a chronic infection that requires lifelong therapy. Therefore, the goals of ARV treatment for HIV-infected children and adolescents are to reduce HIV-related mortality and morbidity, preserve and restore immune function, achieve

virologic suppression, prevent the emergence of drug resistance, minimize ARV adverse effects, maintain normal physical growth and neurocognitive development, and improve quality of life (Reference 28).

### Nonpharmacologic Therapy

Micronutrient (multivitamin and trace element) deficiencies are common in HIV-infected patients, especially those with advanced disease progression and those living in developing countries. Therefore, vitamin supplementation has been explored as an avenue for reducing HIV disease burden. A Cochrane review analysis showed that several micronutrient supplements reduced mortality and morbidity in HIV-infected pregnant women and their children (Reference 41). Multivitamin supplementation in African pregnant patients has also been associated with decreased adverse pregnancy outcomes such as fetal death, low birth weight, and severe preterm births. The children also had better growth, better micronutrient status, and higher CD4<sup>+</sup> counts in the first 6 months to 2 years of life (References 41, 42). As a whole, multivitamin supplementation seems to be beneficial to HIV-infected patients and may also serve as an indicator for assessing adherence to medications before considering the initiation of ARVs.

### Herbal Therapy

Herbals may also play a role in the treatment of HIV infection. The catechins contained in green tea have been associated with several health benefits (Reference 43). In vitro studies have shown that epigallocatechin gallate (EGCG), the most plentiful catechin in green tea, inhibited gp120 of the HIV virion binding to the CD4<sup>+</sup> cell receptor (Reference 44). However, studies of EGCG suggest that a significant quantity of green tea would need to be consumed to produce an in vivo effect (References 45, 46). Other potentially beneficial herbals include *Hypoxis hemerocallidea* (African potato) and *Sutherlandia frutescens*. The African potato is used as an immune-stimulant and has antioxidant properties. *Sutherlandia* possesses a constituent L-canavanine, which is thought to have antiviral activity.

One disadvantage of the *Hypoxis* and *Sutherlandia* spp. is the potential for drug interactions with ARVs because they may inhibit the cytochrome P450 (CYP) 3A4 isoenzyme (CYP3A4) and P-glycoprotein (an efflux transporter). Other herbals such as St. John's wort (*Hypericum perforatum*) or garlic supplements are inducers of CYP3A4 and may decrease the serum concentrations of the PIs, NNRTIs, and maraviroc (Reference 47). Health care providers, especially pharmacists, are encouraged to ask patients about vitamin supplementation and herbal use to rule out any potential drug interactions with ARVs. Furthermore, another major

limitation to using herbals for treating HIV infection is the lack of U.S. Food and Drug Administration (FDA) regulation and approval based on efficacy and safety. Thus, caution should be taken if HIV-infected children are using herbals and ARVs concomitantly.

## Prevention

One of the best ways to prevent HIV transmission is to use safe sex practices such as condoms. When latex condoms are used consistently and correctly, they are highly effective in preventing sexual transmission of HIV. One study found that consistent condom use resulted in an 80% reduction in HIV incidence in HIV serodiscordant heterosexual couples (Reference 48). A review study also showed that among men who have sex with men (MSM), condom use reduced the per-contact risk of HIV infection by 78% compared with unprotected anal intercourse (Reference 49). Furthermore, other methods to prevent HIV transmission have been explored, including male circumcision, vaccines, and microbicides. Male circumcision is associated with reduced transmission of sexually transmitted diseases, including HIV. Three large randomized controlled trials evaluated the impact of voluntary adult circumcision on HIV transmission rates in Kenya, South Africa, and Uganda. These trials showed a 50% to 60% reduction in the incidence of HIV infection for circumcised men compared with uncircumcised men (References 50–52). Another clinical trial in Uganda evaluated male-to-female HIV transmission rates when the males were circumcised and had viral loads less than 50,000 copies/mL, showing a significantly lower rate of transmission in this group compared with the uncircumcised group (Reference 53).

An effective HIV vaccine has yet to be found, despite decades of continuous research. At least two trials failed to show a protective benefit of vaccination (References 54, 55). However, a more recent study conducted in a community province in Thailand found a moderate protective effect for those who received the ALVAC/AIDS VAX vaccine regimen compared with those on placebo (Reference 56). Obstacles that make it so difficult to find a successful HIV vaccine are the virus's great genetic diversity, its ability to evade adaptive immune responses, its inability to induce a broadly reactive antibody response, and the establishment of latent reservoirs early in infection.

Recently, two promising clinical trials reported some benefits in the role of microbicides for preventing HIV transmission in adults. The first study (CAPRISA) found that a 1% tenofovir vaginal gel was associated with at least a 40% significantly reduced risk of transmission of HIV infection compared with placebo at 24 months (Reference 57). Another study was performed in transgender

women and MSM using a preexposure prophylaxis oral regimen of daily tenofovir/emtricitabine compared with placebo. Those who received daily tenofovir/emtricitabine had a 44% relative risk reduction for HIV infection (Reference 58). With the exception of MTCT, no data exist on preventing HIV transmission with microbicides in children.

## Pharmacologic Therapy

Since the development of the first ARVs in the late 1980s, treatment of pediatric HIV infection has evolved tremendously, especially with the arrival of the first PI. Use of combination antiretroviral therapy (cART) has improved survival, decreased the development and risk of OIs, improved growth and neurocognitive function, and enhanced the quality of life for HIV-infected children. Treatment of pediatric HIV infection, however, is very complex and should be tailored as well as possible to the patient's individual circumstances (Table 3) (References 28, 29). Moreover, it is worth emphasizing that the monthly average wholesale price of ARVs is very expensive (ranging from \$361 to \$3248 depending on the choice of ARV) (Reference 29). Annual costs of cART may range from \$25,000 to \$35,000; the monthly average wholesale price of NRTIs and NNRTIs tends to be considerably less than PIs and newer ARVs such as raltegravir, maraviroc, etravirine, and rilpivirine. These average wholesale price costs, which are derived from January 2012 data, may not represent the pharmacy acquisition costs or price paid by consumers (Reference 29). Affordability of cART may be considerably improved by insurance coverage as well as financial assistance programs such as AIDS drug assistance programs (ADAPs) and Ryan White funding. Because very few randomized clinical trials have been conducted in children, most of the ARVs indicated for treatment of pediatric HIV infection derive their approval from efficacy data in adults, pharmacokinetic and safety data from phase I/II trials of children, and nonrandomized open-label studies. Furthermore, very few phase III trials compare the effects of different ARV regimens in HIV-infected children.

The decision about when to start treatment is debatable because there are both advantages and disadvantages to initiating ARV therapy earlier when the patient is asymptomatic versus delaying treatment until the patient becomes symptomatic. Advantages of initiating ARV therapy early include having control of viral replication, allowing a lower viral load set point, reducing mutant viral strains, preserving immune function, preventing HIV disease progression, preventing sexual transmission of HIV, and preventing non-AIDS malignancies and other complications. However, delaying ARV therapy may also have some advantages such as reduced development of drug-resistant virus (because

**Table 3.** Factors to Consider When Choosing ARV Therapy for HIV-Infected Children (References 28, 29)

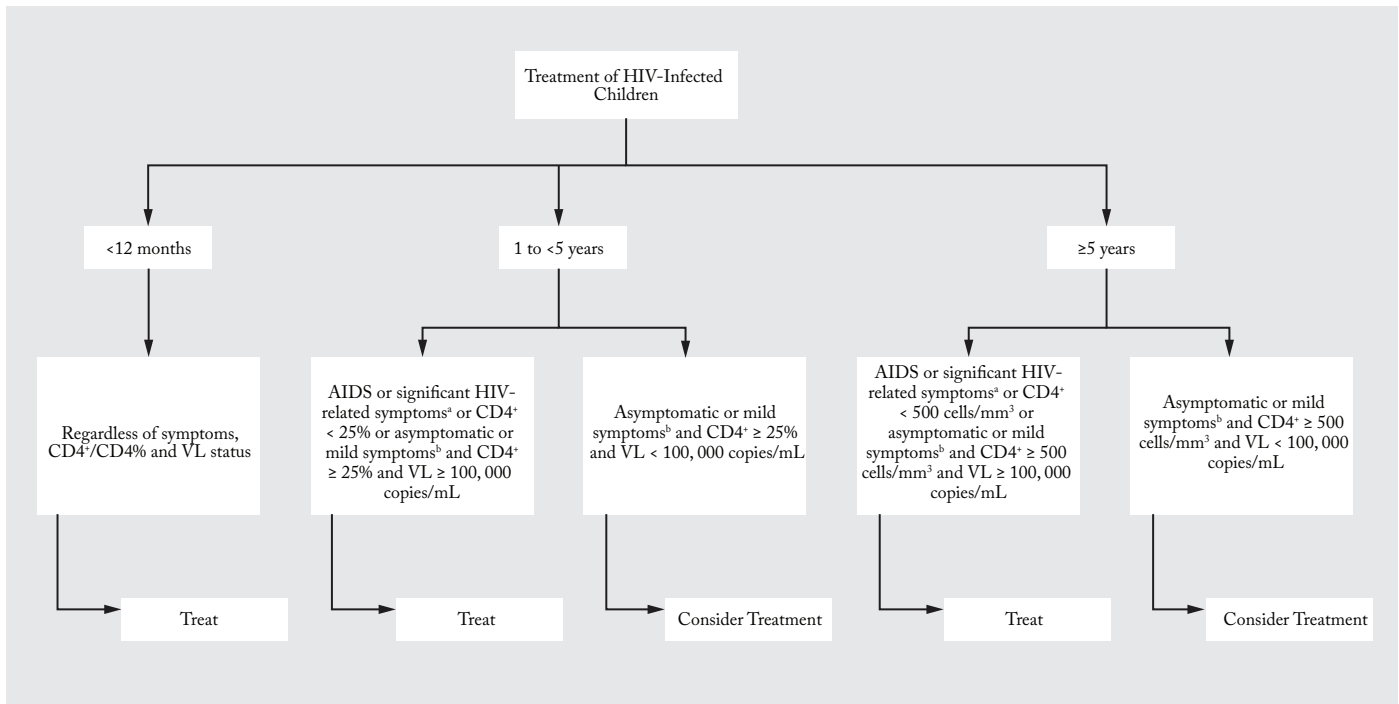

Factors for Consideration	Comments
Age of child	Different levels of caregiver involvement
Severity of disease	Virologic, immunologic, and clinical status
Affordability of ARVs	Annual costs of ARVs are very expensive (insurance coverage, ADAP, etc., can help offset costs)
Availability of appropriate dosage formulations	Liquid formulations including palatability Crushable/chewable tablets
Availability of relevant PK data for different age groups	Limited PK data available in the pediatric and adolescent HIV-infected populations
Potency of ARV regimen	Use three fully active drugs if possible.
Complexity of ARV regimen	Pill burden Dosing frequency Administration conditions (e.g., food considerations) Medication storage conditions (e.g., refrigeration) Expiration dates
Toxicity of ARV regimen	Adverse effect minimization and management
Preservation of future ARV treatment options	Maintain virologic control to avoid development of drug resistance/cross-resistance to other ARVs.
ARV treatment history	Potential for cross-resistance to other ARVs and previous intolerance of specific ARVs
Presence of ARV drug-resistant virus	Knowledge of previous resistance tests including genotypes and phenotypes is useful for determining appropriate ARV regimen (though complexity of regimen may be increased).
Presence of comorbid conditions	Potential for drug-drug or drug-disease interactions, including overlapping toxicities of drugs
Potential drug-drug interactions	Dose adjustments may be necessary with some medications; however, some ARVs may need to be avoided if contraindications exist.
Adherence potential	Critical for determining choice of appropriate ARV therapy (a good support system can benefit a patient greatly)

ADAP= AIDS drug assistance programs; ARV=antiretroviral; PK = pharmacokinetic.

of no drug-selective pressure), improved adherence to ARV regimen because the patient is symptomatic, and reduced or delayed adverse effects of ARV therapy. Of importance, CD4<sup>+</sup> cell count and viral load show considerable variability by age in children. Although these surrogate markers are poorly predictive of mortality and disease progression in infants, it is recommended to start treatment for all infants with a diagnosis of HIV infection because they are at greatest risk of rapid disease progression. Studies have shown that infants who receive early treatment have a significantly reduced risk of disease progression and achieve greater CD4<sup>+</sup> cell recovery compared with those who receive no ARV treatment (References 59–61). In the HIV Pediatric Prognostic Markers Collaborative Study meta-analysis, both CD4<sup>+</sup> percentage and HIV viral load were independent predictors of the risk of clinical progression or death in children older than 12 months (Reference 62). Furthermore, CD4<sup>+</sup> cell count is associated with risk of progression in children 5 years and older, similar to young adults. Therefore, recommendations for starting treatment for HIV-infected children between 1 and 4 years of age are

based on CD4<sup>+</sup> percentage and, for those 5 years and older, on CD4<sup>+</sup> cell count. See Figure 1 for a summary of criteria and recommendations for when to initiate ARV therapy in HIV-infected children.

When initiating ARV therapy in treatment-naive HIV-infected children, the general approach is to use cART with at least three active ARV drugs from two different classes. Combination therapy is important because ARV resistance can develop more easily with monotherapy or dual therapy. The choice of initial cART for treatment-naive HIV-infected children is critically important because the selection of the first regimen can affect the consideration of future treatment options. Before starting treatment, adherence barriers to ARV therapy should be fully assessed and discussed with both the caregiver and patient. If possible, identifying potential problems and resolving them before starting ARV therapy are ideal. Adherence to ARVs is the cornerstone for achieving the goals of therapy because poor adherence to ARVs can lead to subtherapeutic levels, which increases the risk of developing ARV resistance and virologic failure.

**Figure 1.** Summary of criteria and recommendations for when to initiate ARV therapy in HIV-infected children (Reference 28).

<sup>a</sup>CDC clinical categories C and B (except for category B condition single episode of serious bacterial infection).

<sup>b</sup>CDC clinical category A or N or the following category B condition single episode of serious bacterial infection.

AIDS = acquired immunodeficiency syndrome; ARV = antiretroviral; CDC = Centers for Disease Control; HIV = human immunodeficiency virus; VL = viral load.

To date, more than 20 ARV drugs are approved for use in the treatment of HIV, of which 17 have an approved pediatric treatment indication. Currently, there are five ARV classes: NRTIs, NNRTIs, PIs, entry inhibitors (including fusion inhibitors and attachment inhibitors such as CCR5 antagonists), and integrase strand transfer inhibitors. See the Pathophysiology section for more information on the pharmacology of antiretrovirals. Common ARV combinations for treatment-naïve pediatric HIV infection include two NRTIs plus one NNRTI, or two NRTIs plus one PI with or without ritonavir. Although monotherapy for treatment of HIV infection is not recommended because of the potential for resistance development, one exception is zidovudine monotherapy for 6 weeks in infants of indeterminate HIV status to prevent perinatal HIV transmission. Should infants have a confirmation of HIV infection while receiving zidovudine monotherapy, zidovudine should be discontinued, and combination therapy with three active ARVs should be used for treatment (this may include zidovudine, if genotype shows no resistance). Antiretroviral drug resistance testing is always recommended before initiating therapy in treatment-naïve HIV-infected children because it is possible for infants to acquire drug resistance from their HIV-infected mothers. For example, infants given single-dose peripartum nevirapine for prevention

of transmission should not use nevirapine as combination therapy, should they later be given a diagnosis of HIV infection, because this maternal-infant prophylaxis could be associated with resistance to nevirapine and subsequent virologic failure (Reference 63). Drug-resistant virus has been detected in 6% to 16% of ARV-naïve adults and in 18% of adolescents with recent infection in both the United States and Europe (References 64–68).

Recommendations for optimal ARV therapy among pediatric patients are continuously updated as new drug formulations are developed and more information regarding efficacy and safety becomes available. The U.S. Department of Health and Human Services guidelines are written by a panel of experts who assimilate the clinical trials of adult and pediatric patients to date (References 28, 29). Their recommendations for specific ARV drugs or regimens are stratified into three different categories for treatment-naïve HIV-infected pediatric patients: preferred, alternative, or for use in special circumstances (Reference 28). Updates to these guidelines can be found at [www.aidsinfo.nih.gov](http://www.aidsinfo.nih.gov). Some primary factors that may affect their recommendations for ARV use can be found in Table 3. See Table 4 for a summary of various ARVs used to treat HIV infection, including dosing formulations, dosing, special instructions, and metabolism/mode of clearance for each ARV.

**Table 4. Summary of ARVs**

Generic (Brand, Abbreviation)	Dosage Formulation	Dosing	Special Instructions	Mode of Clearance/ Metabolism	Adverse Effects	Management/Monitoring

**Zidovudine**  
(Retrovir, AZT or ZDV)

**Syrup:**  
10 mg/mL

**Concentrate for injection/intravenous infusion:**  
10 mg/mL

**Capsules:**  
100 mg

**Tablets:**  
300 mg

**Dose for infant younger than 35 weeks' gestation for prevention of transmission or treatment:**  
(IV) 1.5 mg/kg or  
(Oral) 2 mg/kg BID, increased to 3 mg/kg BID at 2 weeks of age (neonates  $\geq$  30 weeks' gestational age) or at 4 weeks of age (neonates < 30 weeks' gestational age)

**< 6 weeks for prevention of transmission or treatment:**  
(Oral) 2 mg/kg every 6 hours  
(IV) 1.5 mg/kg every 6 hours

**6 weeks to < 18 years:**  
**BSA dosing:**  
(Oral) 180–240 mg/m<sup>2</sup> BID or 160 mg/m<sup>2</sup> TID

**Wt-based dosing:**

Wt (kg)	BID
4 to < 9	12 mg/kg
$\geq$ 9 to < 30	9 mg/kg
$\geq$ 30	300 mg

**Adolescent ( $\geq$  18 years)/Adult dose:**  
200 mg TID or 300 mg BID  
Tirizivir (abacavir/lamivudine/zidovudine)  
1 tablet BID ( $\geq$  40 kg)  
Combivir (lamivudine/zidovudine) 1 tablet BID ( $\geq$  30 kg)

**Renal recovery of unchanged drug is less than 20%, extensive liver metabolism including glucuronide conjugates**

**With or without food**

**Macrocyclic anemia**

- Granulocytopenia
- Gastrointestinal intolerance
- Headache
- Fatigue
- Myopathy
- Lipodystrophy
- Lactic acidosis with hepatic steatosis
- Nail pigmentation
- Insulin resistance/diabetes mellitus
- Hyperlipidemia

**Discontinue AZT if severe granulocytopenia or anemia; use of erythropoietin 50–200 international units/kg/dose TID, or filgrastim 5–10 mcg/kg QD, or transfusion may be necessary**

- If feasible, discontinue non-ARV marrow-toxic drugs.
- CBC
- LFTs
- Blood glucose
- Lipids
- Dose adjust in renal failure.
- May need to dose adjust in hepatic impairment

**Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)**

**Efavirenz**  
(Sustiva, EFV)

**Tablets:**  
600 mg

**Capsules:**  
50 mg,  
200 mg

**> 3 years and > 10 kg:**

Wt (kg)	QD (mg)
10 to < 15	200
15 to < 20	250
20 to < 25	300
25 to < 32.5	350
32.5 to < 40	400
$\geq$ 40	600

**Adolescent ( $\geq$  40 kg)/Adult dose:**  
600 mg QD  
Atripla (tenofovir/emtricitabine/efavirenz)  
1 tablet QD

**Take on an empty stomach at bedtime.**

- Avoid administration with high-fat meal because this may increase EFV concentrations.

**CNS adverse effects (may include insomnia, abnormal dreams, dizziness, somnolence)**

- Rash
- Hepatotoxicity
- Teratogenic
- Potential lipohypertrophy

**Hepatic**

- CYP 3A4 and 2B6 inducer
- CYP3A4 and 2B6 substrate

**EFV may cause false-positive cannabinoid and benzodiazepine tests.**

- LFTs
- EFV should be avoided in first trimester of pregnancy (pregnancy category D).
- Lipids
- Use with caution in hepatic impairment.

Table 4. Summary of ARVs (continued)

Generic (Brand, Abbreviation)	Dosage Formulation	Dosing	Special Instructions	Mode of Clearance/ Metabolism	Adverse Effects	Management/Monitoring
Etravirine (Intelence, ETR)	Tablets: 100 mg, 200 mg	Adult dose (> 16 years and ARV experienced): 200 mg BID  Investigational dosing for children 6–17 years: 5.2 mg/kg (max 200 mg) BID (lower exposure of ETR seen in adolescents 12–17 years than in adults)	<ul style="list-style-type: none"> <li>Take after meals (AUC decreased by 50% on an empty stomach).</li> <li>Store at RT in original container because of sensitivity to moisture.</li> <li>Tablets can be dispersed in small amount of water to make slurry; once dispersed, stir well and consume immediately. Also, rinse glass with water a few times, swallowing each rinse to make sure entire dose is taken.</li> </ul>	<ul style="list-style-type: none"> <li>Hepatic</li> <li>CYP3A4 inducer</li> <li>CYP 2C9 and 2C19 inhibitor</li> <li>CYP3A4, 2C9 and 2C19 substrate</li> </ul>	<ul style="list-style-type: none"> <li>Nausea</li> <li>Diarrhea</li> <li>Rash</li> <li>Hypersensitivity reaction (including rash and hepatic failure)</li> </ul>	<ul style="list-style-type: none"> <li>LFTs</li> <li>History of NNRTI-related rash with EFV or NVP does not increase risk of developing rash with etravirine (however, etravirine should be avoided in patients with a history of severe rash with EFV and NVP).</li> <li>No dosage adjustment in patients with mild-moderate hepatic impairment</li> </ul>
Nevirapine (Viramune, NVP)	<p>Suspension: 10 mg/mL</p> <p>Tablets: 200 mg, 400 mg XR</p>	<p>&lt; 14 days (when used for prophylaxis of mother-to-child transmission of HIV): Single dose of 2 mg/kg (given to infants between birth and 72 hours after birth)</p> <p>≥ 15 days and &lt; 8 years: 200 mg/m<sup>2</sup> of BSA (max dose 200 mg) BID</p> <p>≥ 8 years: 120–150 mg/m<sup>2</sup> of BSA (max dose 200 mg) BID</p> <p>Adolescent/Adult dose: 200 mg BID</p>	<ul style="list-style-type: none"> <li>With or without food</li> <li>NVP is initiated at a lower dose and increased in a stepwise fashion because of autoinduction.</li> <li>Shake suspension well and store at RT.</li> </ul>	<ul style="list-style-type: none"> <li>Hepatic</li> <li>80% excreted in urine as glucuronidated metabolites</li> <li>CYP3A and 2B6 inducer</li> </ul>	<ul style="list-style-type: none"> <li>Rash</li> <li>Hepatotoxicity</li> </ul>	<ul style="list-style-type: none"> <li>If rash occurs during 14-day lead-in period, do not increase dose until rash resolves.</li> <li>If NVP has been discontinued for &gt; 7 days, reintiate NVP with QD for 2 weeks, followed by full BID dosing.</li> <li>Avoid starting NVP in females with CD4<sup>+</sup> &gt; 250 and in males with CD4<sup>+</sup> &gt; 400 cells/mm<sup>3</sup>.</li> <li>LFTs at baseline, 2 weeks, 4 weeks, and then every 3 months (if clinical hepatitis or hypersensitivity reactions occur, NVP should be permanently discontinued)</li> <li>Use with caution in children having elevated pretreatment LFTs.</li> <li>NVP should not be used in patients with moderate to severe hepatic impairment.</li> </ul>
		Initiate therapy with 200 mg given QD for the first 14 days; then increase to 200 mg BID if there is no rash or elevated LFT.				
		No data exist for 400-mg XR tablet for patients < 18 years.				

Rilpivirine (Edurant, RPV)	Tablets: 25 mg	Adult dose and ARV naive: 25 mg QD Complera (tenofovir/emtricitabine/rilpivirine) 1 tablet QD	• Take with a meal.	• Hepatic • CYP3A substrate	• CNS adverse effects (depression, mood changes, insomnia) are less common than with EFV. • Headache • Rash	• Use with caution when using with another drug that has known risk of torsade de pointes. • Use with caution in patients who have a viral load greater than 100,000 copies/mL because of increased risk of virologic failure. • No dosage adjustment in patients with mild-moderate hepatic impairment • Use with caution in patients with severe renal impairment or ESRD.
-------------------------------	-------------------	--	---------------------	-----------------------------------	--	---

**Protease Inhibitors (PIs)**

Atazanavir (Reyataz, ATV)	Capsules: 100 mg, 150 mg, 200 mg, 300 mg	For children 6–18 years: Treatment-naive children only* 15 to < 25 kg   ATV 150 mg + RTV 80 mg Treatment-naive and treatment-experienced children* 25 to < 32 kg   ATV 200 mg + RTV 100 mg 32 to < 39 kg   ATV 250 mg + RTV 100 mg ATV ≥ 39 kg   ATV 300 mg + RTV 100 mg	• Take with food to improve absorption of ATV. • Separate ATV dosing from acid-suppressive therapy (antacids should be separated by 1–2 hours; histamine-2 blockers should be separated by 12 hours) (if TDF is also used, use ATV 400 mg + RTV 100 mg QD); proton pump inhibitors (≤ 20 mg equivalent dosing of omeprazole) should be separated by 12 hours from boosted ATV). • Proton pump inhibitors not recommended in treatment- experienced patients taking ATV.	• Hepatic • CYP3A4 and UGT1A1 inhibitor • CYP3A4 substrate	• Indirect hyperbilirubinemia (sclera icterus) • Nephrolithiasis (rare) • Rash	• Hyperbilirubinemia may resolve with time (may discontinue if cosmetically unappealing). • Total bilirubin • Urinalysis • Dose adjust in hepatic failure (should not be given to patients with severe hepatic impairment). • Treatment-experienced patients with ESRD on hemodialysis should not use ATV.
*Take ATV/RTV QD with food.						
<b>Adolescent (≥ 18–21)/Adult dose:</b>						
<i>Treatment naive:</i> ATV 300 mg + RTV 100 mg or ATV 400 mg QD with food						
<i>Treatment experienced:</i> ATV 300 mg + RTV 100 mg QD with food						
<b>With EFV (only in treatment naive):</b> ATV 400 mg + RTV 100 mg + EFV 600 mg QD						
<b>With TDF:</b> Always use ATV 300 mg + RTV 100 mg + TDF 300 mg QD with food because TDF can decrease ATV exposure

**Ritonavir (Norvir, RTV)**

**Oral solution:** 80 mg/mL (contains 43% alcohol by volume)

**Capsules:** 100 mg

**Tablets:** 100 mg

• RTV is used as a pharmacokinetic booster (increases concentrations of coadministered PIs).

• Dosing of RTV varies with different PIs (see individual PIs to determine dosing of RTV).

• May take with food to minimize gastrointestinal intolerance and improve absorption

• Refrigerate capsules if not used within 30 days.

• Tablets need not be refrigerated.

• Store oral solution at RT (must not be refrigerated); shake well before use.

• Use oral solution within 6 months.

• Hepatic

• CYP3A4 and CYP2D6 inhibitor

• Circumoral paresthesias

• Hypertriglyceridemia

• Taste perversion

• Hepatitis

• Lipids

• LFTs

• Use caution when using RTV in patients with moderate to severe hepatic impairment.

**Saquinavir (Invirase, SQV)**

**Hard gel capsules:** 200 mg

**Tablets:** 500 mg

**Investigational dosing for treatment-experienced children ( $\geq 2$  years based on limited data):**

Wt (kg)	Dosing (BID)
5 to < 15	SQV 50 mg/kg + RTV 3 mg/kg
15–40	SQV 50 mg/kg + RTV 2.5 mg/kg
$\geq 40$	SQV 50 mg/kg + RTV 100 mg

SQV may be coadministered with LPV/r in patients  $\geq 7$  years for salvage therapy.

**Adolescent ( $\geq 16$  years)/Adult dose:**  
SQV 1000 mg + RTV 100 mg BID

• Take within 2 hours after food to improve absorption.

• Always take with RTV (never boosted because of poor bioavailability).

• May cause photosensitivity reactions if exposed to sun; recommend protective clothing or sunscreen use

• Hepatic

• CYP3A4 substrate and inhibitor

• Headache

• Abdominal discomfort

• QT prolongation and torsades de pointes

• Photosensitivity

• An electrocardiogram is recommended before initiation of SQV (patients with baseline QT intervals greater than 450 milliseconds should not receive SQV).

• SQV is also not recommended in patients who are taking other drugs that can cause QT prolongation.

• Use caution in patients with mild to moderate hepatic impairment.

• Contraindicated in patients with severe hepatic impairment

**Tipranavir (Aptivus, TPV)**

**Oral solution:** 100 mg/mL

**Capsules:** 250 mg

**2–18 years:**  
BSA dosing  $\rightarrow$  375 mg/m<sup>2</sup> + RTV 150 mg/m<sup>2</sup> BID or  
Wt-based dosing  $\rightarrow$  14 mg/kg + RTV 6 mg/kg  
[maximum TPV 500 mg + RTV 200 mg BID]

**Adult dose:**  
TPV 500 mg + RTV 200 mg BID

• Take with food.

• Oral solution contains 116 international units of vitamin E per milliliter.

• Because TPV has a sulfamoyl moiety, use caution in patients with sulfonamide allergy.

• Store oral solution at RT; do not refrigerate or freeze.

• Once oral solution is opened, it must be used within 60 days.

• Capsules can be kept at RT if used within 60 days; refrigerate capsules if longer storage is anticipated.

• Hepatic

• CYP3A4 substrate and inducer

• Rash

• Hepatotoxicity

• Intracranial hemorrhage (rare)

• Hypertriglyceridemia

• Use caution in patients at risk of increased bleeding from surgery, trauma, or other medical conditions or receiving drugs such as antiplatelets, anticoagulants, or excessive vitamin E supplemental doses.

• Lipids (especially triglycerides)

• Contraindicated in patients with moderate or severe hepatic impairment

(continued)

Table 4. Summary of ARVs (continued)

Generic (Brand, Abbreviation)	Dosage Formulation	Dosing	Special Instructions	Mode of Clearance/ Metabolism	Adverse Effects	Management/Monitoring												
<b>Entry Inhibitors</b>																		
Enfuvirtide, (Fuzeon, ENF or T-20)	<b>Lyophilized powder for injection:</b> 108-mg vial reconstituted with 1.1 mL of sterile water will make 90 mg/mL.	<b>6–16 years:</b> 2 mg/kg SC BID Maximum dose is 90 mg (1 mL) BID.  <b>Adolescents (&gt; 16 years)/Adult dose:</b> 90 mg (1 mL) SC BID	<ul style="list-style-type: none"> <li>Inject subcutaneously into the upper arm, anterior thigh, or abdomen.</li> <li>Allow up to 45 minutes for reconstituted powder to dissolve completely in solution; do not shake.</li> <li>Once reconstituted, inject immediately or keep refrigerated until use.</li> <li>Reconstituted vial must be used within 24 hours.</li> </ul>	<ul style="list-style-type: none"> <li>Catabolism to constituent individual amino acids</li> </ul>	<ul style="list-style-type: none"> <li>Injection site reactions</li> <li>Bacterial pneumonia and local site cellulitis</li> <li>Hypersensitivity reaction</li> </ul>	<ul style="list-style-type: none"> <li>Rotate injection sites to minimize reactions.</li> <li>Local reactions may also be minimized by applying heat or ice after injection; alternatively, may gently massage the injection site to better disperse the dose</li> <li>Discontinue if signs and symptoms of hypersensitivity reaction are suspected; seek medical attention immediately.</li> </ul>												
Maraviroc (Selzentry, MVC)	<b>Tablets:</b> 150 mg, 300 mg	<b>Adolescent (&gt; 16 years)/Adult dose:</b> When given with potent CYP3A inhibitors (with or without CYP3A inducers); exception: TPV When given with ENF, NRTIs, RAL, NVP, TPV/r, and no other CYP3A inhibitors or inducers When given with potent CYP3A inducers such as EFV and ETR (without strong CYP3A inhibitor)	<ul style="list-style-type: none"> <li>Use CCR5 tropism assay to determine the feasibility of ARVs.</li> <li>Take with or without food.</li> </ul>	<ul style="list-style-type: none"> <li>Hepatic</li> <li>CYP3A4 substrate</li> </ul>	<ul style="list-style-type: none"> <li>Abdominal pain</li> <li>Cough</li> <li>Dizziness</li> <li>Musculoskeletal symptoms</li> <li>Fever</li> <li>Rash</li> <li>Upper respiratory tract infections</li> <li>Hepatotoxicity</li> <li>Orthostatic hypotension</li> </ul>	<ul style="list-style-type: none"> <li>LF-Ts</li> <li>Blood pressure if taking other antihypertensive drugs</li> <li>Use caution in patients with underlying cardiac disease.</li> <li>Use caution in patients with hepatic impairment.</li> <li>Do not use MVC in patients with creatinine clearance &lt; 30 mL/minute who are also taking other drugs that are potent CYP3A4 inhibitors or inducers.</li> </ul>

ARV = antiretroviral; AUC = area under the curve; AV = antioventricular; BID = twice daily or every 12 hours; BSA = body surface area; CBC = complete blood cell count; CNS = central nervous system; CYP = cytochrome P450; DXA = dual-energy x-ray absorptiometry; EC = enteric coated; ESRD = end-stage renal disease; IV = intravenous; LFT = liver function test; QD = once daily; RT = room temperature; SC = subcutaneous; TID = three times/day or every 8 hours; TIW = three times/week; UGT1 = UDP glucuronosyltransferase 1 family, wt = weight. Information taken from Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection. August 11, 2011. (Reference 28)

Most clinical data for pediatric and adult treatment-naïve HIV-infected patients include three basic regimens: NNRTI-based (two NRTIs and NNRTI), PI-based (two NRTIs and PI), and NRTIs only (three NRTIs). Regimens that are NNRTI or PI based are preferred as initial therapy. Advantages and disadvantages of both NNRTI and PI ARV classes can be seen in Table 5 (Reference 29). Protease inhibitor-based regimens are preferred over NNRTI-based regimens in children younger than 3 years because of superior virologic suppression (References 69, 70). Nonnucleoside reverse transcriptase inhibitor-based regimens include either nevirapine or efavirenz. Efavirenz is commonly used in children 3 years and older. It was shown to be superior to nevirapine as first-line therapy in children and adolescents in Uganda (Reference 71). Unfortunately, there is no efavirenz pediatric formulation for children, limiting its use to those 3 years and older. Nevirapine is available as a palatable liquid formulation and may be an acceptable alternative to lopinavir/ritonavir in children younger than 3 years if they cannot tolerate lopinavir/ritonavir. However, nevirapine should not be used in infants who received nevirapine exposure as part of MTCT prevention (Reference 63). Etravirine is a second-generation NNRTI and can be used in treatment-experienced adolescents 16 years and older. This drug may be effective in patients who may have acquired resistance to efavirenz or nevirapine. Rilpivirine is the most recently approved NNRTI and is indicated for use in treatment-naïve adults.

As previously noted, PI-based regimens are effective for treatment-naïve pediatric patients with HIV. Protease inhibitors are coadministered with ritonavir because of its advantageous pharmacokinetic properties. Ritonavir is referred to as a “booster” because it is a strong CYP3A4 inhibitor that increases the concentrations of the other PIs by prolonging their half-life. Most clinical pediatric data exist for co-formulated lopinavir/ritonavir in infants and children older than 6 weeks. However, no efficacy data exist for comparison of this PI with other PIs in children. Another advantage of lopinavir/ritonavir is its different dosing formulations and its co-formulation with ritonavir. Other PIs include atazanavir, fosamprenavir, and darunavir coupled with low-dose ritonavir for use in children 6 years and older. If patients cannot tolerate ritonavir, the following PIs could be used in special circumstances: unboosted fosamprenavir in children 2 years and older, unboosted atazanavir in children 13 years and older weighing more than 39 kg, or nelfinavir in children 2 years and older. Extensive pediatric data exist for nelfinavir use, but it has varying rates of virologic potency. Studies have also reported correlation between nelfinavir trough concentrations and virologic response in treatment-naïve pediatric patients (Reference 72). For example, for those who had trough concentrations less than 0.8 mg/L, only 29% of children had a virologic response. In contrast, virologic responses were observed in 80% of children who had trough concentrations greater than 0.8 mg/L. Furthermore, the pharmacokinetics of the nelfinavir pediatric powder formulation are extremely variable in children. However, nelfinavir tablets can be dissolved in water or

**Table 5.** Advantages and Disadvantages of NNRTI and PI ARV Classes (Reference 29)

Antiretroviral Class	NNRTIs	PIs
Advantages	<ul style="list-style-type: none"> <li>• Lower pill burden</li> <li>• Convenience of use</li> <li>• Fewer metabolic complications (less dyslipidemia and fat maldistribution) than PIs</li> <li>• PI sparing</li> <li>• Long half-lives</li> </ul>	<ul style="list-style-type: none"> <li>• Virologic and immunologic efficacy well established</li> <li>• Higher genetic barrier to resistance (requires the accumulation of several mutations for class not to work)</li> <li>• Different mechanism of action from NNRTIs (do not act on same enzyme reverse transcriptase as NRTIs)</li> <li>• NNRTI sparing</li> </ul>
Disadvantages	<ul style="list-style-type: none"> <li>• Low genetic barrier to resistance (single mutation can confer resistance to class)</li> <li>• Rare but serious cases of rash and hepatotoxicity</li> <li>• Potential for several CYP450 drug interactions</li> </ul>	<ul style="list-style-type: none"> <li>• Higher pill burden</li> <li>• GI adverse effects</li> <li>• More metabolic complications (dyslipidemia, fat maldistribution, and insulin resistance) than NNRTIs</li> <li>• Potential for multiple CYP450 drug interactions</li> <li>• Poor palatability of liquid formulations, which may reduce adherence potential</li> </ul>

ARV = antiretroviral; CYP = cytochrome P450; GI = gastrointestinal; NNRTI = nonnucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; PI = protease inhibitor.

other liquids to make an ingestible slurry, which showed pharmacokinetics similar to swallowing whole tablets in an adult study (Reference 73). Saquinavir is not recommended in children because of the lack of a pediatric formulation and limited dosing information, although it provides virologic and immunologic outcomes similar to lopinavir/ritonavir in adult treatment-naïve patients (Reference 74). Indinavir is not recommended as initial therapy in children because there is no liquid formulation and it causes a high incidence of hematuria, sterile leukocyturia, and nephrolithiasis (References 75–78). Tipranavir is also not recommended as initial therapy because of limited data but may be considered in treatment-experienced children 2 years and older. Unlike in adults, once-daily dosing of darunavir, fosamprenavir, and lopinavir/ritonavir is not recommended in children because of the potential for increased clearance of these ARVs.

Triple NRTI regimens include zidovudine, lamivudine, and abacavir. These regimens are reserved for special circumstances in patients who are considered long-term nonprogressors and in those who cannot use PI- or NNRTI-based regimens because of significant drug-drug interactions, intolerance, or adherence concerns. An advantage of triple NRTI therapy is the availability of palatable liquid formulations and favorable tolerance. However, this combination has been shown inferior to efavirenz-based regimens in ARV-naïve adults with a higher incidence and earlier time to virologic failure after 48 weeks of therapy (Reference 79). Other triple NRTI combinations are associated with poor virologic response because of the development of resistance to lamivudine (References 80, 81). Tenofovir, didanosine, and lamivudine combinations and tenofovir, abacavir, and lamivudine combinations are not recommended in children because of significantly increased rates of virologic failure in adults (References 82, 83).

Two NRTIs form the backbone of ARV treatment in combination with either a PI or an NNRTI. Six NRTIs are approved for use in children younger than 13 years: didanosine, zidovudine, lamivudine, stavudine, abacavir, and emtricitabine. Preferred dual NRTI combinations include abacavir or tenofovir or zidovudine with either lamivudine or emtricitabine. The most extensive clinical data in children are derived from the zidovudine and lamivudine combination, which is generally well tolerated. In a large retrospective study of children, zidovudine and didanosine showed the lowest toxicity rates (Reference 84). Emtricitabine and lamivudine are both cytosine NRTI analogs and can be substituted for one another. Some advantages of emtricitabine are its once-daily administration, possible coadministration with didanosine as a once-daily dual NRTI combination, and availability as a liquid formulation. However, didanosine requires fasting conditions for optimal

absorption and is recommended only for children who can take it on an empty stomach. Abacavir and lamivudine is a potent dual NRTI combination for children, maintaining significantly better virologic suppression and growth rates (height and weight) than zidovudine and lamivudine or zidovudine and abacavir in 5 years of follow-up (Reference 85). However, a primary limitation of abacavir is the requirement for *HLA-B\*5701* genetic testing before its use because of its association with hypersensitivity reactions. Prevalence of this genotype is more common in whites than in African Americans and Hispanics in the United States (8% vs. 2% to 2.5%). Genetic screening for *HLA-B\*5701* before using abacavir has shown significant reductions in the hypersensitivity reaction from 7.8% to 3.4% (Reference 86). This testing should be done before considering abacavir for treatment of HIV-infected children, and abacavir should not be used in those who test positive for *HLA-B\*5701*. Tenofovir may also be used with lamivudine or emtricitabine, but its preferred use is for HIV-infected adolescents who are 12 years and older in Tanner stage 4 or 5 or who are postpuberty because of the potential for adverse events such as decreased bone mineral density in young children. Other NRTI combinations include zidovudine and abacavir or zidovudine and didanosine. Dual NRTIs (e.g., stavudine with lamivudine or emtricitabine) are recommended only in special circumstances because stavudine is associated with mitochondrial toxicity, which could lead to a higher risk of lipoatrophy and hyperlactatemia than with other NRTIs (References 87–89). A stavudine and didanosine dual NRTI backbone is not recommended because of the higher rates of toxicity observed in adults such as neurotoxicity, pancreatitis, hyperlactatemia and lactic acidosis, and lipodystrophy compared with those taking zidovudine and lamivudine (References 90, 91). Other dual NRTI combinations that are not recommended are abacavir and didanosine, abacavir and tenofovir, and didanosine and tenofovir because of insufficient data in children. Of note, these dual NRTI combinations are not recommended as initial treatment for newly infected HIV-infected adults because of insufficient data and higher rates of resistance with some of the combinations. Furthermore, lamivudine and emtricitabine or stavudine and zidovudine combinations should not be coadministered because of competing pharmacologic activation pathways.

One of the problems in the treatment of HIV-infected children includes the scarcity of data regarding the newer ARVs such as rilpivirine, maraviroc, and raltegravir. These ARVs are not recommended as initial therapy for children because they have been studied and are approved only for treatment-naïve adolescents 16 and older. Furthermore, one of the newer ARVs, etravirine, is only approved for treatment-experienced

adolescents 16 and older. In addition, the NRTI/NNRTI/PI combination and enfuvirtide are not approved for use as initial therapy in children. The risk of using the former combination is the development of multidrug class resistance, thus limiting future treatment options. Enfuvirtide is approved for use in treatment-experienced children 6 years and older in combination with other ARVs, with evidence of continuing viral replication despite current ARV therapy. Some of the main limitations to using enfuvirtide is that it is the only ARV given subcutaneously (twice daily), and local injection site reactions are very common (98%).

If first-line therapy with ARVs fails, defined as having a suboptimal virologic response to the current cART regimen, the etiology of treatment failure must be assessed before considering changes in ARV therapy. Treatment failure in many cases could be multifactorial; some of the most common reasons for treatment failure are inadequate adherence to ARVs, drug intolerance, pharmacokinetic variability and drug-drug interactions, or the presence of drug-resistant virus. First, adherence to ARVs should be evaluated. Adherence to therapy refers not only to taking medications according to their prescribed schedules, but also to the timing of the doses, food considerations with certain ARVs, and the avoidance of drug-drug interactions, especially given the wide availability of some herbal and over-the-counter products having important interactions with ARVs that could affect treatment response. Adherence plays a key role in the success of a treatment regimen because suboptimal adherence can lead to drug resistance and inadequate virologic control and has been associated with an increased risk of disease progression and mortality (Reference 92). If the patient has not been adherent to current ARVs, reasons for nonadherence should be addressed, and adherence to current ARVs should be reinforced, together with developing strategies to help patients overcome their adherence barriers. Drug intolerance may be one of the reasons for nonadherence to ARVs. If possible, adverse effects should be treated symptomatically, depending on severity. Pharmacokinetics, especially drug metabolism, may differ during puberty, necessitating a reevaluation of drug dosing, because some adolescents may require higher dosing by weight or by body surface area compared with adults. Concomitant drugs should be evaluated for each patient because drug-drug interactions could also be responsible for ARV treatment failure. If the patient has been adherent to ARVs and has not had a timely virologic response, then a genotype may be considered to determine whether the patient developed any resistance to current ARVs. However, if a patient is on a failing ARV regimen and no evidence of resistance is identified on a genotype, then poor adherence should be suspected.

Genotype resistance tests are recommended at baseline before starting ARV therapy. Genotypic assays can detect resistance to ARVs by PCR amplification and analysis of reverse transcriptase and protease coding sequences from a patient's HIV viral load. For these tests to be done, HIV viral load should be greater than 1000 copies/mL. Some of these tests might also be considered if a patient's viral load is between 500 and 1000 copies/mL. A specialist in pediatric HIV infection should be consulted for appropriate interpretation of genotypic results. Furthermore, the International AIDS Society-USA and the Stanford University HIV Drug Resistance Database are two useful resources that compile significant resistance-associated mutations to current ARVs (see [www.iasusa.org/resistance\\_mutations](http://www.iasusa.org/resistance_mutations) or [www.hivdb.stanford.edu](http://www.hivdb.stanford.edu)). For the genotype to accurately reflect whether a patient may have resistance to the current ARV regimen, the patient must have been taking these ARVs within the past 4 weeks (i.e., drug-selective pressure). This is very important because reversion from resistant virus to wild-type virus can occur in the first 4 weeks after ARVs are discontinued. The genotype test should help elucidate which ARVs are still active for the patient. It is also critical to review ARV history as well as all other resistance tests when selecting a new ARV regimen because previous resistance tests may reveal archived resistance not evident on current resistance tests.

Other resistance tests such as phenotypic assays are reserved for those who have developed resistance to previous ARV regimens, especially PIs. These assays are useful in deriving a direct assessment of the effect and interaction of mutations acquired by viral strains on viral replication. Phenotypic assays involve PCR amplification of HIV gene sequences from a patient's viral strain, which are then inserted into a laboratory HIV strain. Replications of this recombinant viral strain at varying ARV concentrations are compared with the replication of a reference or wild-type viral strain. Fold resistance change is reported as the ratio of  $IC_{50}$  (median inhibitory concentration of ARVs needed to inhibit 50% of viral replication) of a patient's viral strain to  $IC_{50}$  of a reference strain. The greater the fold change, the more likelihood of ARV resistance. Two advantages of a genotype over a phenotype are a quicker turnaround time (1–2 weeks vs. 2–3 weeks) and a lower price. Virtual phenotypes are another type of resistance test that predicts the likelihood of a drug-resistant phenotype from a genotype. This test takes the patient's genotype and predicts a phenotype from a large known database of matching genotypes and phenotypes. This test may be insufficient for reliably detecting predictable phenotypes, especially with newer ARV drugs, because there may be fewer matching genotypes and phenotypes available for these drugs.

In addition to resistance testing history, factors to consider in creating a new ARV regimen should include ARV treatment history and toxicities, CD4<sup>+</sup> and viral load trends, adherence potential, and available treatment options. Furthermore, pill size, palatability, pill burden, and dosing frequency should be considered when developing a new ARV regimen. The goal of the new ARV regimen should be complete virologic suppression, ideally using three fully active drugs. If an HIV-infected child were on an NNRTI-based regimen and developed resistance to the NNRTI, a PI-based regimen would be recommended. If a child were on a PI-based regimen and developed resistance to the PI, an NNRTI-based regimen or an alternative PI-based regimen or a combination of an NRTI, an NNRTI, and an alternative PI regimen would be recommended. With respect to using potential NRTIs, special attention should be given to ensure the correct combination is used. For example, some patients can easily develop resistance to either emtricitabine or lamivudine if they are nonadherent to these NRTIs. If the patient has very few other NRTI mutations (especially thymidine analog mutations), using lamivudine or emtricitabine in a future treatment regimen can be advantageous because selection of a common mutation by these drugs could increase susceptibility to concomitant NRTIs such as tenofovir, stavudine, or zidovudine (References 93–95).

CCR5 tropism assays should be considered in adolescents 16 years and older to determine whether maraviroc is a feasible treatment option. Treatment-naïve HIV-infected patients usually have CCR5 (R5) tropic virus. However, a co-receptor switch from CCR5 to CXCR4 (X4) or CCR5 to CCR5 and CXCR4 dual/mixed (D/M) tropic viruses is possible with time, especially in treatment-experienced patients and those who have HIV disease progression. The Trofile (Monogram Biosciences, South San Francisco, Calif.) phenotypic assay is used in the United States to determine CCR5 tropism. This assay usually takes about 2 weeks to report results and requires that the patient's viral load be greater than 1000 copies/mL. Of note, these assays have good sensitivity in detecting X4 or D/M tropic virus, representing up to 0.3% of the patient's plasma virus. Genotypic assays (Trofile DNA) recently became available in the United States, which are useful for detecting mutations associated with X4 or D/M tropic viruses. These assays also have the advantage of being able to be performed in patients with an undetectable viral load. Because maraviroc is a CCR5 antagonist, it is only effective for patients who have R5 tropic virus. Other ARVs such as etravirine and raltegravir are approved for treatment-experienced adolescents 16 years and older. Pediatric trials are under way to explore the

feasibility of these newer ARVs. Should the patient have resistance to efavirenz or nevirapine, etravirine may still retain activity because at least three mutations are needed for this ARV to lose its potency.

Enfuvirtide and dual PI therapy may also be considered in children with extensive treatment resistance. Common dual PI combinations include lopinavir/ritonavir with saquinavir or atazanavir in both adults and children (References 96–101). However, some of the disadvantages of dual PI regimens are poor tolerability (particularly hyperlipidemia) and increased drug-drug interactions. Therapeutic drug monitoring (TDM) may be necessary to determine the appropriateness of target trough concentrations and will be discussed later. If a patient has very limited treatment options, children should be considered for newer therapeutic ARVs in clinical development. Information for clinical trials can be found at [www.aidsinfo.nih.gov/clinicaltrials](http://www.aidsinfo.nih.gov/clinicaltrials). If a patient has extensive treatment resistance, a pediatric HIV specialist should also be consulted, because he or she may have access to unpublished data regarding the efficacy and safety of newer agents approved for adults. Also worth noting, off-label use of newer ARVs in children should be done with caution because the adverse effects of these agents are unknown and may have observable differences in children compared with adults. Furthermore, changing pharmacokinetics in a growing child makes the extrapolation of dosing from adults to children on the basis of body weight or body surface area unpredictable and often may underestimate appropriate pediatric dosing, potentially leading to ARV resistance (Reference 102).

Antiretroviral treatment considerations may be different in certain special populations such as HIV-infected adolescents, HIV-infected women, those with HBV/HIV coinfection, and those with HCV/HIV coinfection. The largest percentage of HIV-infected children in the United States is made up of adolescents. Adolescents who acquire HIV infection sexually or by intravenous drug use follow a clinical course similar to that of adults compared with children, who are perinatally infected with HIV and have a long and complicated treatment history. Dosing of ARVs for adolescents can be complicated by factors such as Tanner staging of puberty and development of fat and muscles, which could influence drug pharmacokinetics. In children, dosing of ARVs may be higher than adult dosing to compensate for faster metabolism and/or higher drug clearance. Therefore, as a patient grows into adolescence, ARV dosing may be higher-than-usual adult dosing. Psychosocial and cognitive development may also present challenges for adolescents regarding adherence to ARVs. Some other challenges may be mood disorders and other mental illnesses that should be addressed adequately to ensure successful adherence to

ARVs. Directly observed therapy may be useful in these situations. The transition from adolescent care to adult HIV care settings can also be complicated and difficult. General guidelines regarding transitional plans and those who may benefit from them are available (References 103, 104).

Human immunodeficiency virus–infected women may have greater risks of certain adverse effects than men. These may include nevirapine-associated hepatotoxicity; lactic acidosis caused by prolonged exposure to NRTIs such as stavudine, zidovudine, and didanosine; and metabolic complications such as central fat accumulation and propensity to osteopenia/osteoporosis postmenopause (References 105–113). However, most of these differences do not require special treatment recommendations at this time. Sexually active females should be encouraged to use effective and consistent contraception methods. Efavirenz should not be used in adolescent girls who are sexually active and not using reliable contraception, or who want to become pregnant, because of the potential for neural tube defects that could occur in the fetus if used in the first trimester. In addition, PIs and NNRTIs may interact with oral contraceptives such as ethinyl estradiol, norethindrone, and norgestimate metabolites (norelgestromin and levonorgestrel) (Reference 29). Nonnucleoside reverse transcriptase inhibitors and boosted PIs are more likely to cause decreases in these oral contraceptives versus unboosted PIs such as atazanavir and fosamprenavir, which may actually increase concentrations. Alternative or an additional contraceptive method should be used in HIV-infected women who are using either NNRTIs or boosted PIs. Depot medroxyprogesterone acetate (DMPA) may also be an effective method of contraception, because some studies have shown unaltered efficacy of DMPA when coadministered with nelfinavir, efavirenz, or nevirapine regimens, as well as no additional adverse effects or significant changes in ARV drug concentrations (References 114, 115). Limited data exist for other forms of contraception such as vaginal rings and transdermal patches, but intrauterine devices have proven safe and effective in HIV-infected women (References 116, 117).

Choice of ARVs for HIV-infected pregnant women may be different from that for nonpregnant women (Reference 118). Initiation of ARV treatment is necessary, regardless of immunologic and virologic parameters, to prevent vertical transmission to the fetus. The goal of therapy is virologic suppression by the time of delivery, when transmission is more likely. Regardless of the antenatal regimen chosen in HIV-positive pregnant mothers, intravenous zidovudine should be administered to the mother during labor, and oral zidovudine should be given to the neonate for 6 weeks. Baseline resistance testing is also recommended before starting

therapy. If the HIV-infected pregnant mother has no ARV resistance from genotypic assay, zidovudine plus lamivudine plus lopinavir/ritonavir should be the preferred ARV regimen. Standard ARV dosing of some PIs such as lopinavir/ritonavir may need to be increased during the third trimester to compensate for reduced bioavailability because of enhanced metabolism and increased clearance during pregnancy. Breastfeeding is also discouraged because of the high risk of transmission. Abrupt discontinuation of ARV therapy for the HIV-infected mother should be done cautiously because certain ARVs such as NNRTIs have a long half-life. Some experts recommend discontinuing NNRTIs at least one week before discontinuing other ARVs, and others recommend substituting an NNRTI with a PI plus two other ARVs for at least 30 days to reduce the development of NNRTI resistance (Reference 29).

If an HIV-infected child is acutely infected with hepatitis B virus (HBV) infection, the risk of developing chronic HBV is markedly greater in infants than in older children and adolescents (References 119–121). Very limited data exist for treatment of HIV/HBV-coinfected children. Only standard interferon alfa and lamivudine are FDA approved for treatment of children 2 years and older with chronic HBV. If treatment of chronic HBV is indicated in an HIV-infected adult, treatment of HBV should use fully suppressive cART with agents such as tenofovir and either emtricitabine or lamivudine, regardless of current CD4<sup>+</sup> cell count, and should also be considered in older children. Combination ARV therapy is important in this case to reduce the risk of developing resistance to ARVs. Caution must be used when discontinuing agents for treatment of chronic HBV because this could potentially cause hepatic damage secondary to reactivation of HBV. Furthermore, caution should be used when discontinuing ARVs that have activity against HBV; if this is the case, another active drug for HBV should be used to avoid a potential flare or reactivation of HBV. Alternative treatment strategies for chronic HBV may also include adefovir for older children who can receive adult dosing. Limited data on peginterferon alfa, entecavir, and telbivudine preclude their use in coinfecting children at this time.

The prevalence of hepatitis C virus (HCV) in HIV-infected children is as much as 3.1% in the United States (References 25, 122). Insufficient data exist for both HCV disease progression and treatment of HCV in coinfecting children. Coinfecting adults with chronic HCV have a higher risk of progressing to cirrhosis than do those with HCV infection alone, especially when CD4<sup>+</sup> cell counts are less than 350 cells/mm<sup>3</sup>. If treatment of HCV is indicated, preference is given to those whose CD4<sup>+</sup> cell counts are greater than 200 cells/mm<sup>3</sup> because better immunologic status will likely improve

HCV treatment response (References 123–126). If CD4<sup>+</sup> cell counts are below 200 cells/mm<sup>3</sup>, ARV therapy should be initiated and HCV treatment delayed until CD4<sup>+</sup> cell counts rebound. Because no studies of coinfecting children have been conducted, recommendations are extrapolated from data in adults. Treatment of HCV in coinfecting adults includes pegylated interferon alfa-2a or -2b plus oral ribavirin for 48 weeks regardless of HCV genotype. Combination therapy with interferon alfa and ribavirin for 48 weeks is also recommended in HIV/HCV-coinfecting children who are 3 years and older. Other treatment options for HCV may include the recently approved PIs boceprevir and telaprevir. However, these drugs are not yet approved for treatment of HCV in HIV-infected patients because use of these drugs will be complicated by several drug interactions. In addition, the role of these drugs for children is unclear because monoinfected HCV studies were conducted only in adults. Didanosine, zidovudine, and stavudine should be avoided when using ribavirin because these NRTIs may lead to mitochondrial and hematologic toxicities. Treating both HCV and HIV can result in drug-induced liver injury with substantially elevated liver enzymes; associated ARV agents include stavudine, didanosine, nevirapine, full-dose ritonavir, or tipranavir boosted with low-dose ritonavir (Reference 127). Dose modification or avoidance of some hepatically metabolized ARV agents may be necessary, depending on the severity of liver disease (particularly Child-Pugh class B and C disease). Antiretroviral therapy may be beneficial in patients coinfecting with HCV because it may slow the progression to liver disease and reduce HIV-related inflammation associated with lower CD4<sup>+</sup> cell counts.

## MONITORING OF THERAPY

### Therapeutic Outcomes

Before initiating ARV therapy, several parameters related to laboratory testing and factors that may affect treatment adherence should be assessed at baseline. Laboratory testing should include CD4<sup>+</sup> count and CD4<sup>+</sup> percentage, HIV viral load, serum chemistries, lipid panel, hematologic panel, resistance testing (in some cases, it may be prudent to initiate therapy before resistance testing, with the understanding that therapy may require modification upon the availability of those results), and any other laboratory parameter that may be affected by the choice of ARV regimen. After ARV therapy is initiated or changed, HIV-infected children and adolescents are monitored for the regimen's efficacy, safety (toxicity, adverse effects), tolerability (medication palatability, dosing frequency, pill burden), and adherence to the regimen. For patients on ARV therapy, the following laboratory parameters are recommended for

monitoring at baseline; at 4–8 weeks; and then every 3–4 months once stable: CD4<sup>+</sup> count, CD4<sup>+</sup> percentage, HIV viral load, complete blood cell count with differential, and serum chemistries. A lipid panel may be drawn every 6–12 months. More frequent monitoring of HIV surrogate markers may be required for patients who are experiencing virologic, immunologic, or clinical failure.

When monitoring the efficacy of ARV treatment, some patients may not have positive CD4<sup>+</sup> and viral load trends. If this occurs, treatment failure may be considered and can be classified as virologic, immunologic, or clinical. Virologic failure may be defined as either not achieving viral suppression or the occurrence of viral rebound after viral suppression. An incomplete virologic response in children is defined as less than a 1-log decrease in viral load from baseline after 8–12 weeks of ARV therapy, a viral load above 400 copies/mL after 6 months of treatment, or a detectable viral load after 12 months of treatment (optimal viral suppression is less than 20–75 copies/mL, depending on the sensitivity of the assay used). Viral rebound is defined by repeated detectable viral loads after a period of viral suppression. Repeated viral loads greater than 1000 copies/mL are indicative of virologic failure in children (Reference 28).

Assessing immunologic response in children is difficult because of the variability in CD4<sup>+</sup> count that occurs in children younger than 5 years. For this reason, CD4<sup>+</sup> percentage (which has less variability) is considered a more reliable measure of immune status in children younger than 5 years. For older children, the absolute CD4<sup>+</sup> count may be used for monitoring immunologic status.

Immunologic failure may be classified as an incomplete response to ARV treatment or as continued immunologic decline. An incomplete response to treatment is characterized differently on the basis of age. For patients younger than 5 years, it is described as not achieving an increase of 5 percentage points or more in CD4<sup>+</sup> levels in those presenting with a CD4<sup>+</sup> percentage less than 15. For patients 5 years and older, it is described as failing to increase CD4<sup>+</sup> levels by 50 cells/mm<sup>3</sup> or more over baseline within the first year of therapy in those presenting with CD4<sup>+</sup> counts less than 200 cells/mm<sup>3</sup>. Patients with low pretreatment CD4<sup>+</sup> counts are at greater risk of experiencing a blunted immunologic response despite virologic suppression. In addition, some ARVs or ARV combinations may contribute to a suboptimal immunologic response (ex. myelosuppression related to zidovudine therapy; the combination of tenofovir and didanosine has been associated with a decline in CD4<sup>+</sup> count; therefore, their concomitant administration is not recommended). Immunologic decline is characterized as a steady decrease

of 5 percentage points in CD4<sup>+</sup> percentage below baseline, regardless of age, or as a decrease in CD4<sup>+</sup> count to below baseline levels in children 5 years and older (Reference 28).

Clinical failure may be identified through the presence of opportunistic infections or disease progression. However, it is important to consider a patient's immunologic and virologic status in the presence of clinical symptoms because those symptoms may not necessarily represent treatment failure. Factors in disease progression that can represent treatment failure in children include failure to grow at a normal rate even when nutritional requirements are met, recurrent infections that may be indicative of progression to AIDS, and impairment in cognitive and motor skills development (Reference 28).

When assessing treatment failure in HIV-infected children, several factors should be considered before modifying ARV therapy. Some of these include pharmacokinetic variability, drug toxicity, and ARV resistance. However, one of the most significant factors affecting treatment outcome is adherence to ARVs. Low rates of adherence to ARVs have been linked to virologic failure, with that risk increasing as more ARV doses are missed. Low adherence rates can also increase the risk of developing ARV resistance, with the potential for cross-resistance if mutations continue to accumulate while a patient is on a suboptimal regimen. This, in turn, could limit future treatment options. On the contrary, high adherence rates are associated with viral suppression, low rates of drug resistance, increased survival rates, and improved quality of life. Although a 95% adherence rate has historically been desired to achieve and maintain virologic suppression, it is possible to do so with lower rates, depending on the medications used for treatment, including some boosted PI-based regimens and those containing efavirenz plus two NRTIs (References 27, 128). It is difficult to predict high or low adherence rates in children because not only do they have their own adherence barriers to overcome, but they may also have to deal with any adherence barriers their own caregivers introduce. Factors that influence adherence rates may include the following: frequency of dosing, pill burden, ARV palatability, refusal of ARVs, forgetfulness, no established daily routine, ARV-related adverse effects, and psychosocial issues (financial concerns, housing stability, transportation limitations, social/familial support, stigma, psychiatric disorders, and active substance abuse) (References 28, 92). In hospitalization cases, it is important that the medical team be in contact with the patient's ambulatory HIV care provider to maintain appropriate HIV treatment (correct medications and doses), ensure continuity of care, recognize the potential for drug-drug interactions with ARVs (e.g., PIs and NNRTIs are

metabolized extensively through the CYP system), and discharge patients on appropriate therapy for HIV and any comorbid condition to maximize therapeutic benefit and minimize adverse events.

Children must depend on their caregivers to administer their drugs appropriately; therefore, any adherence barriers that affect the caregiver may also directly affect the success or failure of the child's treatment regimen. Caregivers may struggle with the decision to disclose a child's status to family or friends, which may lead to disguising or hiding prescription labels, not refilling medications in a timely manner, and skipping doses when away from the home. Furthermore, in vertical transmission, parents may have feelings of guilt or regret and seek to avoid reminders of their own HIV status (Reference 28).

Adherence to ARVs in HIV-infected adolescents may be influenced by various factors. These patients are very concerned with being perceived as different from their peers, and they may refuse to take their ARVs. They may skip doses to avoid disclosing their status to their peers. In vertical transmission, many adolescents have been taking ARVs for several years, and it is not unusual for them to experience pill fatigue. Instability in the home, mental health issues, neurocognitive delay, and active substance abuse may also negatively affect a patient's ability to remain adherent to a drug regimen. Educating patients, as well as caregivers, on the need to maintain a consistently high rate of adherence to the ARV regimen for achieving therapeutic goals and to avoid the development of drug resistance and providing them with strategic tools to help overcome adherence barriers are essential to achieving therapeutic goals, avoiding medication errors, and empowering patients to take control of their health care.

Because many of the adherence barriers previously described are perceived by patients and caregivers as of more immediate concern than taking their ARVs consistently, it is essential to work with them to overcome these barriers. Although studies of the adolescent population have used technology, peer support groups, and motivational interviewing techniques to improve adherence and virologic outcomes, their positive effects have been short-lived (References 129, 130). Several strategies may still be employed by the health care team to help patients/caregivers attain a higher rate of adherence to ARVs. Some of these may include using a multidisciplinary approach to care, providing referrals for specialty services (medical and/or social), maintaining effective communication/follow-up, assessing adherence rates/barriers at each medical visit, and providing adherence tools (pillboxes, visual aids) to the patients. Antiretroviral regimens should be tailored to a patient's lifestyle with respect to dosing frequency, tolerability profile (e.g., potential adverse effects, drug interactions),

and the patient's daily routine. Educating both patients and caregivers on the importance of ARV adherence, working with them to establish a plan to manage potential adverse effects of ARVs, identifying adherence barriers and the reasons behind them, and encouraging a reliable support system are critical for optimizing adherence to ARVs (Reference 92).

### Therapeutic Drug Monitoring

Therapeutic drug monitoring looks at drug concentration measurements to determine appropriate drug dosing to minimize adverse effects while achieving/maintaining positive treatment outcomes. Therapeutic drug monitoring is typically employed as a therapeutic management strategy, with medications used to treat seizures, heart arrhythmias, and bacterial infections. Because of inter-patient variability in plasma concentrations of certain NNRTIs and PIs, low plasma concentrations of ARVs that can lead to decreased treatment response, and high concentrations that can lead to toxicities for certain ARVs, TDM may occasionally be employed in the therapeutic management of pediatric patients with HIV. However, there are insufficient data that correlate TDM with positive changes in virologic or clinical outcomes. Furthermore, definitive therapeutic ranges for maximizing clinical response and minimizing adverse effects are not well established for all ARVs, and few laboratory facilities within the United States are adequately equipped to perform TDM with ARVs. Although not recommended for routine use in HIV management, TDM may be useful in the following instances: as a tool to help explain a suboptimal treatment response; for a drug-resistant virus—comparing drug concentration with virus susceptibility; for medication administration issues—crushing/chewing/dissolving a medication may change the pharmacokinetics of a drug, dietary habits may alter a medication's pharmacokinetic profile, and incorrect dosing may occur because of administration errors by caregivers; for problems related to adherence that lead to low plasma concentrations of ARVs such as missed doses or inconsistent dose timing; as a tool for identifying drug toxicity that may be caused by an agent exceeding the normal therapeutic range; and for identifying drug interactions—many ARVs have significant interactions with other medications and/or food that could lead to altered plasma concentrations (References 28, 29).

### Adverse Effects

Table 4 summarizes common adverse effects of ARVs and their management as well as relevant monitoring parameters. Class-related adverse effects of NRTIs include lactic acidosis and hepatic steatosis. These are commonly representative of prolonged stavudine,

didanosine, or zidovudine use. Lactic acidosis is characterized by fatigue, weakness, myalgia, weight loss, and unexplained nausea or vomiting. Although it is rare, some patients present with acute organ failure such as fulminant hepatic, pancreatic, and respiratory failure. Blood lactate concentrations are considered in those with clinical signs and symptoms consistent with lactic acidosis. If lactic acidosis and hepatic steatosis occur with stavudine, zidovudine, or didanosine, switching to tenofovir or abacavir with either emtricitabine or lamivudine may be appropriate because these agents tend to have less mitochondrial toxicity. Some physicians will use an NRTI-sparing regimen, when possible, if the lactic acidosis is severe. Facial or peripheral lipoatrophy is also commonly associated with thymidine analog NRTIs such as stavudine and zidovudine, as well as didanosine. Lipoatrophy is manifested as a loss of subcutaneous fat in the face, buttocks, and extremities. If lipoatrophy is present, switching from zidovudine or stavudine to another NRTI that has less mitochondrial toxicity and is active against HIV may help reduce further progression of lipoatrophy. Diminished bone density (osteopenia and/or osteoporosis) is also a possible adverse effect with tenofovir, stavudine, or PIs. Monitoring should include serum 25-hydroxyvitamin D concentrations and DXA (dual-energy x-ray absorptiometry) scans. Appropriate management may include sufficient calcium and vitamin D supplementation and avoidance of steroids and medroxyprogesterone, if possible. The role of bisphosphonates in children is not established, but considering ARVs other than tenofovir, stavudine, or PIs may reduce the incidence of osteopenia and osteoporosis.

Class-specific adverse effects of PIs include dyslipidemia, hyperglycemia, prolonged PR interval (first-degree symptomatic atrioventricular block), fat maldistribution, increased bleeding episodes in patients with hemophilia, elevated liver enzymes, and gastrointestinal intolerance such as diarrhea. Lipodystrophy and central lipohypertrophy are mostly associated with PIs. These may manifest as central fat accumulation in the abdomen, trunk (gynecomastia), or back of neck (buffalo hump). Lipodystrophy is more common in adolescents than in children. Lifestyle modification including exercise and diet or using other ARVs may help with the management of central lipohypertrophy. Of note, liposuction, metformin, and rosiglitazone are not useful for treatment in children. Tesamorelin was recently approved for treatment of lipodystrophy in HIV-infected adults, but efficacy and safety have not been established in children. Effects of PIs on dyslipidemia are related to ritonavir dosing; higher ritonavir doses lead to worsening effects of dyslipidemia, especially hypertriglyceridemia. For PI use, the following should be monitored routinely: lipid panel (total

cholesterol, triglycerides, LDL-C [low-density lipoprotein cholesterol], and HDL-C [high-density lipoprotein cholesterol]), blood glucose, and liver enzymes. If triglycerides are greater than 500 mg/dL, the risk of pancreatitis is increased. Although fibrates are only approved for adults, one study showed that fibrates significantly decreased triglyceride levels among children in clinical practice (Reference 131). Primary pharmacologic interventions used for the treatment of dyslipidemia in HIV-infected children include fish oils and some statins. Fish oils containing PUFAs (n-3 polyunsaturated fatty acids) may be considered, as well as pravastatin 20 mg once daily for children 8–13 years of age and 40 mg once daily for adolescents 14–18 years of age, atorvastatin 10–20 mg once daily for children older than 6 years, and rosuvastatin 5–20 mg once daily for those 10–17 years of age (Reference 28). Dyslipidemia should be appropriately treated with drugs, when necessary, or switching to alternative ARVs, which have less effect on dyslipidemia. Caution should also be used when taking ARVs with certain statins because drug-drug interactions are possible. Lovastatin and simvastatin are contraindicated with PI use. Protease inhibitors should also be used with caution in those with preexisting cardiac conduction problems or those taking other drugs such as calcium channel blockers,  $\beta$ -blockers, digoxin, and verapamil because these are known to prolong the PR interval. Rash is also possible with some of the PIs, especially with fosamprenavir, tipranavir, and darunavir, which possess a sulfonamide moiety. Mild to moderate rash can be treated with antihistamines with continuation of ARVs. For patients who develop a severe rash such as Stevens-Johnson syndrome, all ARVs should be discontinued. The FDA recently issued a new warning for labeling for lopinavir/ritonavir regarding a serious health problem reported in premature babies receiving lopinavir/ritonavir oral solution (Reference 132). The oral solution contains alcohol and propylene glycol; premature babies have a decreased ability to eliminate propylene glycol, which has led to adverse events such as serious heart, kidney, or breathing problems.

Class-related adverse effects of NNRTIs include rash and elevated liver enzymes. Limitations for efavirenz use include central nervous system adverse effects such as fatigue, insomnia, vivid dreams, depression, suicidal ideation, poor concentration, and agitation. If any of these adverse effects occur, they are usually transient and should subside after 2–4 weeks. Some patients, particularly African Americans, may have a genetic polymorphism in the CYP2B6 enzyme, which could exacerbate the adverse effects of efavirenz (Reference 133). If a patient has underlying depression or other preexisting psychiatric conditions, caution should be used when considering efavirenz because it could exacerbate or

worsen depression. Of note, efavirenz is the only ARV with a pregnancy category D rating, which assumes potential teratogenicity to the fetus should efavirenz be used during the first trimester of pregnancy. Efavirenz is not recommended in adolescent females who are sexually active and may become pregnant unless reliable contraception is used. Major limitations for nevirapine use in children are higher rates of toxicity, which may include rare cases of hypersensitivity reactions including Stevens-Johnson syndrome and life-threatening hepatitis. Hepatic toxicity tends to be less common in children than in adults who receive chronic nevirapine (References 134, 135). Rash and elevated liver enzymes occur more commonly in females than in males, and nevirapine should not be initiated in women whose CD4<sup>+</sup> cell counts are greater than 250 cells/mm<sup>3</sup> or in men whose CD4<sup>+</sup> cell counts are greater than 400 cells/mm<sup>3</sup> because of the increased risk of liver toxicity observed when nevirapine is initiated above these CD4<sup>+</sup> cell thresholds (Reference 136).

The severity of adverse effects experienced with ARVs determines whether these medications are discontinued. Some mild or moderate adverse effects of ARVs such as diarrhea or mild rash can be treated symptomatically without discontinuation or substitution of ARVs. However, some adverse effects may be more severe and necessitate a change in ARV therapy. If the responsible ARV agent can be identified, caution should be taken to make sure that an active ARV is substituted. Careful attention should be given to history of treatment with ARVs and resistance testing when selecting an alternative ARV. If adverse effects are severe or life threatening, all ARVs should be discontinued at the same time. Once the patient is stabilized, implementation of a completely new ARV regimen that does not include the prior offending agent should be considered.

## CONCLUSIONS

The availability of newer ARV agents and new research on the progression of disease and the efficacy and safety of treatment modalities will continue to affect the management of HIV infection in the pediatric and adolescent populations. It is important to consider a patient's individual characteristics (e.g., past ARV exposure, resistance profile, comorbid conditions, additional drug therapy, family/social situation) when determining an appropriate initial or modified treatment regimen to maximize effect and minimize adverse events. The treatment of HIV infection in children and adolescents is not simplistic, and a specialist in this field should be consulted when necessary.

## CLINICAL CAVEATS FOR PEDIATRIC HIV INFECTION

- Since the development of the first PI in the mid-1990s, potent combination ARV therapy has transformed HIV infection from a death sentence to a chronic disease state.
- HIV-infected children are living longer and are able to experience a better quality of life because of an armamentarium of newer ARVs that are more potent, convenient, and tolerable.
- One of the best ways to prevent HIV transmission is to use safe sex practices such as condoms (especially important for adolescent population).
- Early initiation of ARV therapy leads to improved virologic, immunologic, and clinical outcomes.
- Many factors must be considered when initiating ARV therapy in children from both the medical and psychosocial standpoint, including appropriateness of certain medications for particular age groups, regimen complexity and palatability, adherence barriers, and issues affecting caregivers.
- Adherence to ARVs should be assessed and evaluated at every chance because this is critical to ensure positive treatment outcomes.
- Treatment failure can be multifactorial; most common reasons are nonadherence to ARVs, drug intolerance, pharmacokinetic variability, drug-drug interactions, or the presence of drug-resistant virus.
- An interdisciplinary health care team approach including physicians, pharmacists, nurses, social workers, dietitians, and others is essential in optimizing care for HIV-infected children.

# CHAPTER 43

## PARASITIC INFECTIONS IN PEDIATRICS

Tracy M. Hagemann, Pharm.D., FCCP, FPPAG

### LEARNING OBJECTIVES

1. List the most common types of parasitic infections seen in the United States.
2. Identify complications in children who are infected with parasites.
3. Describe the routes of infection of parasites in children.
4. List preventive steps for avoiding parasitic infections.
5. Identify two options for prophylaxis of malaria in children.
6. Discuss treatment options for malaria infection in children.
7. Identify routes of infection of toxoplasmosis in children.
8. List effective therapies for ascariasis and enterobiasis.
9. Explain the transmission, etiology, and epidemiology of lice and scabies.
10. Explain the differences in pharmacologic versus nonpharmacologic treatment plans for lice.

### ABBREVIATIONS IN THIS CHAPTER

CDC	Centers for Disease Control and Prevention
FDA	U.S. Food and Drug Administration
HIV	Human immunodeficiency virus
O&P	Ova and parasites
PCR	Polymerase chain reaction

For coverage of cryptosporidiosis, see the *Infectious Diarrhea* chapter.

### INTRODUCTION

Parasitic infections, which are common worldwide, are associated with significant morbidity and mortality. The greatest impact of these infections is seen in developing countries in Central and South America, Africa, and Asia (Reference 1). In the United States, those likely to become infected are immigrants and travelers from endemic countries, as well as individuals with immunocompromised conditions such as AIDS (acquired immunodeficiency syndrome).

Parasites are seen more often in areas where sanitation is suboptimal, and they are spread through contact with food or water contaminated with fecal matter. However, other routes of transmission include contact with infected dirt, contaminated freshwater, or an insect vector, such as a mosquito bite. Although rare, transmission may also occur through blood transfusion, by sharing of infected needles, or congenitally from mother to baby.

A parasite lives in or on another species (the host) to survive, using the host for food, water, or shelter. Parasites may infect their host by being ingested or through the external surface. Some parasites will require several hosts of different species to complete their life cycles. Parasites typically cause some degree of injury to the host. The extent of injury depends on factors such as parasite load as well as on the nutritional status and immunologic competence of the host. Parasitic infections in children may lead to malnutrition and stunted growth and development, especially chronic infections in the gastrointestinal tract (References 2, 3).

Parasites are defined as eukaryotic unicellular or multicellular microorganisms. They are usually classified into two groups: single-celled protozoa and multicellular helminthes, including worms. Protozoa that multiply in their human hosts may increase in number to cause overwhelming infection. By contrast, helminthes have life cycles that are more complex and that typically involve substantial time outside their human hosts. As they migrate through tissue, they may cause systemic reactions. This chapter will focus on parasitic infections most commonly seen in children in the United States and will be divided into three main sections: (1) protozoa, both gastrointestinal and systemic; (2) helminthes; and (3) ectoparasites, including lice and scabies.

### GASTROINTESTINAL PROTOZOA

#### *Giardia*

Giardiasis is caused by *Giardia intestinalis*, also known as *Giardia lamblia* and *Giardia duodenalis*. Humans, as well as domesticated animals and wildlife, can be infected with *Giardia*. The most common animal reservoirs include beaver, cattle, dogs, rodents, and bighorn sheep (Reference 4). This flagellated protozoan is the most common intestinal parasitic cause of enteritis worldwide and the second most common in the United States: in 2009, there were 19,399 cases reported to the Centers for Disease Control and Prevention (CDC)

(References 5, 6). Children aged 1–9 years are considered a high-risk group, and they may transmit the infection to their caregivers (Reference 6). Each year, there is a seasonal variation, with spikes of cases seen in the United States between June and October.

*Giardia* is transmitted by the fecal-oral route; thus, the incidence is higher in populations with poor sanitation. It may also be contracted through close contact with infected individuals (Reference 5). *Giardia* cysts are ingested through fecally contaminated sources, often water, but they may be ingested through fecal-oral transmission. *Giardia* is resistant to the chlorine levels in normal tap water. Because *Giardia* survives well in cold mountain springs for extended periods, giardiasis often occurs in those who camp, backpack, or hunt; it has been called “backpacker’s diarrhea” or “beaver fever” (Reference 5). The relative infectious dose is small; as few as 10–25 cysts may cause infection in humans (Reference 5). Once the cysts are ingested, they are activated in the acidic environment of the stomach, where they produce two trophozoites. These trophozoites migrate to the duodenum and proximal jejunum, attach to the mucosal wall, and replicate. This results in malabsorption, dyspepsia, and diarrhea. Trophozoites can transform into cysts and pass back into the feces, where they are excreted. They can remain actively infectious for months in a moist environment (References 5, 6).

Clinical presentation can vary between individuals, but it typically includes symptoms of diarrhea, abdominal cramps, bloating, weight loss, and malabsorption that may have had a gradual onset and lasts for 2–4

weeks (References 5–7). An incubation period of 1–2 weeks will typically precede symptoms. Chronic giardiasis may develop after the acute infection if not treated appropriately. Symptoms of chronic infection vary but may include loose stools, steatorrhea, malabsorption, weight loss of 10% to 20%, fatigue, and malaise that may last for months (Reference 5). Some patients exhibit rash as part of a sensitivity reaction.

Because *Giardia* infection is noninvasive, the gold standard for diagnosing giardiasis is stool studies for ova and parasites (O&P). Cyst excretion can be found in both formed and loose stools, whereas trophozoites are mostly found in diarrhea. Examination of a single stool specimen has a sensitivity of 50% to 70%, but the sensitivity increases to 85% to 90% with the use of three serial stool samples (Reference 7). Fecal immunoassays, such as direct fluorescent antibody testing, are very sensitive and specific and may be used to confirm diagnosis (References 8–11).

The treatment goal in *Giardia* infections is to eradicate the organism, which will resolve the diarrhea, malabsorption, and other symptoms. The drug of choice is oral metronidazole, administered three times/day for 5–7 days (Table 1). Typical cure rates with metronidazole range from 80% to 95% (References 7, 14). In pediatric patients too young or unable to swallow a tablet, a liquid preparation may be required; however, there is no commercially available preparation. Metronidazole suspension can be extemporaneously compounded; however, the taste of these preparations is often foul, and some children will not tolerate it. An alternative

**Table 1.** Medications for *Giardia* Infections (References 15, 51)

Medication	Pediatric Dosage (Oral)	Dosage Forms	Common Adverse Drug Reactions	Comments
Albendazole	10 mg/kg/day once daily for 5 days (max dose 400 mg/day)	Tablet: 200 mg	Abdominal pain, nausea, headache	Tablets may be crushed or chewed.
Metronidazole	15–30 mg/kg/day in divided doses every 8 hours for 5–7 days (max dose 750 mg/day)	Capsule: 375 mg Tablet: 250 mg, 500 mg	Nausea, headache	May compound oral suspension 50 mg/mL (Reference 12)
Nitazoxanide	Children 1–3 years: 100 mg every 12 hours for 3 days Children 4–11 years: 200 mg every 12 hours for 3 days Adolescents ≥ 12 years: 500 mg every 12 hours for 3 days	Suspension: 100 mg/5 mL Tablet: 500 mg	Abdominal pain, diarrhea, nausea, headache	Store reconstituted suspension at room temperature. Discard unused portion after 7 days.
Tinidazole	50 mg/kg once (max dose 2 g)	Tablet: 250 mg, 500 mg	Nausea, altered sense of taste	Only in children > 3 years Oral suspension 67 mg/mL can be compounded (Reference 13) Take with food.

product, nitazoxanide, is U.S. Food and Drug Administration (FDA) labeled for the treatment of *Giardia* infections in both pediatric and adult patients and is commercially available in both tablet and suspension formulations. Nitazoxanide should be administered every 12 hours for 3 days, and it may be taken with food to minimize gastrointestinal upset. Other alternative products include albendazole, an antihelminthic, and tinidazole. Albendazole has been shown to be as effective as metronidazole in treating *Giardia* infections in pediatric patients (Reference 15). This is a good option in children with mixed helminth and *Giardia* infections. A single dose of tinidazole may be more effective than metronidazole or albendazole in children older than 3 years; however, like metronidazole, tinidazole is not commercially available as an oral liquid preparation and will need to be extemporaneously compounded.

Patients being treated for giardiasis should be monitored for resolution of symptoms, including reduction in diarrhea, resolution of bloating and abdominal cramps, and improved oral tolerance. It is especially important to monitor for signs and symptoms of dehydration and weight loss in children and to initiate oral rehydration as necessary. Diarrhea may begin to resolve in a few days but can take as long as 1–2 weeks for full resolution. Some patients may develop post-*Giardia* lactose intolerance and will improve with the institution of a lactose-free diet. Patients who appear unresponsive to treatment should be evaluated for possible reinfection or antibiotic resistance. Patients with reinfection who initially received a course of metronidazole should receive a second course of 5–7 days, or they may be treated with one of the alternative medications. Patients with true antibiotic resistance should be treated with an alternative medication (Reference 15).

Strategies for preventing giardiasis include proper and frequent handwashing and use of proper sewage disposal and water treatment. In endemic areas, ingestion of bottled water is preferred to consumption of tap water or from freestanding bodies of water. In day care settings, proper disposal of diapers, as well as exceptional handwashing techniques when changing soiled diapers, should be employed. When intake of potentially contaminated water is necessary, giardiasis may be prevented by boiling water for 1 minute (at altitudes higher than 6562 ft, boil for 3 minutes), heating water to 158°F (70°C) for 10 minutes, using portable camping filters, or using iodine purification tablets in potable water (Reference 16).

### Amebiasis

*Entamoeba* are nonflagellated protozoa that are ubiquitous worldwide, but they do not typically cause pathogenic diseases in human hosts. The exception is *Entamoeba histolytica*, which causes amebic colitis and

liver abscess. *E. histolytica* is most prevalent in tropical and developing countries (Reference 10). Worldwide, about 10% of the population is infected, 90% of whom are asymptomatic (Reference 4). Of the 10% who are symptomatic, there are around 100,000 deaths annually, making *E. histolytica* the world's second leading cause of protozoan-related death after malaria (Reference 6). Most cases in the United States occur in travelers returning from endemic countries or in recent immigrants from Mexico, India, West and South Africa, and parts of Central and South America. In the United States, the prevalence of amebiasis is about 4% of the general population (Reference 17). Infection is common in individuals with compromised immune systems (Reference 6). Transmission is by the fecal-oral route and is increased by crowding and poor sanitation.

The infective cysts of *E. histolytica* are ingested and hatch into trophozoites in the small intestine, where they continue through the digestive tract to the colon. Some of these trophozoites become cysts that are passed into the feces; after they are excreted, they can survive for months in a moist environment, like *Giardia*. However, trophozoites can also invade the intestinal mucosa and produce flask-shaped ulcers in the submucosa; they may spread to the liver, lungs, and brain through the bloodstream (References 6, 7, 17). The intestinal ulcerations may bleed and lead to colitis within 2–6 weeks of the initial infection (Reference 16). Colitis is followed by weight loss, severe abdominal pain, bloody diarrhea, malaise, and fever. A chronic active infection of *E. histolytica* may mimic the symptoms of inflammatory bowel disease. In disseminated disease, trophozoites penetrate the mucosal wall, enter the liver, and release toxins that cause hepatocyte damage and lead to amebic liver abscesses and periportal fibrosis, usually within 5 months of the initial infection (Reference 6). Amebae are chemotactic, which may lead to a significant leukocytosis with left shift and high temperature. Other objective findings include elevated alkaline phosphatase, liver tenderness, dull pleuritic right upper quadrant pain that radiates to the right shoulder, and hepatomegaly (References 6, 17, 19). Liver abscesses can spread to the lungs and pleura and may rupture into the pericardial, peritoneal, or pleural spaces (Reference 6).

Effective diagnosis relies on a reliable patient history, including any recent international travel, as well as serial stool samples for O&P and an *E. histolytica* stool antigen test (References 6, 17). Because only 10% to 35% of patients with liver abscesses have concomitant gastrointestinal symptoms, magnetic resonance imaging, serology, and liver ultrasonography should be performed if amebic liver involvement is suspected (Reference 17). Biopsy may be needed.

The goal of therapy for amebiasis is to eradicate the parasite by amebicides. However, supportive care may be necessary for 6 months to 1 year as the ulcerations and abscesses resolve and heal (Reference 6). Because of the different manifestations of amebiasis, including invasive liver abscess, intraluminal colitis, or asymptomatic cyst carriage, drug therapy may differ, depending on the type and site of infection. Asymptomatic cyst carriers should receive either oral paromomycin every 8 hours for 7 days or oral iodoquinol every 8 hours for 20 days (Table 2). These treatments have cure rates of 84% to 96% (Reference 20). These agents act only in the lumen of the intestines and are only minimally absorbed by the gastrointestinal tract. The mainstay for invasive amebiasis is oral metronidazole taken three times/day for 7–10 days. Once-daily tinidazole for 3–5 days may be used in children older than 3 years for both localized intestinal and invasive infections. Both erythromycin and tetracycline may be used in patients with contraindications to or intolerance of metronidazole or tinidazole. After completing the treatment course for invasive amebiasis, patients should receive a full course of a luminal amebicide (paromomycin or iodoquinol) to ensure complete eradication (Table 2).

Drug effectiveness should be monitored by resolution of symptoms, and by repeat negative stool examinations after 5–7 days of treatment, at the end of the treatment course, and at 1 month after therapy is completed. Intestinal symptoms will abate within 3–5 days of treatment initiation. Patients with colitis may need a colonoscopy if serial stool samples are negative. Colonoscopy with tissue sample may be able to identify amebiasis in patients with bloody diarrhea if other tests are inconclusive. In invasive disease, serology should be monitored for resolution at end of treatment and 1 month after completion of therapy. Patients with liver abscesses may require repeat imaging, although some radiographic evidence of liver abscesses may persist for up to 1 year after the end of treatment (Reference 20).

Prevention of amebiasis includes the use of proper sanitation to eradicate the carriage of cysts. Travelers to endemic areas should be cautioned to avoid the consumption of unpeeled fruit and vegetables, salads, ice cubes, and untreated water. If bottled water is unavailable, water should be boiled, which will eradicate *E. histolytica* cysts. Water may be disinfected with iodine or bleach solutions and may also be filtered (References 6, 17).

**Table 2.** Medications for Amebiasis Infections (References 15, 51)

Infection Type	Medication	Pediatric Dosage (Oral)	Dosage Forms	Common Adverse Drug Reactions	Comments
Asymptomatic or intraluminal	Iodoquinol	30–40 mg/kg/day divided every 8 hours for 20 days (max dose 1.95 g/day)	Tablet: 210 mg, 650 mg	Pruritis, urticaria, diarrhea, nausea, headache	Tablets may be crushed and mixed with applesauce or chocolate syrup.
	Paromomycin	25–35 mg/kg/day divided every 8 hours for 7 days (max dose 4 g/day)	Capsule: 250 mg	Abdominal cramping, diarrhea, nausea	
Dysentery <sup>a</sup>	Metronidazole	35–50 mg/kg/day in divided doses every 8 hours for 10 days (max dose 2.25 g/day)	Capsule: 375 mg Tablet: 250 mg, 500 mg	Nausea, headache	May need to compound oral suspension 50 mg/mL (Reference 12).
Extraluminal <sup>a</sup>	Metronidazole	35–50 mg/kg/day in divided doses every 8 hours for 7–10 days (max dose 2.25 g/day)		Nausea, headache	May need to compound oral suspension 50 mg/mL (Reference 12).
	Tinidazole	50 mg/kg/day for 3–5 days (max dose 2 g/day)	Tablet: 250 mg, 500 mg	Nausea, altered sense of taste	Only in children > 3 years Take with food. Oral suspension 67 mg/mL can be compounded (Reference 13).

<sup>a</sup>After completion of treatment for dysentery or extraluminal disease, patients should be treated with an intraluminal medication (paromomycin or iodoquinol) to clear the intestinal organisms.

## SYSTEMIC PROTOZOA

### Malaria

Malaria is a significant cause of morbidity and mortality in developing nations worldwide, with around 2 million deaths per year, mostly in children younger than 5 years (Reference 19). Although uncommon in the United States, 1484 cases of malaria in the United States in 2009 were passively reported to the CDC, including four deaths (Reference 22). Most of these cases occurred in individuals who had traveled to endemic areas and did not adhere to chemoprophylaxis guidelines. Most of the other cases were seen in immigrants and visitors from endemic areas. In 2009, 16% of cases in the United States occurred in children younger than 18 years, accounting for 225 children total, mainly between age 2 and 17 years (Reference 22). Most of these infections were attributed to travel to Africa, and only 31% of those infected reported having taken chemoprophylaxis (Reference 22).

Malaria is caused by four different species of the *Plasmodium* parasite: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* (Reference 21). Presentation in humans is similar in all four species and can make it difficult to differentiate during diagnosis, but of these, *P. falciparum* is the most deadly. *P. vivax* and *P. ovale*, though not often fatal, are responsible for significant morbidity in endemic areas and may lie dormant in liver hepatocytes for months to years after exposure (Reference 21). *P. vivax* is endemic to India, Pakistan, Bangladesh, Sri Lanka, and Central America, and it has the greatest burden of disease with a long incubation period but rarely causes severe complications. *P. falciparum* is endemic in Africa, Haiti, the Amazon region, the Dominican Republic, and New Guinea, and infected individuals may progress to life-threatening illness within hours of infection (Reference 23). *P. malariae* has worldwide distribution and often manifests with proteinuria. *P. ovale* infections mainly occur in Africa, and infections are usually less severe and relapse less often; spontaneous recovery is not uncommon (Reference 24).

Transmission of malaria occurs when an infected female *Anopheles* mosquito bites a human host. During the blood meal, the mosquito injects sporozoites of *Plasmodium* spp. into the bloodstream of the victim (Reference 24). These sporozoites travel to the liver, where asexual reproduction of the parasites enters a latent stage that lasts between 8 and 30 days (Reference 21). *P. vivax* and *P. ovale* form dormant hypnozoites that will remain in the liver unless targeted therapy is administered. Without directed therapy to these dormant hypnozoites, a relapsing form of the disease can occur. After the latent stage, merozoites, or daughter cells, are released from

the liver back into systemic circulation. The merozoites infect erythrocytes and begin another asexual reproductive cycle that results in the lysing of the red blood cells within 2–6 days (Reference 21).

Initial presentation of malaria may involve nonspecific symptoms such as fever, chills, malaise, diaphoresis, vomiting, and rigors (References 21, 24). Patients may experience headache, myalgia, abdominal pain, arthralgia, and cyclic shivering and sweating. Anemia and splenomegaly may develop because of the extensive hemolysis seen during the erythrocytic phase of infection. The most severe complications, including hypoglycemia, thrombocytopenia, acute renal failure, heart failure, seizures, and coma, are seen in patients infected with *P. falciparum* because of its ability to invade erythrocytes of all ages, resulting in high levels of parasitemia (Reference 25). Patient groups at highest risk of these complications from *P. falciparum* are children younger than 5 years and pregnant women (Reference 20). Most young children will become restless or drowsy and experience loss of appetite, persistent fever, flulike symptoms, seizures, vomiting, and/or diarrhea (References 26, 27). Typically, young children do not exhibit the cyclic shivering and sweating, but older children may. Neonates who exhibit signs and symptoms of parasitemia within 1 week of birth contract malaria through transplacental transmission and have congenital malaria. They often present with fever and poor feeding in addition to objective findings of anemia, hepatosplenomegaly, and jaundice (References 26, 28).

The gold standard for diagnosing malaria is the detection of parasites on blood smear by light microscopy (Reference 22). Blood smears should be obtained every 12–24 hours on 3 consecutive days; a positive finding indicates infection (Reference 21). Diagnosis of malaria can be difficult in children because only 50% who are infected will have a positive blood smear, even with repeated examinations. Blood antigen capture tests have a high sensitivity and specificity and can produce rapid results. Both DNA and RNA probes as well as polymerase chain reaction (PCR) also have good sensitivity and specificity and may be used to confirm a diagnosis (References 21, 24).

Pharmacotherapy for malaria can be grouped into two categories: chemoprophylaxis for travelers to endemic areas and treatment of the active infection. The goal of chemoprophylaxis is to lessen the likelihood of transmission because no preventive regimen is 100% effective. The goals of care are to quickly and effectively identify the infecting *Plasmodium* spp. and eradicate the infection to avoid complications.

## Prevention

Prevention of malaria infection should consist of a combination of mosquito avoidance measures and chemoprophylaxis. Malarial transmission usually occurs between dusk and dawn in endemic areas, secondary to the feeding habits of the *Anopheles* mosquito. Contact with mosquitos may be reduced by wearing clothes that cover most areas of the body, remaining in well-screened areas, using mosquito bed nets, and using a pyrethroid-containing insect spray in both living and sleeping areas, especially during evening and nighttime hours (Reference 29). Children older than 2 months should have a DEET-containing spray (*N, N*-diethyl-meta-toluamide) of up to 50% applied to exposed parts of the skin when mosquito exposure is expected. The CDC also recommends the use of a permethrin-containing product for application to clothes and bed nets as additional protection (Reference 29).

Before choosing a chemoprophylaxis regimen, several patient-specific factors should be considered, including other medical conditions, concurrent medications, and potential adverse effects of the antimalarial medication (Reference 29). All chemoprophylaxis regimens involve taking a medication before, during, and after leaving the endemic area (Reference 29). It is vital that a thorough assessment of the travel plan with respect to location and any known information on the area's transmission rates and antimalarial drug resistance patterns occur well in advance of departure. An excellent resource on endemic area transmission rates and resistance is the CDC *Yellow Book on Traveler's Health*, which is updated regularly and available online at [wwwnc.cdc.gov/travel/page/yellowbook-2012-home.htm](http://wwwnc.cdc.gov/travel/page/yellowbook-2012-home.htm). Another helpful resource is the World Health Organization International Travel Web site at [www.who.int/ith/en/](http://www.who.int/ith/en/).

All pediatric patients are at high risk of complications and transmission of malaria. Children traveling to endemic areas should be taking prophylactic antimalarial medications (Table 3). Depending on the incidence of drug resistance at the destination, chloroquine and mefloquine are good options. *P. falciparum* is chloroquine resistant in most endemic areas, except for Central America, including Mexico, the Caribbean, and some countries in the Middle East (Reference 29). In areas where *P. falciparum* is resistant, mefloquine is an alternative option. Children traveling to areas where *P. vivax* is predominant may use primaquine, provided they are not G6PD (glucose-6-phosphate dehydrogenase)-deficient (Reference 29). Doxycycline is an option for use in children older than 8 years in chloroquine- or mefloquine-resistant malaria areas (References 21, 29).

Unfortunately, antimalarial drugs available in the United States come only in tablet form, and the taste can be quite bitter. If the child cannot swallow tablets, a compounding pharmacy may be able to produce an appropriate extemporaneous liquid formulation. Alternatively, the caregiver can crush and mix the tablet with a small amount of applesauce or syrup to ensure that the entire dose is delivered to the child.

## Treatment

Treatment strategies depend on the species of malaria, drug resistance patterns in the area where the infection was acquired, age, pregnancy status, and disease severity (Reference 29). Medications used for the treatment of malaria are active against the erythrocyte attack phase. Chloroquine, quinine, quinidine, mefloquine, doxycycline, atovaquone/proguanil, and artemether/lumefantrine are used for treatment. *P. vivax* and *P. ovale* have dormant stages in the liver, and their treatment regimens must include primaquine to eradicate these forms to prevent disease relapse (Table 4).

Children who are exhibiting fever yet able to maintain adequate hydration and nutrition can be treated as outpatients. Acetaminophen can be used for the treatment of fever at 10–15 mg/kg/dose orally every 4–6 hours. Although many children with malaria develop anemia, transfusions with packed red blood cells are rarely needed. Any child with vomiting, signs of dehydration, altered consciousness, convulsions, or difficulty breathing should be admitted to the hospital for treatment and supportive care.

Patients treated with antimalarial therapy should be monitored for resolution of symptoms. Unfortunately, prior malarial infection does not necessarily produce immunity in patients, and research has not yet provided an effective vaccine. Health care providers should stress the importance of prophylactic measures for any travelers to malaria-endemic areas.

## TRYPANOSOMIASIS (CHAGAS DISEASE)

Chagas disease is caused by infection with *Trypanosoma cruzi*, a protozoan parasite carried by Reduviid bugs, which are also known as cone-nosed bugs or kissing bugs because of their propensity to feed at night, usually on an uncovered face (Reference 32). Infection occurs when the bug defecates while feeding, and fecal material containing *T. cruzi* is introduced into the host through the bite or through mucous membranes (Reference 33). Other methods of transmission are blood transfusion, congenital transfer from mother to fetus, or ingestion of food or water contaminated with bug feces (Reference 32). Reduviid bugs live in the wall cracks of houses in rural areas of Central and South America, and it is estimated that 10 million people worldwide are

**Table 3.** Prophylactic Antimalarial Medications (References 15, 21, 29, 52)

Medication	Dosage	Dosage Forms Available	Duration	Common Adverse Drug Reactions
Chloroquine	5 mg/kg base once weekly (max dose 300 mg base)	Tablet: 250 mg (150 mg base), 500 mg (300 mg base)	Start 2 weeks before and continue for 4 weeks after exposure. Suspension (compounded): 15 mg/mL (9 mg base/mL) (Reference 30)	Nausea, abdominal pain, diarrhea, blurred vision
<i>Chloroquine-Resistant Areas</i>				
Atovaquone/ proguanil	5–8 kg: 31.25 mg/12.5 mg once daily 9–10 kg: 46.88 mg/18.75 mg once daily 11–20 kg: 62.5 mg/25 mg once daily 21–30 kg: 125 mg/50 mg once daily 31–40 kg: 187.5 mg/75 mg once daily > 40 kg: 250 mg/100 mg once daily	Pediatric tablet: atovaquone 62.5 mg/ proguanil 25 mg Tablet: atovaquone 250 mg/ proguanil 100 mg	Start 2 days before and continue for 1 week after exposure. Tablet may be crushed or chewed.	Photosensitivity, pruritis, abdominal pain, diarrhea, nausea, changes in liver function, headache, cough
Doxycycline <sup>a</sup>	2 mg/kg once daily (max dose 100 mg/day)	Tablet: 50 mg, 100 mg Capsule: 50 mg, 100 mg Suspension: 25 mg/5 mL Syrup: 50 mg/5 mL	Start 2 days before and continue for 4 weeks after exposure.	Photosensitivity, diarrhea, nasopharyngitis
Mefloquine	≤ 9 kg: 5 mg/kg once weekly 10–19 kg: ¼ tablet once weekly (62.5 mg) 20–30 kg: ½ tablet once weekly (125 mg) 31–45 kg: ¾ tablet once weekly (187.5 mg) > 45 kg: 1 tablet once weekly (250 mg) (max dose 250 mg/week)	Tablet: 250 mg	Start 1 week before and continue for 4 weeks after exposure. Take with food.	Abdominal pain, diarrhea, nausea, vomiting, bradycardia
Primaquine	0.5 mg/kg base once daily (max dose 30 mg base/day)	Tablet: 26.3 mg (15 mg base)	Start 2 days before and continue for 1 week after exposure.	Abdominal pain, nausea

<sup>a</sup>Only for use in children ≥ 8 years.

infected with *T. cruzi* (Reference 15). Most individuals infected with *T. cruzi* in the United States are immigrants from endemic areas of Latin America, but seven vector-borne cases have been reported in the United States since 1995 (Reference 33).

The clinical course of Chagas disease consists of two phases: acute and chronic. The acute phase in adults is mostly asymptomatic, but children are more likely to exhibit a red nodule at the site of inoculation within 1 week of infection (Reference 15). If the inoculation site is the eye, unilateral orbital edema may result, also known as the Romaña sign. This is followed by fever, malaise, hepatosplenomegaly, and lymphadenopathy (References 15, 34). Complications from acute infection

may include myocarditis and meningoencephalitis (Reference 35). The acute phase usually lasts between 4 and 8 weeks, after which the parasitic load drops to undetectable levels, and is then followed by asymptomatic chronic infection (References 36, 37).

Most patients who are infected will never develop symptoms but will remain infected throughout their lives (Reference 37). However, 20% to 30% (mostly adults with long-standing disease) will develop manifestations of chronic Chagas disease, including cardiac aneurysms, megaesophagus, and megacolon. Infected mothers may pass the infection to their infants. In the United States, it is estimated that between 65 and 315 congenital *T. cruzi* infections occur annually (Reference 33). Most infected

**Table 4.** Treatment of Malaria (*P. falciparum* or unidentified species) (References 21, 29, 53)

Medication	Pediatric Dosage (Oral)	Dosage Forms Available	Comments
<i>Chloroquine Sensitive (Uncomplicated)</i>			
Chloroquine	10 mg base/kg, followed by 5 mg base/kg at 6, 24, and 48 hours Total dose = 25 mg base/kg	Tablet: 250 mg (150 mg base), 500 mg (300 mg base)	Do not exceed 600 mg base for first dose and 300 mg base for subsequent doses. Suspension (compounded): 15 mg/mL (9 mg base/mL) (Reference 30) Common ADR: nausea, abdominal pain, diarrhea, blurred vision
Hydroxychloroquine	10 mg base/kg, followed by 5 mg base/kg at 6, 24, and 48 hours Total dose = 25 mg base/kg	Tablet: 200 mg (155 mg base)	Do not exceed 620 mg base for first dose and 310 mg base for subsequent doses. Suspension (compounded): 25 mg/mL (19.4 mg base/mL) (Reference 31) Common ADR: headache, abdominal pain, nausea, corneal disorders
<i>Chloroquine Resistant<sup>a</sup> (Uncomplicated)</i>			
Artemether/ lumefantrine	From 5 to < 15 kg: 1 tablet per dose From 15 to < 25 kg: 2 tablets per dose From 25 to < 35 kg: 3 tablets per dose ≥ 35 kg: 4 tablets per dose	Tablet: 20 mg of artemether/ 120 mg of lumefantrine	3-day treatment totals six oral doses: initial dose, followed by second dose in 8 hours; then one dose twice daily for the next 2 days Common ADR: diarrhea, vomiting, headache, cough, fever
Atovaquone/proguanil	5–8 kg: 2 pediatric tablets daily for 3 days 9–10 kg: 3 pediatric tablets daily for 3 days 11–20 kg: 1 adult tablet daily for 3 days 21–30 kg: 2 adult tablets daily for 3 days 31–40 kg: 3 adult tablets daily for 3 days > 40 kg: 4 adult tablets daily for 3 days	Pediatric tablet: atovaquone 62.5 mg/ proguanil 25 mg Adult tablet: atovaquone 250 mg/ proguanil 100 mg	May cause photosensitivity reactions Common ADR: pruritis, abdominal pain, diarrhea, nausea, changes in liver function, headache, cough
Mefloquine	13.7 mg base/kg for first dose, followed by 9.1 mg base/kg given 6–12 hours after initial dose Total dose = 22.8 mg base/kg (max dose = 1250 mg or 1140 mg base)	Tablet: 250 mg (228 mg base)	Take with food. Common ADR: abdominal pain, diarrhea, nausea, vomiting, bradycardia

(continued)

**Table 4.** Treatment of Malaria (*P. falciparum* or unidentified species) (References 21, 29, 53) (continued)

Medication	Pediatric Dosage (Oral)	Dosage Forms Available	Comments
Quinine sulfate + one of the following: doxycycline, tetracycline, or clindamycin <sup>b</sup>	Quinine: 10 mg/kg every 8 hours for 3–7 days <sup>c</sup> Doxycycline: 2.2 mg/kg every 12 hours for 7 days Tetracycline: 25 mg/kg/day divided every 6 hours for 7 days Clindamycin: 20 mg/kg/day divided every 8 hours for 7 days	Quinine sulfate: capsule 324 mg Doxycycline: tablet: 50 mg Capsule: 50 mg, 100 mg Suspension: 25 mg/5 mL Syrup: 50 mg/5 mL Tetracycline: capsule: 250 mg, 500 mg Clindamycin: capsule: 75 mg, 150 mg, 300 mg Solution (oral): 75 mg/5 mL	Doxycycline and tetracycline should not be used in children younger than 8 years. Common ADR Quinidine: syncope, photosensitivity, rash, diarrhea, nausea, vomiting, loss of appetite
<i>Severe Malaria</i> <sup>c,d</sup> (Complicated)	Intravenous Therapy		
Quinidine gluconate + one of the following: doxycycline, tetracycline, or clindamycin	Quinidine gluconate: 6.25 mg base/kg loading dose IV over 1–2 hours; then 0.0125 mg base/kg/minute infusion for at least 24 hours: once parasite density is less than 1% and patient can take oral medications, change to quinine oral dosing as above <sup>c</sup> Doxycycline: 2.2 mg/kg IV every 12 hours (< 45 kg), or 100 mg IV every 12 hours (≥ 45 kg) for 7 days. Change to oral dosing as above when able. Tetracycline: 25 mg/kg/day orally divided every 6 hours for 7 days Clindamycin: 10 mg/kg IV loading dose, followed by 5 mg/kg IV every 8 hours for 7 days. Change to oral dosing as above when able.	Quinidine gluconate: IV: 80 mg/mL (base 50 mg/mL) Doxycycline: IV: 100 mg of powder for reconstitution Clindamycin: IV: 150 mg/mL	During administration of quinidine, monitor for hypotension, hypoglycemia, and cardiac changes. Doxycycline and tetracycline should not be used in children younger than 8 years. Common ADR Quinidine: syncope, photosensitivity, rash, diarrhea, nausea, vomiting, loss of appetite

<sup>a</sup>Treatment with atovaquone/proguanil, artemether/lumefantrine, or quinine + doxycycline, tetracycline, or clindamycin is equally recommended. Mefloquine should only be used when there are contraindications to the other preferred treatments because of severe neuropsychiatric reactions seen with mefloquine at treatment doses.

<sup>b</sup>Quinine in combination with doxycycline or tetracycline is generally preferred to combination with clindamycin because of better efficacy data.

<sup>c</sup>Infections acquired in Southeast Asia should receive quinine/quinidine for 7 days; all others should continue for 3 days.

<sup>d</sup>Patients with a diagnosis of severe malaria should be aggressively treated with parenteral antimalarial therapy. Intravenous quinidine should be initiated as soon as diagnosis is confirmed. Consultation with a physician experienced in treating malaria and a cardiologist is recommended. Severe cardiac complications with quinidine may require temporary discontinuation of the drug or a decrease in the intravenous infusion rate.

ADR = adverse drug reactions; IV = intravenous(ly)

newborns are asymptomatic, or they may have nonspecific symptoms such as low birth weight, low Apgar scores, prematurity, anemia, or thrombocytopenia (Reference 36). Although serious complications, such as myocarditis, meningoencephalitis, and respiratory disease, are rare in newborns, they carry a high risk of mortality (Reference 36). Before 2007, when widespread blood bank screening in the United States was initiated, it was possible to contract *T. cruzi* from infected donated blood products (Reference 32). From 1993 to 2007, five transfusion-related cases were documented in the United States, all occurring in immunocompromised individuals (Reference 32). Reactivation of disease and symptoms may occur in chronically infected individuals who become immunocompromised (Reference 37).

Diagnosis of acute trypanosomiasis is made through microscopic examination of the blood for the presence of the parasite. Suspected cases of chronic trypanosomiasis infection should be evaluated through serologic testing for antibodies to *T. cruzi*. Because the available assays may yield low sensitivity and/or specificity rates, WHO Chagas experts recommend that each specimen be tested with two types of assays, such as ELISA (enzyme-linked immunosorbent assay), IIF (indirect immunofluorescence), or indirect hemagglutination (References 34, 37).

The goals of therapy for treating acute and congenital *T. cruzi* infections are to reduce disease duration and prevent chronic infection. Two medications have proven efficacy against *T. cruzi*: nifurtimox and benznidazole. Although neither drug is FDA labeled for use in the United States, each may be obtained directly from the CDC under investigative protocols. Drug treatment is always recommended for acute and reactivated *T. cruzi* infections in individuals of all ages, in early congenital infections, and in children younger than 18 years with chronic *T. cruzi* infection (References 32, 37). If treatment is initiated in the acute phase of infection, the parasitologic cure rate is about 85%, and it is about 90% in congenitally infected infants treated in the first year of life (Reference 36). In children younger than 18 years with chronic asymptomatic disease, benznidazole has shown 60% efficacy in attaining cure and appears to slow the development and progression of Chagas cardiomyopathy in chronically infected older children and adults (Reference 36). Benznidazole is typically given for 60 days and nifurtimox for a 90-day course of therapy. In children younger than 12 years, benznidazole should be dosed at 5 mg/kg orally twice daily, and for those 12 years and older, the dose is 2.5–3.5 mg/kg orally twice daily. Common adverse effects include anorexia and weight loss, allergic dermatitis, peripheral neuropathy, and insomnia. Dosing for nifurtimox in children 10 years or younger is 5–6.5 mg/kg orally three times/day; for those 11–16 years of age, 4–5 mg/

kg orally three times/day; and for those 17 years and older, 2.5–3 mg/kg orally three times/day. Common adverse effects of nifurtimox include anorexia, weight loss, nausea, vomiting, headache, dizziness, vertigo, and polyneuropathy. Both drugs are contraindicated in severe hepatic and/or renal disease and in breastfeeding (Reference 37). Treatment efficacy can be assessed through monitoring for the disappearance of *T. cruzi*-specific antibodies, although antibody disappearance may take up to several years in some patients. Treatment failures can be assessed by repeated hemoculture or PCR-based assay (Reference 37).

Preventive measures of infection should include the use of insecticides in the sleeping areas of infested houses. Travelers to endemic areas are rarely at risk, but if they will be camping, sleeping outdoors, or sleeping in houses with poor construction, the use of insecticide-impregnated bed nets is recommended (Reference 37).

## TOXOPLASMOSIS

*Toxoplasma gondii* exists worldwide in animals and birds, although felines are the most common source (Reference 15). Oocytes of *T. gondii* can survive in moist soil for up to 18 months; however, their survival is decreased in dry, extremely cold or hot climates and at higher altitudes. Human infection may occur through the ingestion of food or water that is contaminated with infected cat feces; through the ingestion of undercooked infected animal meats from cattle, sheep, or pigs containing *T. gondii* sporozoites; or congenitally from an infected mother to fetus (References 38, 39). Congenital toxoplasmosis occurs in around 500–5000 newborns per year in the United States (Reference 40). In most cases in children and adults, infection is asymptomatic and will resolve spontaneously without treatment; however, treatment is indicated for pregnant mothers, neonates, and immunocompromised individuals (Reference 15).

Cats become infected with toxoplasmosis by eating infected birds, rodents, or other small animals. Sporozoites, which are eliminated in cat feces, must undergo sporulation to become infectious, which usually takes 2–3 days in temperate climates. Cats may shed 1–100 million sporozoites up to 3 weeks after their first infection. The risk of infection from cat litter boxes may be minimized if the litter is changed daily before this process occurs (Reference 40). Human infection results from ingesting contaminated or inadequately cooked food infected with tissue cysts or sporozoites. It is theorized that flies and cockroaches transport sporozoites to water and food. Once infected, only 10% to 20% of acute infections produce symptoms, of which the most common is lymphadenopathy without fever (Reference 38). Other physical findings may include fever, malaise, myalgia,

hepatosplenomegaly, and lymphocytosis. Toxoplasmosis in immunocompetent individuals is self-limited, though lymphadenopathy may persist for a few months (Reference 38). In immunocompromised hosts, such as those undergoing chemotherapy for malignancy, those with human immunodeficiency virus (HIV), or those who take immunosuppressive medications posttransplant, severe toxoplasmosis can follow acute infection or reactivation of prior infection (Reference 38). Severe toxoplasmosis can lead to complications such as encephalitis, chorioretinitis, myocarditis, or pneumonia. Pregnant women who are infected are of special concern because they may pass the infection to their baby. Infection early in pregnancy may result in fetal demise, miscarriage, or severe congenital effects in the infant, whereas infection in the later stages of pregnancy is more likely to be associated with vertical transmission to the baby (Reference 15). Although most neonates are asymptomatic at birth, symptoms may include fever, microcephaly or hydrocephaly, hepatosplenomegaly, jaundice, chorioretinitis and/or blindness, seizures, intracranial calcifications, myocarditis, strabismus, thrombocytopenia, and an erythroblastosis-like syndrome (Reference 41). The overall mortality rate of congenital toxoplasmosis is around 10%, and newborns with acute symptoms often die within the first month of life (Reference 42).

Toxoplasmosis is diagnosed by the identification of *Toxoplasma*-specific IgG, IgM, or IgA (immunoglobulin G, M, and A) antibodies, either through indirect fluorescent antibody test or enzyme immunoassays. Direct observation of the parasite in biopsy tissue is also diagnostic (Reference 39). In pregnant women, PCR can be performed on amniotic fluid at 18 weeks' gestation (Reference 43).

The treatment goal is to eradicate the rapidly dividing parasitic organisms in acute infection. Treatment may not be needed in patients who are immunocompetent with acute infection because the infection is usually self-limited. Treatment of existing acute infection will not reverse central nervous system damage that is already present, but it may prevent further sequelae. Treatment of infected pregnant women may reduce vertical transmission to the fetus and the frequency of adverse outcomes (Reference 38).

Children who are immunocompetent with toxoplasmic lymphadenopathy should not be treated unless the symptoms are severe because the disease is usually self-limited. Immunocompromised patients should receive a three-drug regimen of pyrimethamine with sulfadiazine plus leucovorin to prevent hematologic toxicity. Patients who are allergic to or cannot tolerate sulfadiazine can use clindamycin instead (Table 5). Alternative therapy with trimethoprim/sulfamethoxazole may be used, but it may not be as active in immunocompromised patients (Reference 38).

Pregnant women with acute toxoplasmosis should receive spiramycin 3 g orally three times daily without food until term or until fetal infection has been documented (Reference 38). If fetal infection is documented after 18 weeks' gestation, the three-drug regimen of pyrimethamine with sulfadiazine plus leucovorin should be initiated and continued until term (References 34, 40). Because pyrimethamine has teratogenic effects, it cannot be used during the first trimester of pregnancy (References 38, 47).

Neonates and infants with congenital toxoplasmosis should be treated for 1 year with pyrimethamine and sulfadiazine plus leucovorin, though treatment practices may vary by neonatal center (References 38, 41). Treatment is generally discontinued when blood tests are negative for *Toxoplasma* antibodies (Reference 41).

Prevention of toxoplasmosis includes proper handwashing techniques, especially for pregnant women and immunocompromised individuals. Hands should be thoroughly washed after handling raw meat and unwashed vegetables and fruits. Cutting boards, dishes, counters, and utensils should be washed in hot, soapy water after contact with raw meat. To limit environmental exposure, gloves should be worn when gardening or coming into contact with dirt or sand because hands may be contaminated with infected cat feces. Cat litter boxes should be changed daily but not by pregnant or immunocompromised individuals. To decrease transmission from cats, they should be kept indoors and fed only canned or dried commercial foods. All outdoor sandboxes should be covered when not in use (Reference 47).

## HELMINTHS

### Ascariasis

Infection with the parasite *Ascaris lumbricoides*, the largest intestinal nematode found in humans, is distributed worldwide, but it is more common in Southeast Asia, Africa, and South and Central America, with more than 1.4 billion individuals infected worldwide (Reference 48). In the United States, 4 million are thought to be infected. Most are immigrants from endemic countries. The southwestern states and those along the Gulf of Mexico were once endemic areas (Reference 49). Although most cases are asymptomatic, morbidity is related to worm burden. Intestinal obstruction is the most common complication, followed by bile duct obstruction, gastrointestinal perforation, peritonitis, and volvulus (Reference 50). Children aged 1–5 years are most likely to have intestinal obstruction, and all children are likely to have malnutrition, leading to growth retardation, cognitive impairment, and poor academic performance (References 50, 51). Some studies have linked *Ascaris* infection with an increased risk of allergic diseases and asthma, although this is controversial (References 51, 52).

**Table 5. Medications for Toxoplasmosis in Pediatrics and Pregnancy (References 15, 38, 47, 56)**

Infection Type	Medication	Dosage (Oral)	Dosage Forms (Oral)	Common Adverse Drug Reactions
Immunocompetent, nonsevere	No treatment needed			
Immunocompromised (not patients with HIV)	Pyrimethamine	2 mg/kg/day for 2 days; then 1 mg/kg/day for 4 weeks (max dose = 25 mg/day)	Tablet: 25 mg Suspension (compounded): 2 mg/mL (Reference 44)	Rash
	Sulfadiazine	50 mg/kg every 6 hours for 4 weeks (max dose = 6 g/day)	Tablet: 500 mg Suspension (compounded): 200 mg/mL (Reference 45)	Rash, abdominal pain, diarrhea, nausea
	Leucovorin	10–25 mg given with pyrimethamine	Tablet: 5 mg, 10 mg, 15 mg, 25 mg Suspension (compounded): 5 mg/mL (Reference 46)	Diarrhea, nausea, stomatitis, fatigue
Alternative	TMP/SMX	TMP 5 mg/kg, SMX 25 mg/kg twice daily for 4 weeks	Tablet: 400 mg SMX/80 mg TMP, 800 mg SMX/160 mg TMP Suspension: 200 mg SMX/40 mg TMP per 5 mL	Rash, urticaria, nausea, loss of appetite
	Clindamycin	5–7.5 mg/kg four times daily (max dose = 1.8 g/day)	Capsule: 75 mg, 150 mg, 300 mg Solution: 75 mg/5mL	Rash, abdominal pain, diarrhea, nausea
Acute toxoplasmosis in pregnancy	Spiramycin	3 million units (1 g) every 8 hours	Not commercially available in United States: may obtain through FDA with an IND, after consultation <sup>a</sup>	Rash, abdominal pain, nausea, blurred vision
Fetal infection after 18 weeks' gestation	Pyrimethamine	50 mg twice daily for 2 days; then 50 mg once daily to term	Tablet: 25 mg Suspension (compounded): 2 mg/mL	Rash
	Sulfadiazine	37.5 mg/kg twice daily for 2 days; then 50 mg/kg twice daily to term (max dose = 4 g/day)	Tablet: 500 mg Suspension (compounded): 200 mg/mL	Rash, abdominal pain, diarrhea, nausea
	Leucovorin	5–20 mg/day during treatment and for 1 week after pyrimethamine	Tablet: 5 mg, 10 mg, 15 mg, 25 mg Suspension (compounded): 5 mg/mL	Diarrhea, nausea, stomatitis, fatigue
Congenital toxoplasmosis in neonates and infants <sup>b</sup>	Pyrimethamine	2 mg/kg/day for 2 days; then 1 mg/kg/day for 6 months; then three times/week for 1-year total treatment (max dose = 25 mg/day)	Tablet: 25 mg Suspension (compounded): 2 mg/mL	Rash
	Sulfadiazine	50 mg/kg twice daily for 1 year (max dose = 6 g/day)	Tablet: 500 mg Suspension (compounded): 200 mg/mL	Rash, abdominal pain, diarrhea, nausea
	Leucovorin	10 mg three times/week during treatment and for 1 week after pyrimethamine	Tablet: 5 mg, 10 mg, 15 mg, 25 mg Suspension (compounded): 5 mg/mL	Diarrhea, nausea, stomatitis, fatigue

<sup>b</sup>Practice varies between centers.

HIV = human immunodeficiency virus; IND = investigational new drug; TMP/SMX = trimethoprim/sulfamethoxazole.

*A. lumbricoides* is acquired through the ingestion of embryonated eggs, which hatch in the jejunum and release larvae that penetrate the intestinal wall and enter the portal venous circulation, migrating to the liver. From the liver, the larvae migrate to the lungs through the venous circulation, break into the alveolar spaces, ascend to the tracheobronchial tree, and pass the epiglottis, where they are swallowed. They return to the jejunum and mature into adult worms. The adult worms can live for 1–2 years and are capable of producing 240,000 eggs per day. The elapsed time from initial ingestion to the development of mature adults is 18–24 days (References 48, 50, 53). Eggs are excreted in feces, where they complete embryonation while in the soil (Reference 50). Mature female worms are from 20 to 40 cm long, whereas male worms may be between 12 and 25 cm (Reference 50). Adult worms move through the gastrointestinal tract and can move in and out of the biliary tract, pancreas, appendix, and diverticula, where they may create obstruction and cause inflammation, necrosis, infection, and abscess formation (Reference 48).

In most cases, individuals are asymptomatic but may exhibit anorexia, abdominal discomfort, and diarrhea. In children, the most common complication is intestinal obstruction secondary to an entangled worm bolus. Symptoms include sharp, colicky abdominal pain; fever; diarrhea; and vomiting. The vomitus may contain worms. Severely malnourished children may progress to sepsis and septic shock. Pulmonary ascariasis symptoms, which may develop 1–2 weeks after infection, are rarely life threatening, but they may include chest pain, dry cough, fever, dyspnea, and wheezing. However, most children with pulmonary ascariasis are asymptomatic (References 49, 50).

Diagnosis can be made by a microscopic examination of the feces for eggs. Adult worms may be coughed out or passed through the rectum. Eosinophilia may be evident, especially in the lung migration phase, and can be profound in pulmonary ascariasis cases. Abdominal ultrasonography is useful for identifying worms in the biliary tree (Reference 49).

The goal of therapy is to eradicate the worms from the intestinal tract; however, antihelminthic medications are not recommended in patients with large worm burdens and abdominal pain because of the risk of precipitating intestinal obstruction as the worms die. The drugs of choice are pyrantel pamoate, albendazole, and mebendazole, which have efficacy rates of 88%, 95%, and 88%, respectively (Reference 54) (Table 6). For both children and adults, the treatment course may be repeated if there is no cure within 3–4 weeks. In symptomatic pregnant women, the drug of choice is pyrantel pamoate, which should only be used when the patient's active symptoms have subsided (Reference 55).

Children receiving any of these medications for eradication of ascariasis should be monitored for adverse reactions, which are rare with short-term use. Pyrantel pamoate should be used with caution in patients with existing liver dysfunction. Patients with phenylketonuria should avoid the use of the chewable tablet, which contains aspartame. Some suspensions of pyrantel pamoate contain sodium benzoate, a metabolite of benzyl alcohol, which has been associated with gasping syndrome in neonates if administered in large amounts. Although it is unlikely that excessive amounts would be reached when treating ascariasis in neonates, caution is warranted. Other adverse effects in children taking pyrantel pamoate include gastrointestinal upset, nausea, diarrhea, abdominal cramps, headache, and rash. Albendazole should be used with caution in patients with abnormal liver function tests and in patients with a decreased leukocyte count. Other adverse effects include rash, urticaria, headache, abdominal pain, nausea, and vomiting. Adverse reactions with mebendazole include gastrointestinal effects such as nausea, vomiting, diarrhea, and abdominal pain. Rash, pruritus, and headache also occur (Reference 56).

Preventive measures include improvement in sanitation and the practice of good hygiene. In endemic areas, school screenings with subsequent treatment have been beneficial in identifying asymptomatic carriers and improving the health and educational outcomes of school-aged children (Reference 49).

## Pinworm

The most common helminth infection in school-aged children in the United States is *Enterobius vermicularis*, or pinworm, with an estimated prevalence of 30% of children (Reference 6). Pinworm, which is found worldwide, especially in temperate regions, occurs in children regardless of socioeconomic level, race, or culture. Humans are the only host of *E. vermicularis*, which does not spread through water or germinate in soil (Reference 57). In addition to school-aged children, other commonly infected groups include adult caretakers of infected children and institutionalized individuals (Reference 58).

Pinworm is transmitted by several methods: finger to mouth, aerogenic, and reinfection. Fingers become contaminated secondary to scratching in the anal area, and when infected fingers are placed in the mouth (through nail biting, poor hygiene, or inadequate handwashing), autoinfection occurs (Reference 29). Infestation may also occur when eggs adhere to bed linens, soiled clothes, tabletops, and bathroom fixtures; once touched, they stick to fingers or are caught under fingernails. Some research also suggests that pinworm eggs are carried by cockroaches (Reference 59). In aerogenic infestation, eggs are inhaled and ingested from

airborne dust containing eggs that have been dislodged from bed linens and clothes (Reference 57). Retroinfection occurs when a pinworm hatches at the opening to the anus and then reenters the rectum and bowel (Reference 60).

Once the eggs are ingested, the larvae hatch in the duodenum and mature into adult worms within 1–2 months. Adult worms attach to the mucosa of the cecum, appendix, and bowel and live for up to 4–6 weeks (Reference 57). Female pinworms, which are about 5–13 mm long, are threadlike and white. At night, the pregnant female migrates to the anus to deposit as many as 16,000 eggs in the perianal skin. In some cases, worms will migrate into nearby orifices, usually in the female genitourinary tract, leading to symptoms of vulvovaginitis and urinary tract infection (Reference 57). Within 6 hours of being deposited, the eggs become infective and can remain so for up to 14–20 days (Reference 57).

Patients with pinworm infestation will present with perianal and perineal pruritus, which is usually more intense at night as the worms migrate. Some individuals will be asymptomatic, and in rare cases of heavy worm burden, bowel inflammation, perforation, and obstruction may occur. Children may exhibit nausea or abdominal pain, as well as restless sleep, bedwetting, and irritability (Reference 58). Severe itching may lead to anal excoriation and secondary bacterial infection. Infestation with pinworm may also lead to appendicitis (Reference 61).

Diagnosis of pinworm is usually made by a careful clinical history and identification of pinworm eggs from the perianal area using the “tape test.” A stool specimen is not very useful because *E. vermicularis* eggs are only detectable in the stool in 5% to 15% of cases (Reference 6). The tape test involves the use of clear adhesive tape to the end of a cotton swab with the sticky side out. The tape should be touched to the areas around the anus in the morning before the child bathes or defecates. The tape should be preserved in a plastic bag and taken to a physician’s office for microscopic examination (Reference 57). To reduce false-negative results, this test should be done on 3 consecutive days, which yields a sensitivity of 90% (References 56, 58).

The treatment goal is to eradicate the infestation and reduce morbidity. Several antihelminthic medications are available and are given as two doses, 2 weeks apart. Drugs of choice include pyrantel pamoate, albendazole, and mebendazole (Table 6). Because medications are not completely effective against both eggs and larvae, re-treatment is recommended, which may decrease recurrence rates from 20% to 1% (Reference 62). When treating the patient, all infected household contacts should also be treated with the same agent. Personal hygiene, including changing underclothes daily, good

handwashing, and changing bed linens and towels frequently, must be improved, and children should be discouraged from putting their fingers in their mouths (Reference 58). Individuals at risk of infestation should bathe in the morning on awakening to reduce egg contamination (Reference 58).

Patients should be reminded that recurrence is common if the dose is not repeated in 2 weeks. Therapy is much more effective if the patient’s household contacts are treated at the same time. Patients should be reexamined after completion of medication therapy to reevaluate for reinfection, especially if perianal itching or pain continues (Reference 58).

## ECTOPARASITES

### Pediculosis (Head Lice)

Head lice infestation (pediculosis) is caused by *Pediculus humanus capitis*. In the United States, head lice are most commonly found in school-aged children, especially in preschool and elementary grades, between 3 and 12 years of age (Reference 63). Household members of infested children, as well as other caretakers, may also contract lice. It is estimated that 6–12 million cases of head lice occur annually in the United States (Reference 63). Treatment costs associated with head lice are estimated at \$1 billion, and because of “no-nit” policies in U.S. schools, about 12–24 million days of school are lost each year (References 64, 65). Head lice, which are not known to spread disease, are much less common among African Americans (Reference 66).

The adult head louse is about the size of a sesame seed (about 3–4 mm long), whereas the eggs (nits) are much smaller at only 1 mm. A female louse can live 3–4 weeks and lay up to 10 nits daily. Nits are attached to the base of the hair shaft near the scalp with a glue-like substance. Nits need the warmth of body heat to incubate, and in 7–12 days, they hatch, releasing a nymph, which matures during the next 9–12 days to reach the adult stage. Lice feed on blood from the human host every few hours, injecting saliva into the scalp. Mature lice cannot survive for more than 1 day away from the scalp (Reference 63).

Lice are transmitted only by direct close contact. Head-to-head contact is common in young and school-aged children, through play activities, sports, slumber parties, and camp (Reference 66). Less often, lice can be spread through the sharing of clothing such as hats, scarfs, and coats or through sharing of other items that have been in recent contact with the infested person such as combs, brushes, towels, ribbons, and barrettes. Placing the head on a pillow, bed, carpet, or upholstered furniture that has recently been used by an infested person may also promote transmission (Reference 66).

**Table 6.** Medications for Pediatric Helminth Infections (References 15, 56)

Parasite	Medication	Pediatric Dosage	Dosage Forms	Comments
Ascariasis ( <i>Ascaris lumbricoides</i> )	Albendazole	400 mg once	Tablet: 200 mg	Tablet may be crushed or chewed.
	Mebendazole	100 mg twice daily for 3 days	Chewable tablet: 100 mg	
	Pyrantel pamoate	11 mg/kg pyrantel base once (max = 1 g)	Suspension: 144 mg/mL (50 mg/mL pyrantel base) Chewable tablet: 720.5 mg (250 mg pyrantel base)	Repeat dose in 2 weeks.
Pinworm ( <i>Enterobius vermicularis</i> )	Albendazole	400 mg once	Tablet: 200 mg	Repeat dose in 2 weeks.
	Mebendazole	100 mg once	Chewable tablet: 100 mg	Repeat dose in 2 weeks.
	Pyrantel pamoate	11 mg/kg pyrantel base once (max = 1 g)	Suspension: 144 mg/mL (50 mg/mL pyrantel base) Chewable tablet: 720.5 mg (250 mg pyrantel base)	Repeat dose in 2 weeks.

Diagnosis of head lice is made by observation of live lice on the scalp or hair, but this can be difficult. Use of a lice comb or other fine-tooth comb can make this process easier (Reference 67). Nits may be easier to find, especially close to the scalp, but of importance, finding nits does not always confirm that a child is infested. If the nits are found attached to the hair more than ¼ inch from the scalp, they are usually dead or already hatched. Nits can also be confused with dandruff particles or hair debris, but nits are usually difficult to remove from the hair. Although head lice may be found anywhere on the scalp, they are commonly found in the postauricular and occipital areas (Reference 63). Patients may or may not present with pruritus, and many children may be asymptomatic (Reference 66). In some cases, pruritus may lead to excoriations on the scalp and secondary skin infections.

The treatment goal is to eradicate the infestation. Treatment is recommended for all individuals with an active infestation. Nonprescription topical medications, such as 1% permethrin or pyrethrins, can be used as first-line therapy unless there is proven resistance to these products in the community (Table 7). Prescription products such as benzyl alcohol 5% can be used in children older than 6 months, and malathion 0.5% can be used in children older than 2 years. Spinosad 0.9% is a newer topical prescription product that may be used in children 4 years and older. It is ovicidal and does not require the use of a nit comb after use (Reference 68). Topical ivermectin lotion 0.5% may be used to treat head lice infestations in children 6 months and older. Like spinosad, it does not require nit combing after use (Reference 69). These products may also be used when resistance to pyrethrins or permethrin is common or when a patient's nonprescription therapy has failed. If nonprescription

treatment is used or if live lice are seen after malathion therapy, product reapplication should occur at the indicated intervals because these products are not completely ovicidal (Reference 63). Lindane, an organochlorine, is only available by prescription and has been reported to cause seizures in children (References 63, 66). The FDA recommends that it be used only for second-line treatment in cases of treatment failure or in those who cannot tolerate other, safer medications. A public health advisory issued by the FDA further emphasized that lindane should not be used in neonates and should be used with extreme caution in all children and individuals who weigh less than 110 lb, who take medications that may lower the seizure threshold, or who are infected with HIV (Reference 63). The state of California has banned the use of lindane, and the American Academy of Pediatrics no longer recommends its use as a pediculicide (Reference 63). If treatment with a pediculicide is contraindicated or parents wish for a nontoxic alternative to pediculicides, "wet-combing" (the use of a fine-tooth comb on wet hair coated with conditioner) can be useful, although it is time-consuming and difficult to perform on active young children. This process should take about 1 hour to complete and should be repeated every 4 days until no more active lice are seen. Another nontoxic option is to employ the use of occlusive products such as petroleum jelly or Cetaphil. Petroleum jelly is massaged into the hair and scalp and left on overnight with a shower cap. This is thought to suffocate the adult louse and block air exchange in the eggs; it may need to be repeated within 2 weeks (Reference 70). Cetaphil is applied to the hair and scalp, dried with a hair dryer, left on overnight, and then washed out in the morning. This process should be repeated once weekly for 3 weeks (Reference 71).

**Table 7.** Medications for Ectoparasite Infestations (References 56, 63)

Parasite	Medication	Instructions	Comments
Head lice	Permethrin <sup>a</sup> 1%	Topical: Apply to clean, towel-dried hair, leave on for 10 minutes, and rinse with water.	Nonprescription Use in children > 2 months old. May repeat in 1 week if needed.
	Pyrethrin	Topical: Completely wet hair with product, leave on for 10 minutes, wash, and rinse well with warm water.	Nonprescription Repeat in 7–10 days to kill newly hatched lice.
	Benzyl alcohol 5%	Topical: Apply to dry hair. Use enough product to completely saturate hair and scalp. Leave on for 10 minutes, and then rinse well with water. Use fine-tooth comb to remove dead lice and eggs.	Nonprescription For children ≥ 6 months old No ovicidal activity Repeat in 1 week.
	Ivermectin 0.5%	Topical: Apply to dry hair. Use enough product to thoroughly coat the hair and scalp. Leave on for 10 minutes, and then rinse well with water.	Prescription only Use in children ≥ 6 months old Nit combing not required
	Lindane	Topical: Apply 15–30 mL to head and lather for 4 minutes, rinse well, and use fine-tooth comb to remove dead lice and eggs.	Not routinely recommended Last-line therapy Prescription only
	Malathion 0.5%	Topical: Sprinkle product on dry hair and rub in until scalp is moistened. Allow hair to dry naturally. Wash hair after 8–12 hours with a non-medicated shampoo, rinse, and use a fine-tooth comb to remove dead lice and eggs.	Prescription only May repeat application in 7–9 days if needed Contraindicated in neonates and infants
	Spinosad 0.9%	Topical: Apply sufficient amount to cover dry scalp and completely cover dry hair. Leave on for 10 minutes; then rinse thoroughly with warm water.	Prescription only Use in children ≥ 4 years May repeat application in 7 days if live lice seen. Nit combing not required Ovicidal
Scabies	Permethrin <sup>a</sup> 5%	Topical: Apply head to toes, leave on for 8–14 hours, and wash off with water.	Prescription only May reapply in 1 week if live mites present.
	Crotamiton 10%	Topical: Apply to entire body, neck to toes, once daily for 2 days. Bathe 48 hours after last application.	Prescription only May reapply after 7–10 days if mites reappear. In infants and young children, may also apply to neck, head, and scalp; avoid face.
	Ivermectin	Oral: 200 mcg/kg as a single dose for children ≥ 15 kg	Prescription only May repeat dose in 10–14 days
	Lindane	Topical: Apply thin layer to skin from neck to toes. Infants: Wash off 6 hours after application. Children: Wash off 6–8 hours after application.	Not routinely recommended Last-line therapy Prescription only

<sup>a</sup>Drug of choice.

Nit removal is not necessary, but it may be cosmetically desired. Because many schools in the United States have a “no-nit” policy requiring children to be free of nits before returning to school, parents may want to remove nits to avoid confusion. Fine-tooth combs or special “nit combs” are used on wet hair, similar to the “wet-combing” process previously described. Some products claim to loosen the nits from the hair shaft, making the process easier, but no clinical benefit has been shown (Reference 63). Shaving the child’s head is very effective in the removal of nits and lice, but it is generally not recommended because of the distress it may cause the child (Reference 63).

Because head lice need a blood meal regularly and do not survive long after they fall off the scalp, aggressive cleaning is not necessary to prevent reinfestation. However, it is recommended that all clothing or washable items that the infested person was in contact with during the 2 days before lice removal treatment be machine washed in hot water and dried on high heat. Because adult lice will not survive long without a blood meal and their eggs typically hatch within 6–10 days, any clothing and items that cannot be washed may be dry-cleaned or tightly sealed in a plastic bag for 2 weeks. All brushes and combs should be washed in hot water for 5–10 minutes. Vacuuming the floor or furniture where an infested person has recently been may be helpful, but the risk of infestation in this circumstance is low (Reference 66).

### Scabies

Scabies is caused by infestation with the human itch mite, *Sarcoptes scabiei* var. *hominis*, into the superficial layers of the skin. It can be seen worldwide, and it affects all age groups, races, and social classes. Risk factors for scabies include crowding, especially in poorer socioeconomic settings where lack of proper hygiene exists. Scabies is transmitted through close body contact, and outbreaks often occur in nursing homes, extended care facilities, prisons, and child care facilities (Reference 71).

Scabies mites are transmitted through prolonged direct human contact. The adult female mite is very small, 0.3–0.5 mm long, and can lay as many as 90 eggs after burrowing beneath the stratum corneum for a blood meal. When the female mite burrows, a trail of eggs, debris, and feces is left behind, which induces an immunologic response, manifested by intense pruritus. Larvae hatch under the skin within 3–4 days and mature over 2 weeks into adult mites. In a patient with classic scabies, the average mite population is 10–20 parasites (Reference 72).

The main symptom of scabies is intense, distressing pruritus that worsens at night or with activities that elevate body temperature. Primary lesions include burrows, which look like faint white zigzags on the skin, papules, vesicles, and pustules (References 72, 73). Secondary

lesions arise from scratching and may include crusted areas and nodules (Reference 72). In infants, the palms, soles, axillae, and scalp are most commonly affected. In older children, lesions are mostly seen below the neck, including the webbed spaces between the fingers; flexor surfaces of the arms; wrists, and axillae; and waistline. Other affected areas include the umbilicus, penis, nipples, and scrotum (Reference 74). In new infestations, symptoms may take as long as 4–6 weeks to manifest (Reference 73).

A definitive diagnosis of scabies is made by direct visualization of the mites, eggs, or feces in a skin scraping on low-power microscopy (Reference 75). Because this is not always feasible, the diagnosis is often based on clinical signs and symptoms, including the characteristic burrow pattern and history of pruritus that worsens at night.

The goal of therapy is to eradicate the infestation and minimize complications. Treatment of both the infested patient and all close contacts with scabicial medications is crucial. The drug of choice is permethrin. All scabicial medications are available only with a prescription, and appropriate application of medication is necessary to ensure successful treatment (Table 7). The medication should be applied to clean skin and left on for the recommended time before washing it off. In older children, the scabicide should be applied to all areas of the body from the neck to the toes, whereas in infants and young children, the head and neck should also be covered. After treatment, clean clothing should be worn. Because the pruritus is typically caused by a hypersensitivity reaction to the mites and their feces, patients may exhibit itching for weeks after treatment, despite killing all mites and eggs. Use of an oral antihistamine or a topical corticosteroid may be helpful to control the itching. Skin sores from itching may become infected and should be treated appropriately with antibiotics (References 72, 73). Patients should be examined 1 month after treatment for complete resolution of signs and symptoms.

All clothing, bedding, and towels used by the infested person should be washed in hot water and dried on the hot setting. Items that are non-washable should be dry-cleaned or placed in a sealed plastic bag and stored for a minimum of 72 hours because scabies mites can live for only 2–3 days without a host. The use of pesticide sprays or fogs is unnecessary (Reference 73).

### CONCLUSIONS

Parasitic infections in children can have a detrimental effect on a child’s well-being, affecting nutritional status, growth, and development. It is vital that clinicians be aware of the signs and symptoms, complications, and available treatment options for the most prevalent parasites, even though they are not as common in the

United States as in other areas of the world. With increasing immigration and travel by children and their families to endemic areas of the world, the impact of parasites in children can be felt in previously unaffected geographic locations in the United States. Public health awareness of transmission risks is important in both the prevention and treatment of parasitic infections in pediatric patients.

# CHAPTER 44

## PEDIATRIC VACCINES

Heather L. VandenBussche, Pharm.D.

### LEARNING OBJECTIVES

1. Classify each of the routine childhood vaccines as a live or inactivated vaccine.
2. Classify each inactivated vaccine as a polysaccharide, conjugate, toxoid, or subunit vaccine.
3. Given a clinical scenario, develop an immunization plan for a child or adolescent.
4. Recognize clinical situations in which a vaccine is contraindicated or should be given with caution.
5. Describe appropriate methods to minimize vaccine-related adverse events.
6. Identify reliable electronic references for current vaccine information.

### ABBREVIATIONS IN THIS CHAPTER

DTaP	Pediatric vaccine containing diphtheria and tetanus toxoids and acellular pertussis vaccine
Hib	<i>Haemophilus influenzae</i> type b
HPV	Human papillomavirus
MMR	Measles, mumps, and rubella vaccine
PCV13	13-valent pneumococcal conjugate vaccine
PPSV23	23-valent pneumococcal polysaccharide vaccine
Td	Adolescent and adult tetanus toxoid and reduced diphtheria toxoid vaccine
Tdap	Adolescent and adult vaccine containing tetanus toxoid and reduced amounts of diphtheria toxoid and acellular pertussis vaccine

### INTRODUCTION

Vaccines are one of the most important advances in modern medicine because of the dramatic impact they have had on infectious disease morbidity and mortality. Since the famous work of Edward Jenner in the late 1700s, global eradication of smallpox and significant declines in polio, diphtheria, tetanus, pertussis, measles, mumps, rubella, and *Haemophilus influenzae* type b (Hib) infections have occurred. However, despite widespread use of routine childhood vaccines in the

Western hemisphere, continued surveillance is necessary to detect outbreaks of disease that can occur from international travel and lack or underuse of vaccination in certain patient populations.

Vaccines are a form of active immunity by which an antigen is administered that induces antibody formation and protection against infection. The immune response is produced when antigens stimulate T lymphocytes that subsequently direct B lymphocytes to produce immunoglobulin G, which provides long-lasting immune protection upon future exposure to the antigen. Some antigens such as bacterial cell wall polysaccharides produce a T cell-independent immune response by directly stimulating B lymphocytes, but the antibody produced is less functional and consists mainly of immunoglobulin M, which provides temporary immunity (Reference 1). Children younger than 2 years do not mount a sufficient response to these antigens because of their immature immune systems. Conjugating a cell wall polysaccharide to a protein molecule such as a nontoxic diphtheria toxin creates a T cell-dependent immune response that invokes a greater antibody response, irrespective of patient age, and provides a booster response when several vaccine doses are given over time.

The different classifications of vaccines vary in their immunity potential. Live vaccines contain attenuated organisms that undergo limited replication mimicking natural infection and can confer lifelong immunity with one or two doses. Development of immunity to live vaccines can be reduced or completely hindered by the presence of circulating antibody to the vaccine antigens. Administration of an antibody-containing blood product (e.g., immune globulin, packed red blood cells, fresh frozen plasma) within 2 weeks after a live injectable viral vaccine is given may interfere with viral replication; if this cannot be avoided, the vaccine dose should be repeated. Alternatively, if blood products are given first, it may be necessary to postpone vaccination with injectable live vaccines for up to 11 months after blood product administration. Similarly, administration of certain live viral vaccines can interfere with immunity to subsequently administered live vaccines. If two live injectable vaccines or live intranasal influenza vaccine are not administered simultaneously, they must be separated by at least 4 weeks to ensure an adequate immune response to the second live vaccine.

In contrast to live vaccines, inactivated vaccines consist of killed whole organisms or specific antigenic components that require several doses to induce long-lasting immunity. In most cases, booster doses are also needed to maintain immunity. These vaccines are not inactivated by circulating antibodies and can be administered any time before or after other inactivated or live vaccines. Inactivated vaccines can also differ in immunogenicity, which is dependent on their composition. Outer membrane polysaccharides are poorly immunogenic in infants, but when conjugated with carrier proteins, the immune response improves dramatically (Reference 2). Toxoids are inactive bacterial toxins usually combined with adjuvants such as aluminum to enhance antibody production against the toxin rather than the bacterial pathogen itself.

## ROUTINE VACCINES

Childhood immunization schedules are published annually in January by the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP). The currently recommended schedules for routine childhood and adolescent immunization are shown in Figure 1 and Figure 2 and can be found at [www.cdc.gov/vaccines](http://www.cdc.gov/vaccines). Schedule updates and new information are published throughout the year in the *Morbidity and Mortality Weekly Report* (MMWR). Table 1 contains vaccine-specific information on administration schedules and requirements, adverse effects, precautions, and contraindications.

When there is an opportunity to vaccinate a child, health care providers must consult the recommended dosing schedule and determine whether any vaccines should be given at that health encounter. Recommended and minimum ages and intervals exist for all vaccines that are dosed in a series. Minimum ages are determined on the likelihood of inducing an immune response. Most inactivated vaccines do not induce an immune response before 6 weeks of age, except for hepatitis B vaccine. Live injectable vaccines such as measles, mumps, and rubella vaccine (MMR) and varicella may not induce immunity if given before 12 months of age because of the presence of maternal circulating antibodies. In general, increasing the interval between recommended doses does not reduce vaccine effectiveness, but decreasing the interval can reduce antibody response and interfere with immunity. Vaccine doses administered before the minimum recommended age or interval are not valid and must be repeated. Catch-up vaccine schedules incorporate the minimum ages and dosing intervals for vaccinations, and they can be used to update a child's immunization status that has fallen

behind; these schedules are also available at [www.cdc.gov/vaccines](http://www.cdc.gov/vaccines). Premature infants should be vaccinated at the same chronologic age as full-term infants and receive the full recommended doses (Reference 2).

## Hepatitis B Vaccine

Hepatitis B virus is transmitted parenterally, perinatally, and sexually, potentially leading to acute or chronic hepatitis, cirrhosis, and hepatocellular carcinoma. Children are most often infected during birth from infected mothers or from contact with infected household members and are at high risk of chronic infection and severe liver disease. Chronic infection is typically asymptomatic initially and may result in the spread of virus to others by those who are unaware of their chronic viremia. In the United States, acute infection occurs mainly during adulthood and can lead to chronic infection in up to 5% (References 1, 3). Because infants are at highest risk of acquiring asymptomatic chronic hepatitis B, vaccination efforts should focus on immunization after birth before hospital discharge. Catch-up vaccination will also help prevent hepatitis B infection and should target all infants, children, and adolescents not previously vaccinated as well as high-risk unvaccinated adults (Reference 3).

Hepatitis B vaccine is prepared through recombinant DNA technology in which hepatitis B surface antigen (HBsAg) is harvested and purified after production in yeast cells. It is available in two single-antigen (Engerix-B and Recombivax HB) and three combination vaccines (Twinrix, Comvax, and Pediarix; refer to Combination Vaccines section and Table 2) containing 10–40 mcg of HBsAg protein per milliliter.

The recommended administration schedule varies with patient age. Routine infant immunization should begin within 12 hours of birth with single-antigen vaccine to prevent perinatal infection, followed by the second and third doses given at 1–2 months and 6–18 months of age. If a combination vaccine containing hepatitis B antigen is used to complete the series after the birth dose, additional doses are given at 2, 4, and 6 months of age. Preterm infants weighing less than 2 kg do not mount a sufficient immune response to the birth dose; this dose can be delayed until the child is 1 month of age if born to an HBsAg-negative mother. If a birth dose must be given to a preterm infant weighing less than 2 kg, the dose should not be counted, and the child should receive three additional doses beginning at 1 month of age (Reference 3). Unvaccinated adolescents should receive a three-dose series of single-antigen vaccine (two doses separated by 4 weeks, with the third dose 4–6 months after the second dose); an alternative two-dose series with Recombivax HB is approved for adolescents 11–15 years of age, but no data exist on its long-term protection.

Vaccine ▼	Age ►	Birth	1 month	2 months	4 months	6 months	9 months	12 months	15 months	18 months	19–23 months	2–3 years	4–6 years	
Hepatitis B <sup>1</sup>		Hep B	HepB			HepB								Range of recommended ages for all children
Rotavirus <sup>2</sup>				RV	RV	RV <sup>2</sup>								
Diphtheria, tetanus, pertussis <sup>3</sup>				DTaP	DTaP	DTaP		see footnote <sup>7</sup>	DTaP				DTaP	
<i>Haemophilus influenzae</i> type b <sup>4</sup>				Hib	Hib	Hib <sup>4</sup>			Hib					Range of recommended ages for certain high-risk groups
Pneumococcal <sup>5</sup>				PCV	PCV	PCV			PCV			PPSV		
Inactivated poliovirus <sup>6</sup>				IPV	IPV			IPV					IPV	
Influenza <sup>7</sup>								Influenza (Yearly)						
Measles, mumps, rubella <sup>8</sup>								MMR			see footnote <sup>9</sup>		MMR	Range of recommended ages for all children and certain high-risk groups
Varicella <sup>9</sup>								Varicella			see footnote <sup>9</sup>		Varicella	
Hepatitis A <sup>10</sup>								Dose 1 <sup>10</sup>				HepA Series		
Meningococcal <sup>11</sup>								MCV4 — see footnote <sup>11</sup>						

This schedule includes recommendations in effect as of December 23, 2011. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at <http://www.cdc.gov/vaccines/pubs/acip-list.htm>. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (<http://www.vaers.hhs.gov>) or by telephone (800-822-7967).

- Hepatitis B (HepB) vaccine.** (Minimum age: birth)  
**At birth:**
  - Administer monovalent HepB vaccine to all newborns before hospital discharge.
  - For infants born to hepatitis B surface antigen (HBsAg)-positive mothers, administer HepB vaccine and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) 1 to 2 months after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).
  - If mother's HBsAg status is unknown, within 12 hours of birth administer HepB vaccine for infants weighing  $\geq 2,000$  grams, and HepB vaccine plus HBIG for infants weighing  $< 2,000$  grams. Determine mother's HBsAg status as soon as possible and, if she is HBsAg-positive, administer HBIG for infants weighing  $\geq 2,000$  grams (no later than age 1 week).**Doses after the birth dose:**
  - The second dose should be administered at age 1 to 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks.
  - Administration of a total of 4 doses of HepB vaccine is permissible when a combination vaccine containing HepB is administered after the birth dose.
  - Infants who did not receive a birth dose should receive 3 doses of a HepB-containing vaccine starting as soon as feasible (Figure 3).
  - The minimum interval between dose 1 and dose 2 is 4 weeks, and between dose 2 and 3 is 8 weeks. The final (third or fourth) dose in the HepB vaccine series should be administered no earlier than age 24 weeks and at least 16 weeks after the first dose.
- Rotavirus (RV) vaccines.** (Minimum age: 6 weeks for both RV-1 [Rotarix] and RV-5 [Rota Teq])
  - The maximum age for the first dose in the series is 14 weeks, 6 days; and 8 months, 0 days for the final dose in the series. Vaccination should not be initiated for infants aged 15 weeks, 0 days or older.
  - If RV-1 (Rotarix) is administered at ages 2 and 4 months, a dose at 6 months is not indicated.
- Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine.** (Minimum age: 6 weeks)
  - The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
- Haemophilus influenzae* type b (Hib) conjugate vaccine.** (Minimum age: 6 weeks)
  - If PRP-OMP (PedvaxHIB or Comvax [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
  - Hiberix should only be used for the booster (final) dose in children aged 12 months through 4 years.
- Pneumococcal vaccines.** (Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])
  - Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
  - For children who have received an age-appropriate series of 7-valent PCV (PCV7), a single supplemental dose of 13-valent PCV (PCV13) is recommended for:
    - All children aged 14 through 59 months
    - Children aged 60 through 71 months with underlying medical conditions.
  - Administer PPSV at least 8 weeks after last dose of PCV to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant. See *MMWR* 2010;59(No. RR-11), available at <http://www.cdc.gov/mmwr/pdf/rr/rr5911.pdf>.
- Inactivated poliovirus vaccine (IPV).** (Minimum age: 6 weeks)
  - If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years.
  - The final dose in the series should be administered on or after the fourth birthday and at least 6 months after the previous dose.
- Influenza vaccines.** (Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])
  - For most healthy children aged 2 years and older, either LAIV or TIV may be used. However, LAIV should not be administered to some children, including 1) children with asthma, 2) children 2 through 4 years who had wheezing in the past 12 months, or 3) children who have any other underlying medical conditions that predispose them to influenza complications. For all other contraindications to use of LAIV, see *MMWR* 2010;59(No. RR-8), available at <http://www.cdc.gov/mmwr/pdf/rr/rr5908.pdf>.
  - For children aged 6 months through 8 years:
    - For the 2011–12 season, administer 2 doses (separated by at least 4 weeks) to those who did not receive at least 1 dose of the 2010–11 vaccine. Those who received at least 1 dose of the 2010–11 vaccine require 1 dose for the 2011–12 season.
    - For the 2012–13 season, follow dosing guidelines in the 2012 ACIP influenza vaccine recommendations.
- Measles, mumps, and rubella (MMR) vaccine.** (Minimum age: 12 months)
  - The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
  - Administer MMR vaccine to infants aged 6 through 11 months who are traveling internationally. These children should be revaccinated with 2 doses of MMR vaccine, the first at ages 12 through 15 months and at least 4 weeks after the previous dose, and the second at ages 4 through 6 years.
- Varicella (VAR) vaccine.** (Minimum age: 12 months)
  - The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose.
  - For children aged 12 months through 12 years, the recommended minimum interval between doses is 3 months. However, if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.
- Hepatitis A (HepA) vaccine.** (Minimum age: 12 months)
  - Administer the second (final) dose 6 to 18 months after the first.
  - Unvaccinated children 24 months and older at high risk should be vaccinated. See *MMWR* 2006;55(No. RR-7), available at <http://www.cdc.gov/mmwr/pdf/rr/rr5507.pdf>.
  - A 2-dose HepA vaccine series is recommended for anyone aged 24 months and older, previously unvaccinated, for whom immunity against hepatitis A virus infection is desired.
- Meningococcal conjugate vaccines, quadrivalent (MCV4).** (Minimum age: 9 months for Menactra [MCV4-D], 2 years for Menveo [MCV4-CRM])
  - For children aged 9 through 23 months 1) with persistent complement component deficiency; 2) who are residents of or travelers to countries with hyperendemic or epidemic disease; or 3) who are present during outbreaks caused by a vaccine serogroup, administer 2 primary doses of MCV4-D, ideally at ages 9 months and 12 months or at least 8 weeks apart.
  - For children aged 24 months and older with 1) persistent complement component deficiency who have not been previously vaccinated; or 2) anatomic/functional asplenia, administer 2 primary doses of either MCV4 at least 8 weeks apart.
  - For children with anatomic/functional asplenia, if MCV4-D (Menactra) is used, administer at a minimum age of 2 years and at least 4 weeks after completion of all PCV doses.
  - See *MMWR* 2011;60:72–6, available at <http://www.cdc.gov/mmwr/pdf/wk/mm6003.pdf>, and Vaccines for Children Program resolution No. 6/11-1, available at <http://www.cdc.gov/vaccines/programs/vfc/downloads/resolutions/06-11mening-mcv.pdf>, and *MMWR* 2011;60:1391–2, available at <http://www.cdc.gov/mmwr/pdf/wk/mm6040.pdf>, for further guidance, including revaccination guidelines.

This schedule is approved by the Advisory Committee on Immunization Practices (<http://www.cdc.gov/vaccines/recs/acip>), the American Academy of Pediatrics (<http://www.aap.org>), and the American Academy of Family Physicians (<http://www.aafp.org>).  
Department of Health and Human Services • Centers for Disease Control and Prevention

**Figure 1.** Recommended immunization schedule for persons aged 0 through 6 years—United States, 2012 (for those who fall behind or start late, see the catch-up schedule).

Vaccine ▼	Age ►	7–10 years	11–12 years	13–18 years	
Tetanus, diphtheria, pertussis <sup>1</sup>		1 dose (if indicated)	1 dose	1 dose (if indicated)	Range of recommended ages for all children
Human papillomavirus <sup>2</sup>		see footnote <sup>2</sup>	3 doses	Complete 3-dose series	
Meningococcal <sup>3</sup>		See footnote <sup>3</sup>	Dose 1	Booster at 16 years old	Range of recommended ages for catch-up immunization
Influenza <sup>4</sup>		Influenza (yearly)			
Pneumococcal <sup>5</sup>		See footnote <sup>5</sup>			Range of recommended ages for certain high-risk groups
Hepatitis A <sup>6</sup>		Complete 2-dose series			
Hepatitis B <sup>7</sup>		Complete 3-dose series			
Inactivated poliovirus <sup>8</sup>		Complete 3-dose series			
Measles, mumps, rubella <sup>9</sup>		Complete 2-dose series			
Varicella <sup>10</sup>		Complete 2-dose series			

This schedule includes recommendations in effect as of December 23, 2011. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at <http://www.cdc.gov/vaccines/pubs/acip-list.htm>. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (<http://www.vaers.hhs.gov>) or by telephone (800-822-7967).

- Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine.** (Minimum age: 10 years for Boostrix and 11 years for Adacel)
  - Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter.
  - Tdap vaccine should be substituted for a single dose of Td in the catch-up series for children aged 7 through 10 years. Refer to the catch-up schedule if additional doses of tetanus and diphtheria toxoid-containing vaccine are needed.
  - Tdap vaccine can be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
- Human papillomavirus (HPV) vaccines (HPV4 [Gardasil] and HPV2 [Cervarix]).** (Minimum age: 9 years)
  - Either HPV4 or HPV2 is recommended in a 3-dose series for females aged 11 or 12 years. HPV4 is recommended in a 3-dose series for males aged 11 or 12 years.
  - The vaccine series can be started beginning at age 9 years.
  - Administer the second dose 1 to 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).
  - See *MMWR* 2010;59:626–32, available at <http://www.cdc.gov/mmwr/pdf/wk/mm5920.pdf>.
- Meningococcal conjugate vaccines, quadrivalent (MCV4).**
  - Administer MCV4 at age 11 through 12 years with a booster dose at age 16 years.
  - Administer MCV4 at age 13 through 18 years if patient is not previously vaccinated.
  - If the first dose is administered at age 13 through 15 years, a booster dose should be administered at age 16 through 18 years with a minimum interval of at least 8 weeks after the preceding dose.
  - If the first dose is administered at age 16 years or older, a booster dose is not needed.
  - Administer 2 primary doses at least 8 weeks apart to previously unvaccinated persons with persistent complement component deficiency or anatomic/functional asplenia, and 1 dose every 5 years thereafter.
  - Adolescents aged 11 through 18 years with human immunodeficiency virus (HIV) infection should receive a 2-dose primary series of MCV4, at least 8 weeks apart.
  - See *MMWR* 2011;60:72–76, available at <http://www.cdc.gov/mmwr/pdf/wk/mm6003.pdf>, and Vaccines for Children Program resolution No. 6/11-1, available at <http://www.cdc.gov/vaccines/programs/vfc/downloads/resolutions/06-11mening-mcv.pdf>, for further guidelines.
- Influenza vaccines (trivalent inactivated influenza vaccine [TIV] and live, attenuated influenza vaccine [LAIV]).**
  - For most healthy, nonpregnant persons, either LAIV or TIV may be used, except LAIV should not be used for some persons, including those with asthma or any other underlying medical conditions that predispose them to influenza complications. For all other contraindications to use of LAIV, see *MMWR* 2010;59(No.RR-8), available at <http://www.cdc.gov/mmwr/pdf/rr/rr5908.pdf>.
  - Administer 1 dose to persons aged 9 years and older.
  - For children aged 6 months through 8 years:
    - For the 2011–12 season, administer 2 doses (separated by at least 4 weeks) to those who did not receive at least 1 dose of the 2010–11 vaccine. Those who received at least 1 dose of the 2010–11 vaccine require 1 dose for the 2011–12 season.
    - For the 2012–13 season, follow dosing guidelines in the 2012 ACIP influenza vaccine recommendations.
- Pneumococcal vaccines (pneumococcal conjugate vaccine [PCV] and pneumococcal polysaccharide vaccine [PPSV]).**
  - A single dose of PCV may be administered to children aged 6 through 18 years who have anatomic/functional asplenia, HIV infection or other immunocompromising condition, cochlear implant, or cerebral spinal fluid leak. See *MMWR* 2010;59(No. RR-11), available at <http://www.cdc.gov/mmwr/pdf/rr/rr5911.pdf>.
  - Administer PPSV at least 8 weeks after the last dose of PCV to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant. A single revaccination should be administered after 5 years to children with anatomic/functional asplenia or an immunocompromising condition.
- Hepatitis A (HepA) vaccine.**
  - HepA vaccine is recommended for children older than 23 months who live in areas where vaccination programs target older children, who are at increased risk for infection, or for whom immunity against hepatitis A virus infection is desired. See *MMWR* 2006;55(No. RR-7), available at <http://www.cdc.gov/mmwr/pdf/rr/rr5507.pdf>.
  - Administer 2 doses at least 6 months apart to unvaccinated persons.
- Hepatitis B (HepB) vaccine.**
  - Administer the 3-dose series to those not previously vaccinated.
  - For those with incomplete vaccination, follow the catch-up recommendations (Figure 3).
  - A 2-dose series (doses separated by at least 4 months) of adult formulation Recombivax HB is licensed for use in children aged 11 through 15 years.
- Inactivated poliovirus vaccine (IPV).**
  - The final dose in the series should be administered at least 6 months after the previous dose.
  - If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.
  - IPV is not routinely recommended for U.S. residents aged 18 years or older.
- Measles, mumps, and rubella (MMR) vaccine.**
  - The minimum interval between the 2 doses of MMR vaccine is 4 weeks.
- Varicella (VAR) vaccine.**
  - For persons without evidence of immunity (see *MMWR* 2007;56[No. RR-4], available at <http://www.cdc.gov/mmwr/pdf/rr/rr5604.pdf>), administer 2 doses if not previously vaccinated or the second dose if only 1 dose has been administered.
  - For persons aged 7 through 12 years, the recommended minimum interval between doses is 3 months. However, if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.
  - For persons aged 13 years and older, the minimum interval between doses is 4 weeks.

This schedule is approved by the Advisory Committee on Immunization Practices (<http://www.cdc.gov/vaccines/recs/acip>), the American Academy of Pediatrics (<http://www.aap.org>), and the American Academy of Family Physicians (<http://www.aafp.org>).  
Department of Health and Human Services • Centers for Disease Control and Prevention

**Figure 2.** Recommended immunization schedule for persons aged 7 through 18 years—United States, 2012 (for those who fall behind or start late, see the schedule below and the catch-up schedule).

**Table 1. Vaccine-Specific Administration Information, Adverse Effects, Precautions, and Contraindications**

Vaccine	Recommended Administration Schedule	Route of Administration	Vaccine-Specific Adverse Effects	Vaccine-Specific Precautions	Vaccine-Specific Contraindications
Diphtheria, tetanus, acellular pertussis (DTaP or Tdap)	DTaP: 2 months, 4 months, 6 months, 15–18 months, and 4–6 years Tdap: single dose between 11–18 years (11–12 years is preferred) Td: booster dose every 10 years following adolescent Tdap dose DT: not routinely recommended	IM	Exaggerated local (Arthus) reaction with limb swelling Pertussis-containing vaccines only: moderate/severe systemic effects (temperature $\geq 105^{\circ}\text{F}$ , febrile seizures, persistent crying $\geq 3$ hours, hypotonic or hyporesponsive episode) Tdap only: syncope in adolescents	GBS within 6 weeks of prior tetanus-containing vaccine Arthus reaction after prior tetanus-containing vaccine; defer vaccine until $\geq 10$ years have elapsed since last tetanus-containing vaccine DTaP only: temperature $\geq 105^{\circ}\text{F}$ or collapse/shock-like state or persistent, inconsolable crying for $\geq 3$ hours within 48 hours of prior vaccine dose; seizures within 3 days of prior vaccine dose Pertussis-containing vaccines: progressive or unstable neurologic disorder, uncontrolled seizures, or progressive encephalopathy; defer until condition stabilizes	Pertussis-containing vaccines only: encephalopathy within 7 days of prior vaccine dose with no other cause
<i>Haemophilus influenzae</i> type b (Hib)	2 months, 4 months, 6 months, and 12–15 months (6 month dose not needed if PedvaxHIB was given at 2 months and 4 months)	IM			Age younger than 6 weeks
Hepatitis A	Two dose series: first dose at 12–23 months; second dose 6–18 months after first dose	IM		Pregnancy	
Hepatitis B	Birth, 1–2 months, and 6–18 months	IM		Newborns weighing less than 2 kg if mother is hepatitis B surface antigen negative Pregnancy	
Human papillomavirus (HPV)	Three dose series: First dose at 11–12 years; second dose 1–2 months after first dose; third dose 6 months after first dose	IM	Syncope in adolescents		
Live attenuated influenza (LAIV)	Annually beginning at 2 years Children between 2 and 8 years of age not vaccinated in previous years require 2 doses separated by at least 4 weeks	Intranasal	Wheezing (between 6 and 23 months of age) Rhinorrhea or nasal congestion	GBS within 6 weeks of prior influenza vaccine Receipt of antivirals (oseltamivir, zanamivir, amantadine, rimantadine) 48 hours before vaccination; avoid these for 14 days after vaccination	Age <2 years or $\geq 50$ years Possible reactive airway disease in children 2–4 years of age (history of wheezing) Pregnancy Immunosuppression Certain chronic medical conditions Chronic use of aspirin Severe egg allergy
Inactivated influenza (TIV)	Annually beginning at 6 months Children between 6 months and 8 years of age not vaccinated in previous years require 2 doses separated by at least 4 weeks	IM	GBS	GBS within 6 weeks of prior influenza vaccine	Severe egg allergy other than hives

Vaccine	Recommended Administration Schedule	Route of Administration	Vaccine-Specific Adverse Effects	Vaccine-Specific Precautions	Vaccine-Specific Contraindications
Measles, mumps, rubella (MMR)	12–15 months and 4–6 years	SC	Transient rash 7–10 days postvaccination Thrombocytopenia Transient lymphadenopathy or parotitis MMRV: febrile seizures MMRV: varicella-like rash within 14 days of vaccine	Receipt of antibody-containing blood product (within up to 11 months); defer for appropriate interval depending on product received (Reference 2) History of thrombocytopenia or thrombocytopenic purpura Need for tuberculin skin testing MMRV only: personal or family history of febrile seizures; administer MMR and varicella vaccines separately MMRV only: chronic aspirin use; avoid salicylates for 6 weeks after receipt of MMRV vaccine (per manufacturer)	Pregnancy Severe immunodeficiency or immunosuppression Severe allergic reaction to neomycin or gelatin
Meningococcal conjugate (MCV)	11–12 years; booster dose at 16 years	IM	Syncope in adolescents GBS	History of GBS	
Pneumococcal conjugate (PCV13)	2 months, 4 months, 6 months, and 12–15 months	IM			
Pneumococcal polysaccharide (PPSV)	Not routinely recommended; use in high-risk groups only	IM			Children younger than 2 years
Poliovirus, inactivated (IPV)	2 months, 4 months, 6–18 months, and 4–6 years	IM or SC			Severe allergic reaction to neomycin, streptomycin, or polymyxin B
Rotavirus (RV)	2 months, 4 months, and 6 months (6 month dose not needed if Rotarix was given at 2 months and 4 months)	Oral		Immunosuppression other than SCID Acute, moderate, or severe gastroenteritis Chronic gastrointestinal disease Spina bifida (Rotarix only) Hospitalized infants	Severe allergy to latex (Rotarix only) History of intussusception SCID Children younger than 6 weeks
Varicella (VAR)	12–15 months and 4–6 years	SC	Varicella-like rash within 14 days of vaccine	Receipt of antibody-containing blood product (within up to 11 months); defer for appropriate interval depending on product received (Reference 2) Receipt of antivirals (acyclovir, famciclovir, valacyclovir) 24 hours before vaccination; avoid these for 14 days after vaccination Chronic aspirin use; avoid salicylates for 6 weeks after receipt of varicella vaccine (per manufacturer)	Pregnancy Severe immunodeficiency or immunosuppression Severe allergic reaction to neomycin or gelatin

GBS = Guillain-Barré syndrome; IM = intramuscular; SC = subcutaneous; SCID = severe combined immunodeficiency.

## Diphtheria and Tetanus Toxoids and Pertussis Vaccine

Diphtheria is a toxin-mediated disease that destroys nasopharyngeal tissue and forms membranes covering the pharynx, uvula, tonsils, and soft palate, which can lead to respiratory obstruction. Diphtheria can also involve the skin, conjunctiva, and vulvovaginal area. *Corynebacterium diphtheriae* produces its toxin only when it is infected by a bacteriophage carrying the tox gene. Systemic toxemia caused by toxin absorption can cause myocarditis, peripheral neuritis, and thrombocytopenia. Diphtheria transmission occurs most frequently by person-to-person spread from the respiratory tract. Although diphtheria disease is rare in the United States with only five cases reported since 2000, *C. diphtheriae* continues to circulate in previously endemic areas, particularly Native American communities (Reference 1).

Diphtheria toxoid is an inactivated *C. diphtheriae* toxin adsorbed to aluminum to enhance its immunogenicity. It is only available in combination with either tetanus toxoid or both tetanus toxoid and pertussis vaccine. There are two diphtheria toxoid strengths; the pediatric strength (designated by capital *D*) contains 3–4 times the amount of the adult strength (designated by lowercase *d*). Routine childhood vaccination begins as early as 6 weeks of age and consists of a five-dose series given in combination with tetanus toxoid and acellular pertussis vaccine (as DTaP; see Table 1). Booster doses in combination with tetanus toxoid (Td) are given every 10 years after completion of the childhood series and adolescent Tdap booster because of waning immunity during adulthood.

Tetanus is a toxin-mediated disease acquired from the environment, mainly soil, and is the only vaccine-preventable disease that is not contagious. *Clostridium tetani* spores enter the body, usually through a wound, and germinate in anaerobic conditions, causing the production

of two toxins that act in the central nervous system. One toxin, tetanospasm, blocks neurotransmitter inhibitor impulses, causing severe muscle contractions and spasms. The most common form of tetanus is generalized; it begins with lockjaw and descends downward to affect the neck, esophagus, and abdomen. Additional manifestations include tachycardia, elevated blood pressure, fever, and sweating. Tetanus is rare in the United States, with up to 100 cases reported annually, but it is common in developing countries and often afflicts neonates whose mothers were not immune (References 1, 4).

Tetanus toxoid is a formalin-inactivated toxin that is available as an adsorbed (onto aluminum hydroxide) or non-adsorbed toxoid. The adsorbed toxoid is preferred because it elicits a stronger and longer-lasting immune response (Reference 1). It is available as a single-antigen product, but it is preferable to administer as a combination product with either diphtheria toxoid (as DT or Td) or diphtheria toxoid and acellular pertussis vaccine (as DTaP or Tdap) to provide continued protection against multiple infections with one vaccine dose. The primary childhood series should be given with DTaP (Table 1). Because immunity wanes with time, booster doses should be given as Td every 10 years after the primary series and adolescent Tdap booster. Patients who present with minor or uncontaminated wounds should receive a tetanus booster if it has been 10 years or more since their last tetanus-containing vaccine. Patients with moderate to severe wounds or contaminated wounds should be vaccinated if they have not received a tetanus-containing vaccine in the preceding 5 years. Individuals who experienced an Arthus reaction characterized by severe pain, swelling, and induration within 4–12 hours after a tetanus vaccine should not receive a tetanus-containing vaccine any earlier than 10 years after the last tetanus dose, even for wound management.

**Table 2.** Combination Vaccines and Indications

Vaccine		
Brand Name	Vaccine Components	Indications
Comvax	Hepatitis B, Hib	For doses at 2, 4, and 12–15 months of age
Kinrix	DTaP, IPV	For fifth DTaP dose and fourth IPV dose at 4–6 years of age
Menhibrix	N. meningitidis serogroups C and Y, Hib	For doses at 2, 4, 6, and 12–15 months of age
Pediarix	DTaP, hepatitis B, IPV	For doses at 2, 4, and 6 months of age; not for boosters
Pentacel	DTaP, IPV, Hib	For doses at 2, 4, 6, and 15–18 months of age
ProQuad	MMR, varicella	For 1–12 years of age; consider for only second dose in series
Twinrix	Hepatitis A, hepatitis B	18 years and older; three-dose series

DTaP = pediatric vaccine containing diphtheria and tetanus toxoids and acellular pertussis vaccine; Hib = Haemophilus influenzae type b; IPV = polio virus, inactivated; MMR = measles, mumps, rubella.

Pertussis, or whooping cough, is a highly contagious respiratory tract infection caused by *Bordetella pertussis*. It is spread through respiratory droplets that are inhaled or through direct contact with contaminated secretions that reach the mucus membranes. Toxins released by *B. pertussis* paralyze the cilia on respiratory epithelial cells and promote inflammation within the respiratory tract, which interferes with the clearance of secretions. Classic pertussis occurs in three stages: catarrhal, paroxysmal, and convalescence. The catarrhal stage is characterized by rhinorrhea, sneezing, low-grade fever, and mild cough, lasting 1–2 weeks. The cough progressively worsens until paroxysms of coughing become interrupted with the characteristic “whoop” sound upon inspiration. In this paroxysmal stage, cyanosis and posttussive vomiting and exhaustion are common, lasting for 1–6 weeks. Gradual improvement occurs in the convalescent stage over a few weeks to months. Adolescents and adults typically have a milder and shorter course of illness than do infants and young children.

The incidence of pertussis in the United States has increased since the early 1980s, when around 3000 cases were reported annually (Reference 1). More than 27,000 cases were reported in 2010, the largest number since 1959. Although the highest annual incidence occurs in infants younger than 6 months, 60% of cases are now reported in people 11 years and older (Reference 5). Increased recognition of disease and waning immunity are possible causes for the large number of cases reported in this age group. Mortality, which remains highest in infants younger than 3 months, is usually caused by secondary bacterial pneumonia (Reference 1).

Pertussis vaccines available in the United States are acellular, containing purified subunits of *B. pertussis* such as pertussis toxin, filamentous hemagglutinin, and pertactin. Acellular vaccines are less reactogenic than their predecessor whole-cell pertussis vaccines, which caused more local reactions, fevers, and systemic effects. Whole-cell vaccines are no longer available in the United States but are still used in many countries. Three pediatric acellular vaccines are available (all in combination with diphtheria and tetanus toxoids, as DTaP) that contain different types and amounts of pertussis antigens: Daptacel, Infanrix, and Tripedia. The primary childhood series consists of five doses given at 2, 4, 6, 15–18 months, and 4–6 years (as DTaP). The series should be completed with the same brand of DTaP when possible, but any available brand can be used for continuation or completion of the series. The DTaP vaccines are also available in combination with other vaccines (Pediarix, Kinrix, and Pentacel; refer to Combination Vaccines section and Table 2), each having different administration schedules.

Two adolescent and adult acellular pertussis vaccines in combination with diphtheria and tetanus toxoids (Tdap, as Boostrix and Adacel) are available for use as single booster doses to combat waning pertussis immunity after childhood and subsequent spread to infants. These combination vaccines contain reduced amounts of pertussis antigens (designated by lowercase *p*) compared with the pediatric formulations (designated by capital *P*), but they have an amount of diphtheria and tetanus toxoids identical to the Td booster vaccines. A single Tdap dose is recommended for all children 11–18 years of age regardless of DTaP series completion and for children 7–10 years of age who are not fully vaccinated against pertussis (Reference 6). In addition, Tdap should be given in place of Td for wound management if the patient has not previously received a dose of Tdap. Other patients who should receive a single Tdap dose if they have not had one previously are health care personnel and those in close contact with infants (i.e., those younger than 12 months), including child care providers and new parents (including postpartum women) and grandparents (References 7, 8). There is no minimum interval recommended between receipt of Tdap and the last tetanus- or diphtheria-containing vaccine. After Tdap is received, all subsequent booster doses should be with Td.

### Hib Vaccine

*H. influenzae* is a common bacterial organism that colonizes the respiratory tract and causes minor infections, such as otitis media and sinusitis, or invasive disease such as meningitis, epiglottitis, pneumonia, and sepsis. Transmission is primarily through respiratory droplet spread. *H. influenzae* can be encapsulated with a polysaccharide capsule that contributes to its virulence, or it can be nonencapsulated. *H. influenzae* type b is an encapsulated strain that causes invasive infections in children younger than 5 years and was historically the most common cause of bacterial meningitis. The incidence of invasive Hib disease in the United States has declined by more than 99% since the Hib vaccine was introduced in the late 1980s. Since 1996, less than 100 cases of invasive Hib disease are reported annually in children younger than 5 years (Reference 1).

The Hib vaccines are conjugated vaccines in which polysaccharide capsular components are chemically linked to protein carriers that elicit a T cell-independent immune response that elicits protection in young children. Earlier Hib vaccines consisted of unconjugated polysaccharides that were poorly immunogenic, particularly in children younger than 2 years. Three conjugated vaccines are available: two of them use tetanus toxoid as the protein carrier (ActHIB and Hiberix), and one uses *Neisseria meningitidis* group B outer membrane protein (PedvaxHIB). In addition, three combination

vaccines contain conjugated Hib vaccine (Comvax, Menhibrix, and Pentacel; refer to Combination Vaccines section and Table 2). The primary childhood series is given at 2, 4, and 6 months (with ActHIB) or at 2 and 4 months (with PedvaxHIB), followed by a booster dose at 12–15 months (with ActHIB, Hiberix, or PedvaxHIB). No Hib-containing vaccine should be given to infants younger than 6 weeks because the immune response to subsequent doses is reduced (Reference 1). PedvaxHIB and ActHIB are considered interchangeable and can be given for any of the primary or booster doses; however, if PedvaxHIB is not given at 2 and 4 months, a 6-month dose of either vaccine must be given. Hiberix is only approved for use as the booster dose.

Although Hib vaccines are only recommended for routine use in children younger than 5 years, certain patient populations may be at increased risk of Hib infection. One dose of any Hib vaccine may be beneficial for patients who were not previously vaccinated in childhood and have sickle cell disease or asplenia, human immunodeficiency virus (HIV) infection, certain immunodeficiencies, immunosuppression from cancer chemotherapy, or who received a hematopoietic stem cell transplant (References 1, 2).

### Pneumococcal Vaccines

*Streptococcus pneumoniae* is a common cause of otitis media, sinusitis, pneumonia, bacteremia, and meningitis that is associated with significant morbidity and mortality in children younger than 2 years. Transmission occurs primarily through respiratory droplet spread from person-to-person and through autoinoculation in individuals who carry the organism in their upper respiratory tract. Ninety capsular polysaccharide serotypes have been identified, and the 10 most common serotypes cause more than 60% of invasive disease globally (Reference 1). Pneumococcal antibiotic resistance has escalated in recent years, and protection against invasive pneumococcal infection through vaccination is vital. Since the introduction of the first conjugated 7-valent pediatric vaccine (PCV7) in 2000, there has been a 99% reduction in invasive disease in children younger than 5 years caused by the seven vaccine serotypes and an additional serotype, 6A, for which the vaccine provided cross-protection (Reference 1). Replacement with non-vaccine serotypes (e.g., 19A) has emerged, contributing to increased rates of invasive disease caused by these serotypes and the subsequent introduction of expanded multivalent vaccines (References 9, 10).

Two pneumococcal vaccines are currently available in the United States: a 13-valent pneumococcal conjugate vaccine (PCV13) and a 23-valent pneumococcal polysaccharide vaccine (PPSV23). The vaccines target different patient populations and age groups, and they

are not interchangeable. Although all children younger than 5 years are at increased risk of invasive pneumococcal disease, some factors increase the risk even further. Asplenia, HIV infection, certain racial groups (Alaska natives, African Americans, American Indians), day care attendance, and cochlear implants are independent risk factors for invasive pneumococcal disease.

The PCV13 is a conjugated polysaccharide vaccine that elicits immunity in young children through a T cell-independent antibody response. It contains purified capsular polysaccharide of 13 pneumococcal serotypes (1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F) conjugated to a nontoxic diphtheria toxin. Available beginning in 2010 as a replacement for PCV7, it is administered at 2, 4, and 6 months of age with a booster dose at 12–15 months of age. An additional dose of PCV13 is recommended for children between 14 and 59 months of age who completed their primary pneumococcal vaccine series with PCV7 (Reference 11). Routine use of PCV13 is not recommended for healthy children 5 years and older, but children with certain chronic medical conditions should receive an additional PCV13 dose (administered at least 8 weeks after the most recent pneumococcal vaccine dose) between 14 and 71 months of age. It may also be considered for those up to 18 years old with certain medical conditions who have not received PCV13 previously. These conditions include chronic heart and lung disease, diabetes, sickle cell disease, cochlear implants, HIV infection, and other immunocompromising states.

The PPSV23 vaccine contains capsular polysaccharides from the 23 pneumococcal serotypes that are most prevalent and most associated with antibiotic resistance. Young children do not mount a sufficient immune response to this vaccine, so it cannot be given to children younger than 2 years. A single dose of PPSV23 (administered at least 8 weeks after the most recent pneumococcal vaccine dose) is recommended for children 2 years and older with the following high-risk conditions: chronic cardiovascular or pulmonary disease, diabetes, asplenia or sickle cell disease, cochlear implants, chronic renal failure, or immunocompromising conditions. This dose is in addition to the PCV13 vaccine series recommended above. Antibody response to PPSV23 declines within 10 years of vaccination and can occur within 3–5 years in children. Revaccination with a single dose is recommended for children who remain at highest risk of invasive disease caused by asplenia, immunosuppression, or chronic renal failure; this revaccination consists of one dose given 3–5 years after the first PPSV23 dose (Reference 1).

## Poliovirus Vaccine

Poliomyelitis is a highly contagious viral infection that, although usually asymptomatic, can result in a rapid deterioration to flaccid paralysis that may be permanent. Poliovirus is spread through the fecal-oral route and can be excreted in stool for several weeks after infection, allowing easy spread to household contacts. After the first inactivated poliovirus vaccine (IPV) was introduced in 1955 and after the subsequent introduction of live oral poliovirus vaccine (OPV) in 1961, the incidence of paralytic polio in the United States dropped dramatically from up to 20,000 cases annually to less than 100 in 1965 (Reference 1). The last endemic case of paralytic polio in the United States was reported in 1979, but vaccine-associated paralytic polio continued to occur because of OPV use. In 2000, ACIP recommended eliminating the use of OPV in the United States, but it is necessary to use in areas of the world where poliovirus continues to circulate.

The inactivated poliovirus vaccine, which is the only available polio vaccine in the United States, contains three serotypes that are inactivated by formaldehyde. It elicits a strong immune response but produces less gastrointestinal immunity than OPV and has an unknown duration of protection. The childhood series should be given at 2, 4, and 6–18 months of age with a booster dose at 4–6 years of age. This vaccine is commonly administered in combination with other antigens (as Pediarix, Kinrix, or Pentacel; refer to Combination Vaccines section and Table 2), but it is also available as a single vaccine.

## Rotavirus Vaccine

Rotavirus is a highly contagious virus spread through the fecal-oral route and is the most common cause of gastroenteritis in children worldwide. In the pre-vaccine era, most children were infected in the first 5 years of life. Clinical manifestations of rotavirus infection vary from asymptomatic to mild, watery diarrhea to severe dehydration from vomiting and diarrhea. Severe dehydration from rotavirus infection occurs mainly among children younger than 2 years and is associated with significant mortality in developing countries. Globally, more than 0.5 million deaths occur annually from rotavirus infection and dehydration, but in the United States, only 20–60 deaths occurred annually before routine rotavirus vaccination (References 1, 12). Direct and indirect costs of rotavirus infection were about \$1 billion annually in the United States because of emergency department and physician office visits and subsequent hospitalizations (Reference 1). The first rotavirus vaccine was a tetravalent rhesus-based vaccine introduced in 1998, but it was associated with a markedly increased risk of intussusception and was withdrawn in 1999. In

2006, a rotavirus vaccine was reintroduced that has led to a more than 67% reduction in rotavirus activity and a delay in its seasonal spike pattern by 2–4 months (Reference 12).

Two live oral rotavirus vaccines are available in the United States: RotaTeq and Rotarix. RotaTeq, which contains five live human-bovine reassortant rotavirus strains, became available in 2006. Rotarix, which contains one live attenuated human rotavirus strain, became available in 2008. These vaccines do not completely prevent rotavirus infection, but studies have shown an 85% to 98% reduction in severe gastroenteritis and an 85% to 100% reduction in hospitalizations after vaccination (Reference 1). ACIP does not prefer one rotavirus vaccine over the other because they have similar efficacy and safety data. The administration schedule varies with each vaccine: RotaTeq is given as a three-dose series and Rotarix as a two-dose series, both beginning at 2 months of age with subsequent doses given 1–2 months apart. The maximum age for any rotavirus vaccine dose is 8 months 0 days because the previously reported high risk of intussusception was associated with increasing age at the time of vaccination. Although the vaccines are not considered interchangeable, the vaccine series can be continued or completed with either product. If any dose of RotaTeq is administered in the schedule, a three-dose series must be given. Rotavirus vaccine should not be administered to immunocompromised individuals (and is contraindicated in severe combined immunodeficiency) because it is a live viral vaccine and could cause rotavirus infection in these patients. Rotavirus vaccine can be given to infants living with immunocompromised individuals, and it can be given to infants regardless of antibody or blood product administration.

## Influenza Vaccine

Influenza is a highly contagious viral respiratory infection that causes significant morbidity and mortality among young children and the elderly. It is spread through respiratory droplets that are inhaled or through direct contact with contaminated secretions that reach the mucus membranes. Infection usually occurs during the winter months in the Northern Hemisphere, and although all age groups are affected, children have the highest infection rate. Classic symptoms of influenza in adults include rapid onset of fever, sore throat, myalgia, headache, nonproductive cough, malaise, and rhinitis, whereas children often also experience nausea, vomiting, and otitis media (see Lower Respiratory Tract Infections chapter). Pneumonia is a severe complication that results from primary influenza infection or secondary bacterial infection. Severe illness, hospitalization, and death are most likely to occur in the elderly, children younger than 2 years, and those with underlying conditions, including cardiopulmonary disease and pregnancy.

Recent data estimate that an average of 24,000 deaths occur annually in all age groups from influenza in the United States (Reference 13). The best method of protection against influenza is through vaccination.

Human influenza disease is caused by influenza A and B viruses that circulate concurrently. Influenza A typically causes moderate to severe infection and affects all age groups. It is further subtyped by its surface antigens, hemagglutinin (H) and neuraminidase (N). Human infections typically occur with subtypes categorized as H1–H3 and N1 and N2, but strains that usually infect animals (e.g., H5N1) rarely infect humans. Influenza B usually causes milder infection and infects children more often. It is not subtyped but is categorized as one of two lineages (Yamagata and Victoria) that have been circulating for many years. New influenza virus variants are created by antigenic point mutations that evade host immunity and perpetuate the infectious cycle, known as antigenic drift. This occurs mainly with influenza A and is responsible for seasonal influenza epidemics and the recommendation for annual vaccination with vaccine composed of strains predicted to be circulating during the upcoming influenza season. Antigenic shift occurs when influenza A virus acquires a new hemagglutinin or neuraminidase surface antigen as a result of genetic reassortment; these strains have pandemic potential because they are dissimilar to previously circulating influenza strains.

Two types of influenza vaccine are currently available for prevention of seasonal influenza in children, both of which contain the same viral strains or subunit antigens of two influenza A subtypes and one influenza B strain. One is a trivalent inactivated injectable influenza vaccine (TIV), and one is a trivalent live attenuated influenza vaccine (LAIV) that is cold adapted, allowing virus replication to occur locally in the nasopharynx after intranasal administration. The LAIV strains do not replicate well in warm environments such as the lung. Studies report that LAIV is 32%–58% more protective against culture-confirmed influenza infections than TIV in children 6 months to 17 years of age with no significant differences noted in adults (Reference 14). A trivalent inactivated intradermal vaccine was recently approved for use by the U.S. Food and Drug Administration (FDA) in adults 18–64 years of age, and it is currently being studied in children. Beginning with the 2013–2014 influenza season, a quadrivalent intranasal influenza vaccine containing two A subtypes and two B strains will be available.

Annual influenza vaccination is recommended for all individuals 6 months and older. In addition, children between 6 months and 8 years of age who receive influenza vaccine for the first time should receive two doses in that season, separated by at least 4 weeks (Reference 15). Children between 6 months and 8 years of age who

received only one influenza vaccine dose in their first year of vaccination usually require two doses the following season, but if the vaccine strains are the same both years, only one vaccine dose is needed in the second season (Reference 16). Despite its potentially increased efficacy in children, there are currently no patient populations where LAIV is preferred over TIV. The LAIV is indicated only for healthy, nonpregnant patients between 2 and 49 years of age, whereas TIV can be administered to all patients, including those with high-risk conditions. Many manufacturers produce TIV annually, and each product has different age indications. Clinicians should refer to [www.cdc.gov/flu](http://www.cdc.gov/flu) on an annual basis for published tables listing influenza vaccine products and the age groups indicated for each vaccine because the products vary each year. Historically, influenza vaccine has been contraindicated in individuals with egg allergies, but recent evidence suggests that TIV can be given safely to these patients, and ACIP recommends giving TIV to patients with egg allergies who experience only hives (Reference 16). Individuals who have had a serious reaction to eggs (angioedema, respiratory distress, lightheadedness, recurrent emesis, or required epinephrine or other emergency interventions) should be referred to a health care provider who specializes in allergic conditions before TIV is considered for use.

### Hepatitis A Vaccine

Hepatitis A virus causes a self-limiting acute viral hepatitis characterized by fever, malaise, jaundice, and abdominal pain in adults and older children, but it is often asymptomatic in children younger than 6 years. Chronic infection does not occur with hepatitis A virus, and complications leading to death are extremely rare. Young children serve as a reservoir for the virus because of their lack of symptoms and prolonged viral shedding. Infection occurs by the ingestion of contaminated water or food, through the spread to household contacts by the oral-fecal route, or by direct person-to-person contact. Although hepatitis A is highly endemic in most areas of the world, epidemics of infection occur about every 10 years in the United States, with the last rise reported in 1989 (Reference 1). An estimated 270,000 infections occur annually when asymptomatic infections are considered (Reference 17). Children between 2 months and 18 years of age and people living in Western states have the highest infection rates. Hepatitis A vaccine, introduced in 1995, initially targeted high-risk groups such as international travelers. In 1999, hepatitis A vaccine was recommended for children 2 years and older who lived in areas where hepatitis A rates were twice the U.S. average. Successful reductions in hepatitis A infection rates in these geographic areas led to an expanded recommendation to vaccinate all children (Reference 17).

Hepatitis A vaccine is an inactivated whole-virus vaccine that is available in two pediatric formulations as a single-virus vaccine (Havrix and Vaqta). The two-dose series should begin at 12 months of age, with the second dose given 6–18 months later. The single-virus vaccines are considered interchangeable. Hepatitis A vaccine is also available in combination with hepatitis B vaccine (as Twinrix; refer to Combination Vaccines section and Table 2), but it is only approved for individuals 18 years and older. In addition to use for routine childhood vaccination, hepatitis A vaccine should be considered for any person 1 year and older who is traveling to a country with high or intermediate endemicity, who will be in close contact with an international adoptee from a country with high or intermediate endemicity, who has a clotting factor disorder, or who has chronic liver disease (References 18, 19).

### Measles, Mumps, and Rubella Vaccine

Measles, or rubeola, is a highly contagious viral systemic illness spread through respiratory droplets that leads to viremia and infection of the respiratory tract and other organs. It begins with high temperature, cough, and rhinorrhea before progressing to its characteristic maculopapular rash, which begins at the hairline and spreads downward and outward. Koplik spots, which are pathognomonic for measles, are small blue-white spots that appear on the bright red buccal mucosa near the time the rash appears. Complications of measles include diarrhea and otitis media in children, pneumonia, encephalitis, and, rarely, death. Before the measles vaccination, an estimated 3–4 million cases occurred annually in the United States, with more than 50% of cases reported in children 5–9 years of age (Reference 1). After introduction of the measles vaccine in 1963, the incidence dropped by more than 98% to a nadir of about 1500 cases reported in 1983. However, between 1989 and 1991, a resurgence occurred, with a disproportionate number of cases reported in children younger than 5 years. Immunization efforts were subsequently enhanced in preschool-aged children, and measles was declared eliminated in the United States in 2000. However, up to 200 cases per year are still reported annually in the United States because of importation and spread from foreign countries, where unvaccinated travelers contract the infection and spread it to unvaccinated individuals when they return from travel. In 2011, the United States reported 222 measles cases, mainly caused by unvaccinated individuals who traveled to endemic areas or countries experiencing large outbreaks (Reference 20).

Measles vaccine is a live attenuated viral vaccine that is only available in combination with mumps and rubella vaccine (as MMR) or in combination with varicella vaccine (MMRV; refer to Combination Vaccines

section and Table 2). After administration, it produces a subclinical and noncommunicable infection that results in immunity in 95% of individuals. A second dose provides immunity to 99% of individuals and forms the basis for the two-dose series recommendation implemented in 1989 (Reference 21).

Mumps is a viral illness spread through respiratory droplets that has a nonspecific prodrome of myalgia, headache, and low-grade fever, followed by its characteristic parotitis in 30% to 40% of cases and aseptic meningitis in up to 15% of cases (Reference 1). Orchitis occurs in up to 50% of postpubertal males, and rare complications include pancreatitis, myocarditis, and deafness. After the mumps vaccine was introduced in 1967, the number of reported cases in the United States dropped by 99% and now averages less than 300 cases per year (Reference 1). However, outbreaks continue to occur, mainly among those who are unvaccinated or have received only one dose of mumps vaccine. Infections have also been reported in fully immunized individuals, which may be a result of antigenic diversity between vaccine and circulating strains.

Mumps vaccine is a live attenuated viral vaccine containing the Jeryl Lynn strain that is only available in combination with measles and rubella vaccine (as MMR) or in combination with varicella vaccine (MMRV; refer to Combination Vaccines section and Table 2). After administration, it produces a subclinical and noncommunicable infection that results in immunity in up to 91% of individuals after one dose, but individuals who receive two doses are better protected during outbreaks (References 21, 22). Two doses of a mumps-containing vaccine are now recommended by ACIP.

Rubella, or German measles, is a viral infection that is often asymptomatic but can cause a maculopapular rash, lymphadenopathy, low-grade fever, and mild respiratory symptoms. It is spread through respiratory droplets that are inhaled or through direct contact with contaminated secretions that reach the mucus membranes. Rubella vaccination was developed to prevent congenital rubella syndrome, which occurred in 25% of infants whose mother was infected during the first trimester of pregnancy (Reference 21). Congenital rubella syndrome is characterized by congenital deafness, cataracts or glaucoma, heart disease, microcephaly and mental retardation, and other organ defects. Rubella acquired during pregnancy can also result in miscarriage or stillbirth. After rubella vaccination began in 1969, there was more than a 98% reduction in all reported rubella cases (Reference 1). It is no longer considered endemic in the United States despite reported outbreaks

that occur mainly among unvaccinated Hispanic populations. About five congenital rubella cases a year have been reported since 1980, and increases generally occur after rubella outbreaks.

Rubella vaccine is a live attenuated viral vaccine that is only available in combination with measles and mumps vaccine (as MMR) or in combination with varicella vaccine (as MMRV; refer to Combination Vaccines section and Table 2). More than 95% of people develop immunity after a single dose of rubella vaccine, and most are protected for at least 15 years (Reference 1). At least one dose of rubella-containing vaccine is recommended to be given at 12 months or older.

The MMR vaccine is given as a two-dose series to elicit an immune response in those who did not respond to the first dose. The first dose should be given no earlier than 12 months of age, and the second dose should be given at 4–6 years of age before the child enters elementary school. The second dose can be given as early as 28 days after the first dose. Children between 6 and 12 months of age who are traveling to endemic areas should be vaccinated before travel, but they must be revaccinated with two doses beginning at 12 months or older. Because MMR contains live viruses, it is contraindicated in pregnancy and immunosuppressed patients, except in asymptomatic or mild HIV infection. Measles can be severe in those infected with HIV, so the benefits outweigh the risks of vaccinating people with asymptomatic or mild HIV infection.

### Varicella Vaccine

Varicella is a highly contagious infection caused by varicella zoster virus that is spread by respiratory droplets. Primary infection causes chicken pox characterized by malaise, fever, and characteristic pruritic macules that progress to vesicles, which erupt and crust over during a period of several days (see Skin and Soft Tissue Infections chapter). Secondary bacterial skin infections are a common complication of chicken pox. Adults and immunocompromised individuals have more severe illness, including pneumonia and encephalitis. After the primary infection resolves, the virus becomes dormant in dorsal nerves and can reactivate as herpes zoster, or shingles, creating a pruritic, vesicular rash along a single nerve track. Zoster usually occurs in elderly and immunocompromised individuals after waning immunity to varicella zoster virus. Up to 20% of individuals with zoster develop postherpetic neuralgia, a painful condition that persists for months after the zoster rash resolves. Before the varicella vaccine was introduced in 1995, varicella was endemic in the United States, infecting around 4 million individuals annually, leading to 11,000 hospitalizations and 100 deaths each year (Reference 1). The highest incidence of infection was in children between 1 and 9 years of age, and near-universal infection

occurred by adulthood. Routine varicella vaccination has reduced infection rates by 83% to 93% and hospitalizations and deaths by more than 90% (Reference 1). The impact of varicella vaccination on zoster is not known.

Varicella vaccine is a live attenuated viral vaccine given as a two-dose series to enhance immunity and minimize breakthrough disease that occurs after single doses (Reference 23). It is available as a single vaccine or in combination with MMR (as MMRV; refer to Combination Vaccines section and Table 2). The first dose is given at 12–15 months of age with a second dose at 4–6 years of age, but the second dose can be given as early as 3 months after the first dose (for children younger than 13 years) or as early as 4 weeks (for children 13 years and older). Varicella vaccine is contraindicated in pregnancy and immunosuppressed patients, but it should be considered for children with HIV infection whose CD4 cell percentage is at least 15% (Reference 23). Vaccine-strain varicella can be transmitted by individuals post-vaccination, particularly those who develop a rash; these individuals should avoid contact with high-risk people who are not immune to varicella.

### Meningococcal Vaccine

*N. meningitidis* is a common cause of meningitis and sepsis in children and adolescents in the United States. Most invasive infections are caused by five encapsulated strains designated serogroups A, B, C, Y, and W-135. Infection is spread through respiratory droplets or contaminated secretions. Meningococcal sepsis is associated with up to 40% mortality despite antibiotics and supportive therapy, and about 20% of survivors have permanent sequelae including deafness, neurologic damage, or loss of limbs (Reference 1). Meningococcal disease was reported in up to 2800 cases annually in the United States, but rates have dropped, particularly for infections caused by serogroups C and Y among children 11–14 years of age, since the introduction of the routine adolescent meningococcal vaccine (Reference 1). Individuals 18–21 years of age continue to have high infection rates despite routine adolescent vaccination. Frequent outbreaks of meningococcal disease are reported, mainly caused by serogroup C, but outbreaks make up less than 5% of reported cases.

Three inactivated meningococcal vaccines are available, all containing serogroups A, C, Y, and W-135: one polysaccharide vaccine (Menomune; available since 1978) and two conjugate vaccines (Menactra, available in 2005, and Menveo, available in 2010) that incorporate different protein carriers. The polysaccharide vaccine is poorly immunogenic in children younger than 2 years, and it does not produce long-lasting immunity. Use of this vaccine is no longer routinely recommended for children. Both conjugate vaccines are licensed for individuals between 2 and 55 years of age (Menactra is also

approved for children as young as 9 months of age), but antibody levels wane within 3–5 years of vaccination. In addition, a combination vaccine containing *N. meningitidis* serogroups C and Y and conjugated Hib vaccine (Menhibrix; refer to Combination Vaccines section and Table 2) was approved for use in 2012. Routine primary vaccination with a single dose of conjugate vaccine is recommended at 11–12 years of age, with a booster dose at 16 years of age that is expected to provide immunity through the high-risk adolescent and early adult period (Reference 24). A two-dose primary series, separated by 2 months, followed by a booster dose at 16 years of age is recommended for adolescents with HIV infection because their immune response to a single primary dose is insufficient for protection. Similarly, children 2 years and older with persistent terminal complement deficiency or asplenia should receive a two-dose primary series separated by at least 2 months. For these high-risk populations, booster doses should be given every 5 years. All individuals 9 months of age and older who travel to an endemic area should receive a single meningococcal conjugate vaccine dose before travel. Menactra is recommended for children 9–23 months of age who have complement component deficiencies, who are in a defined risk group for outbreaks, or who are traveling to endemic areas. These patients should receive a two-dose series beginning at 9 months of age, with the second dose given at least 3 months after the first dose.

### Human Papillomavirus Vaccine

Human papillomavirus (HPV) is the most common sexually transmitted disease in the United States and is associated with genital warts, cervical cancer, and other anogenital cancers. More than 100 different types have been identified, but four types are most commonly found to cause genital warts and cervical cancer. Low-risk types HPV 6 and 11 cause 90% of genital warts, and high-risk types HPV 16 and 18 cause 70% of all cervical cancers (Reference 1). Most HPV infections are asymptomatic, which allows viral propagation to occur among unknowing partners. More than 6 million new infections are estimated to occur annually in the United States, most commonly among adolescents and young adults (Reference 1). Although more than 80% of sexually active women have been infected by 50 years of age, HPV infection occurs in at least 20% of men (Reference 1).

Two inactivated HPV vaccines are available, both containing virus-like particles from types 16 and 18: HPV2 (Cervarix) and HPV4 (Gardasil). The HPV4 vaccine also contains virus-like particles from types 6 and 11. Both vaccines were around 95% effective in preventing precancerous lesions from types 16 and 18 in females who were not infected with these types at the time of vaccination (References 25, 26). The HPV4

vaccine was also shown to protect against 90% of genital warts caused by types 6 and 11. It is ideal to vaccinate before HPV exposure through sexual contact, but sexually active females should still be vaccinated. Routine vaccination with HPV2 or HPV4 is recommended for females in a three-dose series between 9 and 26 years of age; the second and third doses should be given 2 and 6 months after the first dose. When possible, the same HPV vaccine should be given for the entire series. The HPV4 vaccine may be given to males between 9 and 26 years of age in an identical dosing fashion to protect against genital warts (Reference 27).

### COMBINATION VACCINES

Combination vaccines reduce the number of injections and increase the chances that the childhood immunization schedule will be completed, particularly for young infants who require several injections at each health encounter. Combination vaccines typically contain components that are given on a similar dosing schedule, and they result in immune responses similar to those of separately administered components. Several combination vaccines are available in the United States, and they have specific administration indications (Table 2). Despite their convenience, these vaccines often cost more than single-component vaccines given separately, and they usually result in higher rates of fever and local skin reactions. One combination vaccine, MMRV, is associated with a higher rate of febrile seizures than MMR and varicella vaccines given separately for the first dose in the series (Reference 28). The ACIP recommends that MMR and varicella vaccines be given separately for the first doses in the series, but MMRV is preferred for the second dose.

### SPECIAL POPULATIONS

#### Immunocompromised

Immunocompromised hosts benefit from vaccines that provide protection against infection, but an individual's response to a vaccine can be altered if given during an immunosuppressed state. All vaccines should be given before immunosuppression, when possible, and live vaccines should not be given to individuals who are significantly immunocompromised. Live vaccines should not be given to patients within 3 months of chemotherapy or to patients receiving immunosuppressive doses of glucocorticoids (2 mg/kg/day of prednisone or equivalent dose of another steroid for at least 2 weeks) (Reference 29). Live vaccines should not be given post-transplantation to patients with solid-organ transplants, but they can be considered 2 years after hematopoietic stem cell transplantation if the child is believed to be immunocompetent (Reference 29). Inactivated vaccines

may be less effective in these populations, but they can be given when immunocompromise is lessened (i.e., at least 6 months post–solid-organ transplant or at least 12 months post–stem cell transplant; 1 month after discontinuing high-dose steroids) (Reference 29). Household contacts of immunosuppressed individuals should receive all routinely recommended vaccines.

### **Pregnancy**

Women who are trying to become pregnant or who are pregnant should receive all routinely recommended vaccines, when possible, to ensure that sufficient antibodies are passed to the fetus to protect the infant after birth. Live vaccines should not be given during pregnancy to avoid the risk of transplacental infection of the fetus. Inactivated influenza vaccine should be given to women who are or will be pregnant during influenza season. Tetanus, diphtheria, and pertussis vaccines should be given to women before pregnancy, when possible, or immediately postpartum. If protection is needed during pregnancy, Tdap may be given if there is a high risk of pertussis; otherwise, Td is preferred. The HPV vaccine is not recommended during pregnancy, but if it is given to a pregnant woman, it should be reported to the manufacturer's vaccine pregnancy registry.

### **VACCINE SAFETY**

Vaccinations are one of the most important public health measures used to prevent disease, but they are not completely free of harm. Although most vaccine adverse reactions are acute, mild, and self-limiting, there are sometimes rarely occurring events that are serious and potentially fatal. Many people have not experienced a time when vaccine-preventable diseases were common in children, and the very low but potential risk of harm from vaccines may be perceived to outweigh their benefit. In the United States, vaccine information statements are required to be provided before vaccinations occur to provide information on the risks and benefits of each vaccine. This provides an opportunity for health care providers to discuss vaccine benefits and risks with patients and caregivers. Public education and vaccine safety surveillance are vital to public confidence in vaccines and the subsequent success of immunization programs.

Vaccine safety is monitored by the CDC and FDA through the Vaccine Adverse Event Reporting System (VAERS), a passive reporting system capturing adverse events that can be reported by health care providers, manufacturers, and the public. Reports to VAERS can occur by mail, by fax, or online at <http://vaers.hhs.gov>. Health care providers are mandated to report specific adverse events that are serious or life threatening. Some vaccine-specific adverse effects are included in Table 1.

### **Mild Reactions**

The most common types of vaccine adverse reactions are local reactions and fever. Pain, swelling, and erythema at the injection site occur after up to 80% of vaccine doses (Reference 1). These reactions are more common with repeated or booster doses because of the presence of preformed antibodies and rapid immune response from previous doses. Local reactions are most common with inactivated adjuvant-containing vaccines, such as those containing diphtheria and tetanus toxoids. Fever, defined as a temperature higher than 100.4°F (38°C), occurs because of cytokine production during the immune response to a vaccine. Fever is most commonly reported after the administration of live virus vaccines. These vaccines can also produce symptoms similar to a mild form of the natural disease they protect against because the administered viruses must replicate to induce immunity. The MMR and varicella vaccines can cause rash and fever within 7–21 days postvaccination, and LAIV can cause mild upper respiratory symptoms similar to the common cold.

Efforts to minimize pain and discomfort from vaccines can benefit both the vaccinee and the parent or caregiver. Effective methods for reducing distress and pain in infants and young children include breastfeeding around the time of vaccination, ingesting 2 mL of 50% sucrose solution 1–2 minutes before vaccination with concomitant pacifier use, holding the child during vaccination, using topical anesthetics such as lidocaine-prilocaine, distracting with toys or videos led by a nurse, or combinations of these interventions (References 2, 30–32). In children 4 years and older, effective methods for reducing distress and pain from vaccines include deep-breathing exercises, child-directed distraction (e.g., music or stories played through headphones), nurse-led distraction, use of topical anesthetics, or combinations of these interventions (References 30, 32). Routine use of acetaminophen or ibuprofen before vaccination is discouraged; this practice does not prevent febrile reactions and may blunt the immune response to vaccines (References 2, 33). These medications can be considered for the treatment of fever or local discomfort that occurs postvaccination.

### **Thimerosal and Autism**

Thimerosal was a commonly used mercury-based vaccine preservative until the late 1990s, when vaccine manufacturers began to produce thimerosal-free products in response to reports that children might receive unacceptably high amounts of mercury through routine vaccines. Methylmercury is neurotoxic at high doses and is found in the environment and in fish; moreover, it accumulates in the body. Ethylmercury is a metabolite of thimerosal whose toxicities are not well studied, but it

has no known limits of exposure and does not accumulate in the body. After concerns arose that thimerosal exposure could cause autism in children, several studies showed that children exposed to thimerosal-containing vaccines did not have a higher autism rate compared with the normal background autism rate, strongly suggesting that there is no association (References 34, 35). Despite a lack of evidence linking thimerosal exposure to autism, all childhood vaccines are now either thimerosal free or contain only trace amounts of mercury (less than 0.3 mcg/0.5 mL), except for the multidose influenza vaccines, which contain 25 mcg of mercury per 0.5 mL.

### Syncope

Syncope after vaccination is a rare adverse event that can lead to considerable complications, including skull fracture and intracranial hemorrhage. It is most likely to occur in adolescents within 15 minutes after vaccination with HPV, Tdap, or meningococcal conjugate vaccines (Reference 2). Adolescents should be vaccinated while seated and encouraged to remain seated for 15 minutes after vaccination to minimize injury, should fainting occur.

### Precautions and Contraindications

Precautions and contraindications are conditions in which vaccines should not be given to avoid adverse events. Precautions are conditions in which there may be an increased risk or increased severity of an adverse event or when there may be a compromised ability for the vaccine to induce immunity. Vaccination is often deferred in these conditions because such conditions are temporary; in some instances, the health care provider may opt to vaccinate the patient because the benefit outweighs the risk. Common precautions for most vaccines include minor acute illnesses with or without fever and mild to moderate local reactions or febrile response to a previous dose of the vaccine. Contraindications are conditions in which there is an increased risk of a serious adverse event; vaccines are rarely administered when contraindications are present. A contraindication for every vaccine is a severe allergic reaction, such as anaphylaxis, to a previous dose of the vaccine or one of its components. Table 1 lists vaccine-specific precautions and contraindications for childhood and adolescent vaccines.

**Table 3. Reliable Vaccine Information Source Web Sites**

Web Site	Source	Types of Information

## VACCINE INFORMATION SOURCES

Health care providers need to stay current with vaccination recommendations and updated schedules to best serve their patients. Many reliable Internet sources are available that provide information on ACIP recommendations, schedules, vaccine safety, and links to other vaccination-related Web sites (Table 3). Many of these sites also provide information for parents or caregivers. Hundreds of Web sites exist that provide incorrect or misleading information on vaccines, so health care providers should direct the public to the proper Web sites for trustworthy vaccine information.

## CONCLUSIONS

Vaccine-preventable diseases are at or near record low rates in the United States because of the successful implementation of routine childhood vaccinations. Health care providers involved in immunization delivery must be knowledgeable about vaccine schedules and recommendations and must evaluate patients for vaccination needs at every health care encounter. Efforts to educate the public about vaccine effectiveness and safety and successful vaccination programs are vital for maintaining widespread immunization coverage and preventing outbreaks of vaccine-preventable diseases.

# CHAPTER 45

## KAWASAKI DISEASE

Jennifer Le, Pharm.D., MAS, FCCP, BCPS (AQ-ID)

### LEARNING OBJECTIVES

1. Assess the risk factors and complications associated with Kawasaki disease (KD).
2. Distinguish the clinical and laboratory features between typical and incomplete KD.
3. Develop a pharmacotherapeutic plan that contains drug name, dose, route, and duration for acute treatment to prevent coronary artery aneurysms.
4. Explain the mechanisms and benefits of intravenous immune globulin and aspirin in the treatment of KD.
5. Develop a pharmacotherapeutic plan for refractory KD.

### ABBREVIATIONS IN THIS CHAPTER

ALT	Alanine aminotransferase
CRP	C-reactive protein
ESR	Erythrocyte sedimentation rate
IVIG	Intravenous immune globulin
KD	Kawasaki disease
TNF	Tumor necrosis factor

### INTRODUCTION

Kawasaki disease (KD) is a multisystem vasculitis of infancy and early childhood classified as a mucocutaneous lymph node syndrome. It is characterized by fever, pleomorphic rash, and a constellation of other symptoms and laboratory abnormalities suggestive of inflammation. The walls of the blood vessels throughout the body become inflamed in patients with KD. Of particular concern, KD may affect the coronary arteries and thereby progress to serious complications, including coronary artery aneurysms or ectasia, which might result in myocardial infarction or sudden death (Reference 1). In fact, KD is the leading cause of acquired heart disease in children in the United States (Reference 2). Furthermore, the reported mortality and recurrence rates of KD are less than 1% and 2%, respectively (References 3, 4).

The current diagnostic criteria for KD consist of clinical symptoms; therefore, diagnosis can sometimes be challenging because of unusual clinical presentations in certain pediatric patients. Nonetheless, early diagnosis

of KD is critical to allow appropriate therapy because prompt treatment initiation has considerably decreased the occurrence of coronary artery aneurysms and associated mortality. The standard therapy for KD consists of intravenous immune globulin (IVIG) and aspirin.

### ETIOLOGY

Although the etiology of KD remains unknown, infectious, immunologic, and genetic factors have been implicated to result in the immune-mediated vascular inflammation and damage observed with the disease (References 5, 6). Selective expansion of specific T-cell receptors on monocytes observed in patients with KD suggests this syndrome is caused by superantigen-producing microorganisms (Reference 7). In addition, the clinical manifestations of fever and rash, seasonal increase in disease incidence during winter and spring months, age distribution (i.e., rare occurrence in infants younger than 6 months, possibly because of passive immunity from residual maternal antibodies), spatial and temporal clustering, and laboratory features suggest an infectious cause (References 1, 8, 9).

Because one infectious source has not been identified definitively, KD appears to result from an immunologic response that is elicited by several infecting organisms (Reference 5). Pathologically, neutrophils predominate in the early course of KD (References 10, 11). This is followed by the formation of large mononuclear cells jointly with CD8<sup>+</sup> T lymphocytes and immunoglobulin A (IgA) plasma cells to stimulate fibroblastic proliferation (Reference 1). In addition to these cells, macrophages, a unique feature evident in KD unlike in other types of vasculitis, contribute to coronary arteritis (References 1, 12).

The striking increase in occurrences of KD in Asian and Asian-American populations and family members suggests the disease has a genetic predisposition (References 13–15). Several genes have been associated with the development of KD, including a single nucleotide polymorphism of the inositol 1,4,5-trisphosphate 3-kinase C gene on chromosome 19q13.2, an array of human leukocyte antigen (HLA) genes, and the angiotensin-1-converting enzyme gene (References 16–19). Furthermore, an increased risk of coronary artery lesions has been observed in patients with the allelic change on the inositol 1,4,5-trisphosphate 3-kinase C gene, possibly because of their heightened T-cell response.

Ethnicity, age, and male sex are the most common risk factors for developing KD. The epidemiologic variation of this syndrome implicates that ethnicity is one risk factor for KD. The incidence of KD is highest among children of Asian or Pacific Islander descent, followed by non-Hispanic African Americans, Hispanics, and whites, respectively (References 9, 20). Up to 90% of KD cases occur in patients older than 6 months and younger than 5 years (References 21, 22). According to the Centers for Disease Control and Prevention, the estimated annual incidence of KD is 17–27 per 100,000 children younger than 5 years in the United States (References 20, 23). Cases of KD are rarely reported in late childhood (older than 12 years) and adulthood. From the Pediatric Health Information System, the median age at first hospital admission for KD is 3.4 years, with 60% aged 1–4 years (Reference 3). Furthermore, in this study, 60% of the patients were male, another risk factor consistently reported by other studies (References 3, 21, 22).

### CLINICAL PRESENTATION

Three clinical phases—acute, subacute, and convalescent—describe the course of KD (Reference 24). The acute phase is marked by fever that usually persists for 1–2 weeks, together with bilateral, nonexudative conjunctivitis; lip and tongue changes (“strawberry” tongue); swelling and erythema of the hands and feet; polymorphous rash; and cervical lymphadenopathy (Reference 1). The resolution of fever completes this acute phase and denotes the beginning of the subacute phase, which occurs in weeks 2 and 3 after the initial

onset of fever (Reference 24). During this phase, patients may experience periungual peeling of fingers and toes, arthritis, arthralgia, diarrhea, vomiting, and thrombocytosis (References 1, 24). Finally, recovery from the clinical symptoms signifies the convalescent phase, which continues until the erythrocyte sedimentation rate (ESR) normalizes (usually during weeks 6–8 of illness) (Reference 24).

### DIAGNOSIS

The signs and symptoms associated with KD are nonspecific; thus, diagnosing KD requires the exclusion of other potential diseases that cause similar clinical presentations. The clinical and laboratory criteria for diagnosing KD, created by Tomisaku Kawasaki in 1967 and updated in 2004, are presented in Table 1. Symptoms may not occur simultaneously, necessitating close monitoring while waiting for clinical presentation. Prolonged, unexplained fever for 5 days or more (the most consistent feature) and at least four other primary clinical signs of mucocutaneous inflammation are required for a diagnosis of typical or classic KD (References 1, 25). However, in the presence of coronary artery disease, only four or fewer primary clinical features, together with fever for 5 days or more, are needed for KD diagnosis. In addition, KD can be diagnosed on day 4 of fever or earlier by an expert clinician when four or more primary clinical symptoms are present. Finally, in a young child with unexplained fever for 5 days or more and any of the principal clinical features, KD should be considered.

**Table 1.** Clinical and Laboratory Signs of Kawasaki Disease (References 1, 25)

Primary Clinical Signs <sup>a,b</sup>	Laboratory Abnormalities
Fever $\geq$ 5 days	Leukocytosis with neutrophilia
Bilateral, nonexudative conjunctivitis	Normocytic, normochromic anemia (appropriate for age)
Changes in lips and oral cavity (cracked, red lips; strawberry tongue; discrete oral vesicles or ulcers)	Thrombocytosis ( $\geq$ 450,000/microliters) after 1–2 weeks of illness onset
Polymorphous rash	Elevated erythrocyte sedimentation rate (ESR, $\geq$ 40 mm/hour) and/or C-reactive protein (CRP, $\geq$ 3.0 mg/dL)
Extremity changes (edema of hands and feet; palmar erythema)	Sterile pyuria ( $\geq$ 10 white blood cells per high-power field)
Cervical lymphadenopathy	Hypoalbuminemia ( $\leq$ 3.0 g/dL)
	Elevated serum aminotransaminases ( $>$ 50 units/L)

<sup>a</sup>Persistent episodes of fever for 5 days or more, with four or more primary clinical features, are diagnostic criteria for classic Kawasaki disease. In the presence of coronary artery abnormalities, fever for 5 days or more and only four or fewer primary clinical signs are required for diagnosis of Kawasaki disease. In addition, Kawasaki disease can be diagnosed on day 4 of fever or earlier by an expert clinician when four or more primary clinical symptoms are present.

<sup>b</sup>Other clinical signs include cardiovascular (coronary artery aneurysms, congestive heart failure, myocarditis, pericarditis, and arrhythmias); diarrhea, vomiting, or abdominal pain; arthritis; central nervous system manifestations (irritability and aseptic meningitis); and mild uveitis.

Although laboratory findings are not required for a diagnosis of typical KD, some are highly suggestive of KD and can be useful for ambiguous cases. Markers for systemic inflammation indicative of KD include elevation of acute-phase reactants (e.g., ESR, C-reactive protein [CRP]) and leukocytosis with a left shift in the white blood cell count. Normocytic, normochromic anemia, sterile pyuria, hypoalbuminemia, and thrombocytosis are other laboratory abnormalities observed in patients with KD (Table 1).

Atypical or incomplete KD occurs when the five clinical diagnostic criteria are not fulfilled, commonly observed in infants younger than 12 months (Reference 26). Infants 6 months or younger with unexplained fever for 7 days or more and no other clinical signs should therefore be assessed for incomplete KD. In addition, children older than 5 years are more likely to have incomplete KD than those aged 1–4 years (Reference 27). The use of laboratory findings and echocardiography proves invaluable in the differential diagnostic workup for incomplete KD (Table 1). The American Heart Association and the American Academy of Pediatrics recommend the use of the following laboratory tests: acute-phase reactants (e.g., CRP, ESR), complete blood cell count, urinalysis by clean catch, serum alanine aminotransferase (ALT) level, and serum albumin (Reference 1). Nonetheless, improvement in the diagnosis of incomplete KD is essential to ensure timely treatment with the goal of minimizing cardiac complications.

## COMPLICATIONS

Although a self-limiting disease, KD can progress to cardiac complications that can result in significant morbidity and mortality. Cardiac sequelae consist of coronary artery aneurysms, congestive heart failure, myocarditis, pericarditis, and arrhythmias. Extensive coronary artery aneurysms (i.e., 8 mm or more) considerably increase the risk of occlusion and myocardial infarction (Reference 28). Prompt initiation of appropriate therapy, particularly within 10 days of fever onset, may prevent cardiac morbidity progression and mortality (Reference 1). Coronary artery aneurysms, the major cardiac complication, occur in one-fourth of untreated children with KD versus 4% with therapy, emphasizing the importance of adequate treatment (Reference 1). Despite treatment, infants younger than 1 year have the highest risk of developing cardiac complications (Reference 29). Additional risk factors for developing coronary artery lesions include male sex, fever for 14 days or more, hyponatremia (less than 135 mEq/L), anemia (hematocrit less than 35%), leukocytosis (more than 12,000/mm<sup>3</sup>), and certain ancestries (American Indians, whites, and non-Hispanics) (References 3, 30, 31). Other complications of KD are peripheral arterial occlusion, painful arthritis or arthralgias usually in the lower extremities, and shock.

Recurrence of KD occurs when the second episode follows the first incident by a minimum of 3 months. The recurrence rate is around 1% to 3%, usually observed within the first 2 years after initial diagnosis (References 22, 30, 32).

## TREATMENT

The severity and range of clinical presentations and potential for serious cardiac complications from KD necessitate hospitalization for diagnostic workup and subsequent treatment. Early diagnosis of KD to allow prompt initiation of appropriate therapy can prevent or ameliorate progression toward cardiac complications, an important goal of therapy. Nonetheless, late diagnosis, defined as more than 10 days after illness onset, has been shown to occur in 16% of patients, especially young infants and incomplete KD cases (Reference 33). Pharmacologic treatment is required for all cases of classic KD as well as for incomplete KD in the presence of an abnormal echocardiograph. Treatment should also be considered in incomplete KD cases without cardiac abnormalities because it may prevent progression to coronary artery aneurysms (Reference 25). Even with adequate treatment, coronary artery aneurysms can still occur in 4% of KD cases (Reference 34).

### Pharmacologic Therapy

The goal of pharmacologic treatment during the acute phase is to alleviate inflammation in the coronary artery wall and prevent coronary thrombosis. In children with coronary aneurysms who require long-term treatment, prevention of myocardial ischemia or infarction is another therapeutic goal (Reference 1). Aspirin and IVIG are the mainstays of KD treatment. From guidelines developed by the American Heart Association and the American Academy of Pediatrics, the standard therapy for KD includes a single dose of IVIG and high-dose aspirin initiated as soon as the diagnosis is made or within the first 10 days of illness. Such therapy optimally decreases the risk of developing subsequent coronary artery aneurysms (Table 2) (References 1, 26, 34, 35). Additional IVIG doses may be needed in patients who do not respond (e.g., fail to defervesce) to initial therapy (Reference 1). Long-term use of antiplatelet and/or anticoagulation therapies may be warranted when the risk of thrombotic events is high, particularly in patients with rapidly enlarging coronary aneurysms.

The anti-inflammatory properties of IVIG, possibly derived from cytokine production modulation, enhanced T-cell suppressor activity, and neutralization of bacterial superantigens, help resolve fever and other acute inflammatory processes in response to disease (Reference 1). In addition, IVIG prevents coronary artery aneurysms, improves left ventricular contractility,

**Table 2.** Treatment of Kawasaki Disease (Reference 1)

Disease Type	Standard Therapy	Additional Therapy	Comment
Newly diagnosed, including incomplete type with cardiac abnormality	IVIG 2 g/kg/day infused over 8–12 hours as a single dose <sup>a,b</sup>	Methylprednisolone 30 mg/kg/day intravenously as a single dose plus standard therapy <sup>c</sup>	IVIG – Toxicities: infusion-related adverse effects, possible transmission of bloodborne pathogens; different brands affect clinical efficacy, but no single product has been proven superior
	PLUS High-dose aspirin 80–100 mg/kg/day orally in four divided doses <sup>a,b</sup> until afebrile for 48–72 hours (or until 14th day of illness), followed by 3–5 mg/kg/day <sup>d</sup> until resolution of acute inflammation markers (total duration ~2 months) <sup>e</sup>	Ibuprofen 5–10 mg/kg every 6–8 hours or naproxen 10–15 mg/kg/day in two or three divided doses for several weeks can be used for prolonged arthritis or arthralgia <sup>f</sup> Clopidogrel 1 mg/kg/day (maximum 75 mg) once daily if allergic to, or intolerant of, aspirin	Aspirin – Toxicities: aminotransaminase elevation, transient hearing loss, and Reye syndrome; annual influenza vaccination recommended; avoid aspirin during acute viral illness (varicella and flu); avoid NSAID therapy in combination with low-dose aspirin
Refractory	IVIG 1–2 g/kg/day infused over 8–12 hours as a second dose <sup>a,g</sup>	Methylprednisolone 30 mg/kg/day intravenously over 2 hours for 1–3 days until symptoms resolve <sup>h</sup> Infliximab 5 mg/kg intravenously over 2 hours as a single dose	Methylprednisolone – Toxicities: cardiac arrhythmias, infarction and arrest at high doses and rapid infusion, decreased lymphocyte and monocyte counts, most other adverse effects (including growth suppression, glucose intolerance) are associated with long-term use  Infliximab – Toxicities: rash, flushing, pruritus, and other dermatologic reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis; hepatotoxicity with particular increase in alanine transferases, transient hepatomegaly; anemia

<sup>a</sup>Anti-inflammatory action.

<sup>b</sup>Initiate immediately upon diagnosis in the acute phase to prevent the development of coronary artery aneurysms.

<sup>c</sup>Consider for cases at highest risk of developing coronary artery aneurysms.

<sup>d</sup>Antiplatelet action.

<sup>e</sup>Duration of aspirin can be indefinite in cases with cardiac abnormalities.

<sup>f</sup>Avoid concurrent use of NSAIDs with low-dose aspirin to maximize the antiplatelet cardioprotective effect of aspirin.

<sup>g</sup>Cumulative doses exceeding 4 g/kg have not been studied.

<sup>h</sup>For continued refractory cases after the completion of two courses of IVIG.

IVIG = intravenous immune globulin; NSAID = nonsteroidal anti-inflammatory drug.

and normalizes serum lipoproteins (References 36, 37). A single high-dose infusion of IVIG at 2 g/kg, compared with low doses over 4–5 days, has been shown to produce a greater decrease in the duration of fever and length of hospital stay as well as faster resolution of laboratory findings for acute inflammation (References 35, 38). Ideally, IVIG should be initiated within the first 10 days after initial symptoms, although data that suggest benefit with earlier treatment within 4–6 days are conflicting (References 39, 40). However, patients who receive a diagnosis of KD on day 3 or 4 of illness are most likely to have very severe disease that warrants immediate treatment to prevent coronary aneurysms. In fact, they may require re-treatment with IVIG. In some

patients with KD, treatment beyond day 10 of illness may be appropriate, particularly in the presence of persistent fever and abnormal cardiac findings.

Different formulations of IVIG vary in biologic effects because they are from donor plasma that undergoes different sterilization processes (Table 3). The risk of coronary artery aneurysms, resolution of fever, and duration of hospital stay differ with brands of IVIG (References 35, 41, 42). Although different brands of IVIG appear to affect clinical outcome, no one brand has been proven superior. Insufficient efficacy data, concerns for fluid overload, product availability, and cost are reasons against exceeding the recommended dose of 2 g/kg, even though IVIG shows a dose-response effect (Reference 38).

Although it does not appear to decrease the development of coronary abnormalities, the anti-inflammatory and antiplatelet activities of aspirin underscore its role in the treatment of KD. Initially, high-dose aspirin (not to exceed 4 g/day) continued until 48–72 hours after fever resolves is recommended to achieve additive anti-inflammatory effects with IVIG. Alternatively, high-dose aspirin can be continued until 14 days after illness onset, with at least 48–72 hours after fever cessation. This is followed by low-dose aspirin for its antiplatelet effect and is continued until resolution of laboratory markers of acute inflammation, or until 6–8 weeks after illness onset to rule out cardiac abnormalities (Table 2). However, in patients who develop coronary abnormalities, aspirin may be continued indefinitely. Although children given diagnoses of KD have decreased aspirin exposure because of reduced absorption and increased clearance, drug monitoring is not necessary. Aneurysm formation and resolution of fever seem to be unaffected by the use of aspirin alone. In fact, most patients who received a single high dose of IVIG without aspirin experienced resolution of fever within 24 hours after completing therapy (Reference 43). Other antiplatelet drugs, including dipyridamole, ticlopidine, and clopidogrel, have been used in KD (Table 2) (Reference 35). Ibuprofen or naproxen may be used for several weeks to treat prolonged arthritis or arthralgia, if present. However, their use should be avoided during low-dose aspirin therapy because they may interfere with the antiplatelet action of aspirin.

Adding methylprednisolone to standard therapy should be considered in KD cases at high risk of cardiac involvement (Table 2) (Reference 44). Factors contributing to significant risk of cardiac abnormalities include CRP of 7 mg/dL or greater, total bilirubin of 0.9 mg/dL or greater, and aspartate aminotransferase of 200 IU/L or greater (Reference 45).

### Refractory Cases

About 10% to 15% of patients treated with standard therapy have persistent or recrudescing fever within 48 hours, placing these patients at a 9-fold increased risk of developing cardiac abnormalities (Reference 29). Fever of any grade is indicative of unresolved vasculitis, and its duration is indicative of coronary artery damage. The risk factors associated with unresponsiveness to standard therapy that therefore necessitate re-treatment are as follows:

- age younger than 1 year,
- early diagnosis with initial treatment after 5 days or less of symptoms,
- bands of 20% or greater, CRP of 8 mg/dL or greater,

- elevation of liver enzymes (ALT of 80 IU/L or greater or  $\gamma$ -glutamyl transferase of 60 IU/L or greater),
- thrombocytopenia (platelet count of 30,000/mm<sup>2</sup> or less), and
- hyponatremia (serum sodium of 133 mmol/L or less) (References 46–49).

To minimize cardiac complications, further therapy should be considered in the presence of any of these risk factors. For patients with persistent or recrudescing fever after receiving standard therapy, additional therapy is necessary and should be initiated at least 36 hours after IVIG completion to allow the exclusion of drug-related fever.

Repeated courses of IVIG or other anti-inflammatory agents for vasculitis, including corticosteroids, inhibitors of tumor necrosis factor (TNF), and plasmapheresis, have been used in refractory cases (Reference 3). In limited studies, re-treatment with a second dose of IVIG 2 g/kg was effective in resolving fever in some patients (References 29, 50, 51). The rationale for re-treatment with IVIG, particularly for the high dose, is because of its dose-response effect (Reference 38). When therapeutic response is not achieved even after two courses of IVIG, methylprednisolone can be used for up to 3 days until symptoms resolve (References 51, 52). For highly resistant KD unresponsive to courses of IVIG and corticosteroids, infliximab (a TNF inhibitor) may be considered (References 53, 54). Other therapies that are not well studied or supported for routine use include pentoxifylline (a methylxanthine that specifically inhibits TNF transcription), plasmapheresis, and cytotoxic agents (cyclophosphamide and cyclosporine) (References 1, 55, 56). Further studies are necessary to understand their benefits in KD, particularly because some of these drugs are associated with significant toxicities.

Surgical intervention may be necessary in some cases, depending on the severity of cardiac abnormalities. Because surgical procedures are beyond the scope of this chapter, more information may be obtained elsewhere (Reference 1).

### Prevention of Coronary Thrombosis

In children with coronary involvement, additional medications may be necessary for thrombosis prevention. In fact, another goal of KD management in patients with coronary abnormalities is to prevent thrombosis. Because platelet activation occurs during all phases of disease, antiplatelet therapy becomes crucial at every stage. The use of antiplatelet, anticoagulation, or combination therapies will depend on the degree of coronary involvement. For mild, asymptomatic cases, low-dose aspirin is recommended. The addition of other antiplatelet drugs

<sup>a</sup>Although products available in the United States are not identical or approved for similar indications, they are generally considered interchangeable. However, some clinically relevant differences may affect product selection (i.e., osmolarity differences, sucrose content, fluid volume, product pH, and IgA content). Ig = immunoglobulin; N/A = not available.

(e.g., clopidogrel and dipyridamole) to low-dose aspirin to further enhance activity through adenosine-5-diphosphate antagonism may be more effective in moderate cases with evidence of enlarged coronary artery aneurysms (Reference 1).

Anticoagulation therapy, particularly in combination with low-dose aspirin, is indicated when the risk of thrombosis is high, as observed in rapidly enlarging coronary aneurysms with abnormal flow conditions and stenoses at the proximal or distal end of the aneurysms. Warfarin with low-dose aspirin is the most common combination therapy used. The targeted range for warfarin's activity is an international normalized ratio of 2.0–2.5 (Reference 1). Because warfarin's full therapeutic effect may take several days, unfractionated heparin may be initiated first to bridge the gap in therapy. Alternatively, low-molecular-weight heparin may be substituted for warfarin, although it requires subcutaneous injections compared with oral administration of warfarin.

## MONITORING OF THERAPY

The targeted therapeutic outcomes for KD are to achieve defervescence, reverse presenting symptoms, normalize any irregular laboratory tests, prevent cardiac abnormalities, prevent coronary thrombosis, and prevent mortality from myocardial infarction or arrhythmias. Hospitalization is required for diagnostic workup and treatment, especially for IVIG administration. Clinical evaluations for the first 2 months after KD diagnosis are needed to obtain information on changes from baseline presentation and treatment response. To ascertain the degree of cardiac involvement, an echocardiogram should be performed within 2 weeks after fever onset and repeated 6–8 weeks later to confirm therapeutic response (Reference 1). As such, referral to pediatric cardiology is required for all patients with KD, particularly after hospital discharge, for close monitoring. Furthermore, additional echocardiographic evaluations are imperative for children at high risk of cardiac effects, including those with persistent fevers or coronary abnormalities. Follow-up echocardiograms every 1–2 years after diagnosis may be warranted to determine the status (e.g., improving or worsening) of coronary aneurysms and to evaluate for other cardiac conditions, including ventricular dysfunction and pericardial effusions. Long-term management of KD depends on the severity of coronary artery involvement and consists of aspirin therapy, anticoagulation, restriction in physical activity, cardiac evaluation, and echocardiogram (Table 4) (Reference 57).

Overall, IVIG is generally well tolerated and less likely to cause adverse effects if infused at the recommended minimum concentration and infusion rate. Infusion-related reactions consisting of flushing, hypotension,

nausea, vomiting, fever, chills, pruritus, malaise, myalgia, and chest tightness have been reported with IVIG administration. These reactions generally occur 30 minutes to 1 hour after initiation of the infusion and usually resolve when the infusion is slowed or temporarily discontinued. Pretreatment with acetaminophen and diphenhydramine may help abate these infusion-related reactions.

Serious adverse effects have been reported with IVIG administration. Anaphylactoid reactions, although rare, are likely to occur in patients who have selective IgA deficiency with serum antibodies to IgA and have not received IVIG within the preceding 8 weeks. Products with the lowest IgA content may be used with caution in these patients (Table 3). In addition, nephrotoxicity, including acute renal failure, as evidenced by increases in serum creatinine and blood urea nitrogen, can occur as soon as 1–2 days after IVIG administration. Reports of renal dysfunction have been mostly associated with the use of IVIG products containing sucrose. Finally, aseptic meningitis syndrome, marked by headache, nuchal rigidity, drowsiness, fever, photophobia, and gastrointestinal intolerance, has been reported from several hours to 2 days after IVIG administration (References 58, 59). Infusion should be ceased in patients displaying aseptic meningitis syndrome or acute hypersensitivity reactions. Epinephrine and diphenhydramine should also be initiated in children with severe hypersensitivity reactions.

Another major concern for the use of IVIG is transmission of bloodborne pathogens, including parvovirus. Once problematic, hepatitis C virus cannot be transmitted under current sterilization methodologies. In addition, antibodies contained in IVIG may interfere with the immune response to certain live virus vaccines (e.g., measles and varicella). As such, these vaccinations should be deferred for at least 11 months in patients receiving IVIG treatment (Reference 60). Repeat immunization is necessary if the live virus vaccine was administered within 14 days before or at the same time of IVIG administration. Other routine childhood vaccinations should be administered, without any alteration, as recommended by the Centers for Disease Control and Prevention.

Patients with KD may be at increased risk of developing adverse effects from aspirin use, consisting of elevation of transaminases, transient hearing loss, and Reye syndrome. Altered protein binding that increases free drug levels as a result of hypoalbuminemia observed in children with KD has been implicated as the potential mechanism for increased toxicity (Reference 44). Children undergoing long-term aspirin therapy should receive their annual influenza vaccine, specifically the inactivated form (Reference 61). Household contacts should also receive their annual influenza vaccine using either the live or inactivated formulations. In addition, aspirin, including the low-dose therapy, should be discontinued in patients with influenza or varicella infection to avoid

**Table 4.** Long-term Management of Kawasaki Disease (Reference 57)

Type of coronary artery abnormality	Management
No coronary artery abnormality, or transient ectasia/dilatation	<ul style="list-style-type: none"> <li>• Low-dose aspirin for 2–3 months</li> <li>• Follow up in 1 year and then at 3- to 5-year intervals for assessment of cardiovascular risk</li> <li>• Normal physical activities</li> </ul>
Small to medium coronary aneurysm (3–6 mm)	<ul style="list-style-type: none"> <li>• Low-dose aspirin until regression is documented with echocardiogram</li> <li>• Physical activities should be guided by biennial stress or myocardial perfusion tests for children ≥ 11 years old (no restriction in those &lt; 11 years old)</li> </ul>
Large coronary aneurysm (> 6 mm)	<ul style="list-style-type: none"> <li>• Low-dose aspirin indefinitely</li> <li>• Warfarin therapy with international normalized ratio at 2.0–2.5 (alternative is subcutaneous low-molecular-weight heparin)</li> <li>• Immediate referral to pediatric cardiologist<sup>a</sup></li> <li>• Cardiac evaluation and echocardiogram every 6 months</li> <li>• Physical activity restricted to stress test results, conducted annually, and level of anticoagulation</li> </ul>
Coronary artery obstruction or ischemia	<ul style="list-style-type: none"> <li>• Evaluate for angioplasty, bypass grafting, stent placement, or cardiac transplantation</li> </ul>

<sup>a</sup>Referral to pediatric cardiology is necessary for all patients with Kawasaki disease, particularly after hospital discharge, for close monitoring. However, immediate referral upon diagnosis of Kawasaki disease is necessary for patients who initially present with significant coronary aneurysm.

Reye syndrome. Furthermore, aspirin should be avoided in the 6 weeks after varicella vaccination. Clopidogrel 1 mg/kg/day (maximum 75 mg) can be temporarily substituted for aspirin in these situations, as well as in patients who are allergic to or intolerant of aspirin. Ibuprofen and other NSAIDs (nonsteroidal anti-inflammatory drugs) should be avoided in combination with low-dose aspirin because of their ability to interfere with the antiplatelet cardioprotective action of aspirin.

Adverse effects for other therapies used in KD are provided in Table 2. Further studies are needed to evaluate the role of corticosteroids as a first-line treatment in conjunction with IVIG and aspirin in certain high-risk KD cases. Other agents, including antioxidants and neutrophil elastase inhibitors, are being evaluated for the treatment of refractory KD, but their efficacy remains unclear.

## CONCLUSIONS

Kawasaki disease is a vasculitis that appears primarily in infancy and early childhood. The current diagnostic criteria for KD consist of clinical symptoms; therefore, diagnosis can sometimes be challenging because of unusual clinical presentations in certain pediatric patients. Aspirin and IVIG are the mainstays of therapy for their anti-inflammatory and antiplatelet effects. Refractory KD cases will require further therapies, including an additional dose of IVIG, corticosteroids, and/or infliximab. Although KD is self-limiting, cardiac

complications can occur that can result in significant morbidity and mortality. Prompt diagnosis and treatment of KD with appropriate follow-up monitoring are critical to improve patient outcomes.

# CHAPTER 46

## ALLERGIES AND ANAPHYLAXIS

*Stephanie D. Natale, Pharm.D.;  
and Nisha N. Shah, M.D., FAAP*

### LEARNING OBJECTIVES

1. Describe the incidence of allergic reactions in children, including allergic rhinitis, food allergies, drug-induced allergies, and anaphylaxis.
2. Illustrate the pathophysiology of the various types of allergic reactions.
3. List risk factors for allergic reactions in children.
4. Explain pharmacologic treatment for various types of allergic reactions.
5. Know adverse reactions and limitations of pharmacotherapy for treatment of allergic reactions.

### ABBREVIATIONS IN THIS CHAPTER

AR	Allergic rhinitis
FGA	First-generation antihistamine
IgE	Immunoglobulin E
INCS	Intranasal corticosteroid
SGA	Second-generation antihistamine
SJS	Stevens-Johnson syndrome

### INTRODUCTION

An allergic reaction is defined as an undesired immunologic response to an allergen. Allergic reactions require a previous sensitization to the offending allergen, which on future exposure gives rise to an immunologic-mediated hypersensitivity reaction. Reactions may manifest as a broad spectrum of symptoms from runny nose to gastrointestinal upset to full airway obstruction and death. Allergic diseases in the United States are increasing, especially in children. With such a widespread scope, it is important to recognize and treat the different types of allergic diseases most prevalent in children to minimize their psychological and medical impact. The focus of this chapter will be allergic rhinitis (AR), drug and food allergies, and anaphylaxis.

### EPIDEMIOLOGY AND ETIOLOGY

Allergic rhinitis is the most common allergic disease in children, affecting up to 40% of children in the United States (References 1–3). Allergic rhinitis is an immunoglobulin E (IgE)-mediated inflammatory immune response, usually to inhaled allergens, in the nasal and sinus passageways. Symptoms may appear seasonally

or persist year-round, depending on the triggering allergen. Its prevalence is almost nonexistent in children younger than 2 years, but it steadily increases, with bimodal peaks during the early school and adolescent periods. Prevalence decreases with age after adolescence (Reference 4). Box 1 shows other associated risk factors for developing AR.

Allergic rhinitis profoundly affects a child's everyday activities, sleep habits, and quality of life. Children with AR are more likely to experience a variety of cognitive and psychiatric issues including poor concentration, attention-deficit/hyperactivity disorder, poor academic and athletic performance during peak pollen season, and low self-esteem (References 8–13). In older children and adults, anxiety and depression rates are higher among those with AR than among those without (Reference 14). Children with AR are also more likely to suffer from other allergic diseases such as asthma and atopic dermatitis. Although AR is not directly associated with fatal reactions, patients with poorly controlled AR are more likely to experience severe and possibly fatal exacerbations of other allergic conditions such as food allergies and asthma (References 13, 15).

Food allergies also profoundly affect children's lives and well-being. They are the most common cause of anaphylaxis in children (Reference 16). Fear of severe reactions, combined with ubiquitous exposure to possible food allergens, causes a high level of anxiety and the presence of social stigmas around children with food allergies. Food allergies involve an immune response to an ingested food and affect anywhere from 4% to 10% of children in the United States (References 17–22). The

#### Box 1. Risk factors associated with allergic rhinitis.

- Family history of allergic diseases
- Male sex
- Birth during the pollen season
- Firstborn
- Early introduction of formula and food (< 6 months)
- Early use of antibiotics
- Maternal smoking exposure in the first year of life
- Exposure to indoor allergens (e.g., dust mites, mold)
- Serum IgE > 100 IU/mL before age 6
- Presence of allergen-specific IgE

IgE = immunoglobulin E.

Adapted from References 5–7.

most common food allergens, accounting for more than 85% of children with food allergies, are peanuts (1% to 2% of all children), milk (1.7%), shellfish (1.4%), tree nuts (1%), and eggs (0.8%) (Reference 22). The most common causes of fatal reaction are peanuts (50% to 62%) and tree nuts (15% to 30%) (Reference 23).

The risk of developing food allergies appears to be greatest in children of Asian or African American descent (Reference 22). The presence of another preexisting allergic disease (e.g., AR, asthma, atopic dermatitis) or a biologic parent or sibling with a history of allergic disease is also associated with an increased risk of developing food allergies (Reference 24).

Allergic reactions from drugs are a subset of adverse drug reactions that are immunologically mediated responses. It is important to distinguish the term *allergic drug reaction* from the more general term *adverse drug reaction*, which may or may not be immune-mediated. The incidence of drug allergies in children is likely to be overestimated because both children and their parents are often unaware of the differences (Reference 25). This can lead to the unnecessary exclusion of a drug class that would otherwise be preferred.

The incidence of allergic drug reactions in the pediatric population is unknown. A 10-year retrospective cohort study found that 51% of all pharmacist-reviewed adverse drug events among hospitalized children were of allergic origin or idiosyncratic (Reference 26). The most common causes of adverse drug reactions in this study were antibiotics (33%), narcotic analgesics (12%), anticonvulsants (11%), and anxiolytic agents (10%). Nonsteroidal anti-inflammatory drugs have also been implicated in an elevated risk of developing Stevens-Johnson syndrome (SJS) (Reference 27).

In the most severe allergic reactions, anaphylaxis may develop. A commonly accepted definition of anaphylaxis is lacking, but it generally includes an acute onset of systemic symptoms involving the skin, respiratory compromise, decreased blood pressure, gastrointestinal

symptoms, and/or other symptoms of end-organ dysfunction (Reference 28). With the increasing prevalence of all pediatric allergies, it is not surprising that anaphylactic allergic reactions are also rising. The mortality from anaphylactic reactions is low, ranging from 100 to 150 cases in the United States per year. However, anaphylaxis causes more than 30,000 emergency department visits each year (Reference 29). Risks of developing anaphylaxis are highest in males, in adolescents, and in children with several allergic diseases (Reference 22). In a series of epidemiologic evaluations of fatalities from anaphylactic reactions, almost all had a positive history for asthma (References 30–33).

## PATHOPHYSIOLOGY

Allergic reactions occur through a variety of immunologically mediated mechanisms. Most allergic reactions may be classified as one of four types of hypersensitivity reactions (Table 1). Although type I hypersensitivity is the only type associated with an IgE response to a drug, food, or other allergen, and is equated with allergic reaction, types II–IV are significant causes of adverse drug events (often interpreted as an allergy by parents) and other common “allergies” such as those to metals, gluten, and topical contact with plants.

Type I hypersensitivity reactions are the immediate reactions usually associated with anaphylaxis. Type I hypersensitivity has a 15- to 30-minute onset and is associated with IgE production in response to a particular allergen. The IgE antibody antigen-mediated degranulation of cells releases histamine, which produces cutaneous, gastrointestinal, respiratory, and cardiovascular symptoms such as flushing, nausea, bronchospasm, and hypotension. First exposure to an allergen does not usually produce enough IgE to create a clinical response; therefore, most patients presenting with a type I reaction are sensitized from a previous exposure (Reference 34).

**Table 1.** Types of Allergic Reactions

Type	Mechanism	Example(s)
I	Allergen binds to specific IgE, which causes degranulation of basophils and mast cells, resulting in release of inflammatory mediators	IgE-mediated anaphylaxis from an antibiotic; localized allergic rhinitis
II	Allergen binds to a cell and elicits an IgG or IgM response to the antigen-cell complex, resulting in cell destruction	Hemolysis secondary to penicillin exposure
III	Antigen-antibody complexes form and deposit on blood vessel walls and in various organs, resulting in complement activation and platelet aggregation	Serum sickness from IVIG
IV	Antigen recognition activates a memory T cell, initiating an inflammatory response	Poison ivy–induced contact dermatitis; gluten sensitivity

IgE = immunoglobulin E; IgG = immunoglobulin G; IgM = immunoglobulin M; IVIG = intravenous immunoglobulin.

Type II hypersensitivity or antibody-dependent cytolytic reactions occur when immunoglobulin M (IgM) and IgG are produced in response to an allergen's binding to a host cell (usually a blood cell). In these cases, the allergen binds as a hapten to a cell and elicits an IgM or IgG response to the allergen-cell complex. For example, penicillin attaches to Coombs-positive red blood cell surface proteins. An IgG then binds to the penicillin and red blood cell protein complex, allowing complement to cross-link and destroy the red blood cell, resulting in hemolytic anemia (References 35, 36). This type of reaction usually targets blood cells and is a common cause of drug-induced agranulocytosis, thrombocytopenia, and hemolytic anemia. The onset of type II hypersensitivity reactions is usually 5–12 hours after drug exposure.

Type III or immune complex hypersensitivities are similar to type II hypersensitivities. In type III, antibody-antigen complexes form and deposit along blood vessels and in various organs and tissues. The complexes may activate complement, cause platelet aggregation, and activate macrophages, all of which result in local tissue damage. Many types of medication-induced kidney and joint damage result from these immune complexes. Examples of these medications include quinine, salicylates, and sulfonamides. Onset is usually 3–8 hours after first exposure but may present as late as 7–10 days.

Type IV, also known as delayed type hypersensitivity, is a reaction caused by memory T-cell recognition of an antigen. Upon antigen recognition, T cells initiate an inflammatory response, resulting in neutrophil and macrophage influx. Onset is 24–48 hours after antigen exposure. Most allergic cutaneous reactions are type IV hypersensitivity reactions. This phenomenon occurs commonly in patients given a  $\beta$ -lactam antibiotic during a concurrent mononucleosis infection (References 22, 36).

## CLINICAL PRESENTATION AND DIAGNOSIS

### Allergic Rhinitis

Clinical manifestations of AR include conjunctivitis, nasal congestion, rhinorrhea, sneezing, cough, wheezing, or headache. Clinical findings may include dark circles under the eyes from sinus congestion (known as allergic shiners) and nasal creases from frequent rubbing of the nose. Diagnosis is largely based on patient history and physical examination. It can be difficult to differentiate symptoms of allergies from congestion and rhinitis secondary to viral illness. Triggers can often be identified when symptoms present concurrently with pollen seasons or exposure to cockroaches, dust, and pets. Symptoms of rhinitis in children younger than 2 years are rarely allergy based because sensitization to environmental allergens takes at least one or

two seasons. Other potential etiologies, such as infection, should be ruled out before considering AR in very young children.

Allergy skin testing may help determine whether a patient's rhinitis is an allergic response and can identify the allergen(s). Skin testing involves introducing an allergen percutaneously by a prick or intracutaneously by intradermal injection. This testing creates an *in vivo* IgE response on mast cells that releases histamine. This creates a wheal and flare that can be measured. However, patients who take commonly prescribed second-generation antihistamines (SGAs) must discontinue them for at least 10 days before testing, and certain skin conditions (e.g., dermatographia) may affect skin test results.

The Allergic Rhinitis and its Impact on Asthma (ARIA) guidelines suggest that AR be subdivided as intermittent or persistent disease and as mild or moderate-severe disease based on the frequency and severity of symptoms as a basis for selecting treatment (Table 2) (Reference 37).

### Food Allergies

Food allergies can manifest as a wide range of symptoms including dermatitis, emesis, diarrhea, abdominal pain, and anaphylaxis. The diagnosis of food allergies is based mainly on symptomatic reports from parents or a clinical history obtained upon acute presentation. A confirmed diagnosis requires a food challenge, but this is not routinely recommended because of the risk of anaphylaxis. Skin testing is a widely used option and was discussed previously. Assays for testing serum for the presence of allergen-specific IgE is another option for diagnosing food allergies, but these are best used as screening tools because the positive presence of IgE may not indicate a true allergy. A positive result simply implies the patient has been sensitized to the food. Patients may use their serum test results as a guide for avoiding or eliminating certain foods from the diet.

### Drug Allergies

Allergic drug reactions can be difficult to diagnose because of their broad and fairly common range of symptoms. However, several criteria may help support an immunologically mediated reaction: (1) the reaction does not resemble the drug's pharmacologic effect; (2) there is a delay, usually ranging from hours to days between the drug exposure and the reaction (unless prior sensitization has occurred, in which case the reaction occurs in minutes to hours); (3) reactions occur with even a small amount of the drug; (4) the symptoms are characteristic of an allergic reaction (e.g., anaphylaxis, pruritus); (5) the reaction resolves after the drug is discontinued; and (6) the reaction can be reproduced on subsequent exposure (Reference 38).

**Table 2.** Allergic Rhinitis and Its Impact on Asthma Classification of Allergic Rhinitis

<b>Intermittent</b>	<i>or</i>	<b>Persistent</b>
Symptoms occur (one of the following): <ul style="list-style-type: none"> <li>▪ &lt; 4 days/week</li> <li>▪ &lt; 4 weeks/year</li> </ul>		Symptoms occur ( <i>both</i> of the following): <ul style="list-style-type: none"> <li>▪ ≥ 4 days/week</li> <li>▪ ≥ 4 weeks/year</li> </ul>
<i>and</i>		
<b>Mild</b>	<i>or</i>	<b>Moderate-Severe</b>
All of the following apply: <ul style="list-style-type: none"> <li>▪ Normal sleep</li> <li>▪ No impairment in daily activities, sports, or leisure</li> <li>▪ No impairment with work or school</li> <li>▪ No troublesome symptoms</li> </ul>		One or more of the following apply: <ul style="list-style-type: none"> <li>▪ Impaired sleep</li> <li>▪ Impaired daily activities, sports, or leisure</li> <li>▪ Impaired performance at work or school</li> <li>▪ Troublesome symptoms</li> </ul>

Adapted from Reference 37.

Drug allergies manifest as a wide variety of symptoms that are associated with specific drugs (Table 3). The most common manifestation of an allergic drug reaction is cutaneous. Although most skin reactions are mild, severe and life-threatening cutaneous reactions can occur, usually in the form of SJS or toxic epidermal necrolysis. Stevens-Johnson syndrome is a widespread rash with characteristic blistering of the mucosal membranes. Fever may be present. Toxic epidermal necrolysis is similar to SJS, but it involves the breakdown of skin layers and subsequent blistering and the sloughing of large areas of skin.

Skin testing can be a useful diagnostic tool; however, penicillin is one of the few agents used in the skin test with a well-validated predictive value. Skin testing is most appropriate for patients with a history of severe type I penicillin reactions or a vague history of penicillin reactions. The methods for diagnosing drug allergies are similar to those for food allergies because the diagnosis is based heavily on symptoms at acute presentation and clinical history. Skin testing may assist in diagnosis, but only penicillin and a limited number of other protein-based agents (e.g., insulin) have well-validated predictive values. A positive response to a skin test indicates that the patient has specific IgE antibodies, but its correlation to a clinical allergic reaction is unclear. Assays for the presence of serum IgE are available, but as with food allergies, their clinical application is limited (Reference 39).

### Anaphylaxis

Anaphylaxis is a systemic allergic reaction that occurs within minutes to hours after allergen exposure. The more severe the reaction, the more quickly it will occur. The first signs are often warm skin with flushing, itching, and a tingling sensation. Skin examination reveals the classic wheal and flare associated with urticaria. In

mild reactions, the skin is often the only organ involved. The upper airway is the second most commonly involved organ, especially if the patient also suffers from AR or asthma. Angioedema of the tongue, pharynx, larynx, and uvula can lead to shortness of breath, voice hoarseness, and rarely apnea.

Symptoms of wheezing and airway edema occur as the reaction progresses to the lower airways. Patients with underlying asthma have more severe bronchoconstriction and lower airway symptoms. A similar process of intestinal edema can result in nausea, vomiting, and abdominal pain. Tachycardia or cardiac arrhythmias may manifest with dizziness and chest pain. Even after initial symptoms resolve, in severe cases a biphasic response can occur 6–8 hours after allergen exposure. Therefore, after any anaphylactic event, the patient should be closely observed for at least 6 hours. Rapid decline in blood pressure is the most worrisome complication of anaphylaxis. Patients can experience rapid vasodilation and collapse of the circulatory system. Most fatal anaphylactic reactions occur within minutes of exposure and involve laryngeal or pulmonary edema.

Diagnosis is primarily based on history and physical examination; however, some laboratory tests can aid in diagnosis. Serum tryptase, a mediator released from mast cells, is elevated in anaphylaxis. Blood should be drawn within 6 hours of symptom onset because tryptase has a 2- to 6-hour half-life. Histamine and *N*-methylhistamine can be measured in urine samples several hours after symptom onset. Plasma histamine is not practical to measure because its half-life is about 2 minutes. Identifying the causative allergen is very important to patient education on avoiding triggers. In rare cases of idiopathic anaphylaxis, the causative agent is never identified, yet these patients often have a history of atopy.

**Table 3.** Common Manifestations of Drug Allergies

Manifestation	Clinical Symptoms	Common Causative Agents
Anaphylaxis (type I reactions)	A rapid onset of cutaneous symptoms associated with respiratory compromise, low blood pressure, and/or persistent gastrointestinal symptoms	Penicillins, cephalosporins
Serum sickness (type III reactions)	Fever, malaise, and lymphadenopathy occurring 1–2 weeks after drug exposure. Cutaneous symptoms such as urticaria and rash may/may not be present.	Penicillins, sulfonamides, cephalosporins, radiocontrast dyes
Drug-induced autoimmune disorders (hemolytic anemia, nephritis, hepatitis) (type II reactions)	Arthralgias, myalgias, polyarthritis, and specific organ involvement (e.g., proteinuria, elevated transaminases, jaundice)	Phenytoin, penicillin, sulfonamides
Respiratory	Rhinitis, asthma	NSAIDs, aspirin
Cutaneous	Mild to severe rash, blistering of the mucosal membranes	Penicillins, cephalosporins, NSAIDs, phenytoin, carbamazepine

NSAIDs = nonsteroidal anti-inflammatory drugs.

## TREATMENT

### Allergic Rhinitis

The goal of AR treatment is to minimize or prevent symptoms so that quality of life and cognitive function are improved. Initial treatment of AR should always be removing or avoiding the offending allergen. This can be managed by performing more frequent and thorough household cleanings, remaining indoors as much as reasonably possible during peak pollen seasons, and avoiding pets, cigarette smoke, perfumes, and poor air-quality conditions (Reference 40). Box 2 lists avoidance techniques for common specific allergens. Although these are likely the safest and most cost-effective options for managing allergies, they require significant lifestyle changes for both patients and their families.

The histamine-1 (H1)-antihistamines (e.g. diphenhydramine) function as direct competitive inhibitors between histamine and the H1-receptors. The H1-antihistamines are effective, inexpensive, and convenient therapy for alleviating the sneezing, itching, rhinorrhea, and conjunctival symptoms of AR. For children with only mild, intermittent symptoms of AR, H1-antihistamines are preferred on an as-needed basis. Nonsedating second-generation antihistamines (SGAs), such as loratidine, cetirizine, and fexofenadine, are strongly preferred over first-generation antihistamines (FGAs) (References 42, 43). The sedating effects of the FGAs can further diminish cognitive function in children affected with AR (Reference 42). If symptoms are present for more than 4 days/week or for more than 4 weeks/year, or if they begin to affect daily activities, advancing

therapy should be considered. See Table 4 for an algorithm on the ARIA guidelines for AR treatment. Dosing recommendations for the various antihistamines are found in Table 5.

First-generation antihistamines have a significant adverse effect profile because they are lipophilic and readily cross the blood-brain barrier, resulting in sedation and cognitive impairment. They are also powerful anticholinergic agents that help alleviate symptoms such as runny, watery nose and eyes, but can cause other undesired effects such as sedation, difficulty urinating, constipation, and dry mouth. A paradoxical hyperstimulation, in addition to seizures, arrhythmias, and apnea, has led the U.S. Food and Drug Administration to recommend that over-the-counter cough and cold medications, including antihistamines, not be used in children younger than 2 years. Manufacturers of some over-the-counter cough and cold medications have taken this recommendation a step further, in accordance with the American Academy of Pediatrics' stricter position, and labeled these products as not for use in children younger than 4 years. First-generation antihistamines should not be used to sedate or promote sleep in children younger than 12 years. For the adolescent population, it is important to educate patients and parents about associated residual daytime sedation caused by a slow elimination of active metabolites.

Second-generation antihistamines are generally preferred over FGAs because they do not have the same central nervous system effects. They are lipophobic, thereby limiting penetration across the blood-brain barrier. Second-generation antihistamines are also preferred

## Box 2. Avoidance techniques for common allergens that cause allergic rhinitis.

---

### Pollen

- Stay inside and keep windows and doors closed during the pollen season.
- Shower and wash clothes after outdoor activities.
- Dry clothes and bedding indoors.

### Mold

- Clean indoor moldy surfaces with 5% bleach; then dry thoroughly.
- Keep damp areas of the house well ventilated and clean regularly.
- Fix and seal all leaky faucets and pipes.
- Avoid carpet on concrete or damp floors.

### Dust Mites

- Use “allergen-proof” covers on all pillows, mattresses, and box springs.
- Wash bedding in hot water (at least 130°F) weekly.
- Maintain an indoor humidity < 50%.
- Remove or minimize carpets and/or upholstered furniture in bedrooms.
- Wash or dry clean throw rugs on a regular basis.
- Remove or minimize any stuffed animals or toys.
- Use a vacuum with a HEPA (high-efficiency particulate air) filter or a double-layer bag.

### Animals

- Remove the pet from the home, if possible.
- Do not allow pets into bedrooms.
- If possible, do not allow pet on/near carpet or upholstered furniture.
- Have a nonallergic relative clean the animal’s house, litter box, and/or cage.

### Cockroaches

- Seal off any area where a cockroach could potentially enter the home.
- Fix and seal all leaky faucets and pipes.
- Keep food and garbage in tightly sealed containers and put pet food away as soon as pets are finished eating.
- Take out garbage and recyclables regularly.
- Wash dishes immediately after use.
- Clean under stoves, refrigerators, and toasters regularly. Wipe off all kitchen surfaces on a regular basis.

### Smoke

- Avoid smoking during pregnancy.
- Do not allow smoking inside the house or car.
- Do not allow smoking around the allergic child.
- Avoid wood-burning stoves, fireplaces, or fires.

### Insect Stings

- Stay away from nests.
- Have any nests around the home destroyed.
- Remain calm and move away slowly if stinging insects are close by.
- Avoid brightly colored clothing and perfume.
- Keep food and drinks covered outdoors.
- Avoid loose-fitting clothes, open-toed shoes, or going barefoot.

---

Adapted from Reference 41.

**Table 4.** Algorithm for Allergic Rhinitis Treatment

Intermittent Allergic Rhinitis		Persistent Allergic Rhinitis	
Mild	Moderate-Severe	Mild	Moderate-Severe
Allergen avoidance Select one or more of the following based on symptoms and tolerability: <ul style="list-style-type: none"> <li>▪ Antihistamine (oral or nasal) or leukotriene inhibitor</li> <li>▪ Mast cell stabilizer</li> </ul> If conjunctivitis, consider an intraocular agent based on symptoms	Allergen avoidance Intranasal corticosteroid ± antihistamine (second-generation or nasal) or leukotriene inhibitor If nasal congestion, consider a short-term nasal decongestant. If rhinorrhea, consider ipratropium. If conjunctivitis, consider an intraocular agent based on symptoms. Consider immunotherapy if (any of the following): <ul style="list-style-type: none"> <li>▪ prolonged season or symptoms induced by succeeding pollen seasons</li> <li>▪ lower airway symptoms</li> <li>▪ insufficiently controlled symptoms on maximal therapy</li> <li>▪ patient does not want to be on constant or long-term pharmacotherapy</li> <li>▪ pharmacotherapy induces undesirable adverse effects</li> </ul> Consider omalizumab if ≥ 12 years, nonresponsive to previous therapies, and/or immunotherapy is undesirable.		

Adapted from References 37, 43.

over the FGAs because they can be dosed less frequently. Cost can be a deterrent with the SGAs, however, because they are considerably more expensive than the FGAs.

Because neither FGAs nor SGAs affect nasal congestion, both are less effective as monotherapy than intranasal corticosteroids (INCSs). Second-generation antihistamines may be used as a primary therapy for mild, intermittent AR but should be reserved as an adjunctive treatment for moderate-severe intermittent or mild-severe persistent symptoms. The evidence is unclear whether an H<sub>1</sub>-antihistamine in addition to an INCS offers more effective symptom management than an INCS alone, and the decision to add one of these agents should be based on a patient's symptoms and tolerance.

An intranasal antihistamine spray (azelastine or olopatadine) offers an alternative route of administration if a child does not tolerate oral antihistamines. The adverse effect profile is minimal as long as the drug is not swallowed, although a bitter taste may make it an unattractive option for many children. Intranasal antihistamines are inferior to INCSs as a monotherapy for persistent and/or moderate to severe AR, but they may be considered for mild, intermittent AR (Table 4).

The ARIA guidelines support the use of an INCS as the first-line therapy after allergen avoidance for persistent AR and moderate-severe intermittent AR

(Reference 37). The superior efficacy of INCSs over H<sub>1</sub>-antihistamines is supported by extensive literature (References 13, 53–55).

Intranasal corticosteroids inhibit the recruitment of inflammatory cells and the release of proinflammatory mediators. Therapy is best initiated before allergen exposure, but if symptoms are already troublesome, the maximal dose for age should be used initially until symptoms are adequately controlled. Once the child's symptoms are controlled, a step-down therapy should be employed to the lowest effective dose. Efficacy does not vary markedly between the various INCSs (Table 5).

Adverse effects of INCSs include mainly local irritation (dryness, burning, and irritation); however, a major concern, especially for the long-term treatment of children, is hypothalamic-pituitary-adrenal axis suppression and growth retardation. Although substantial evidence exists to suggest that these agents have a minimal effect on growth rates, some literature suggests the preferred use of the newer INCSs with low-to-undetectable bioavailability in children to minimize any potential long-term effects (References 13, 56–58). Table 6 lists the bioavailability of available INCSs. Oral corticosteroids carry a significant adverse effect profile and are not preferred for the routine treatment of AR.

Decongestants (such as pseudoephedrine) are highly effective for relieving nasal congestion. They act by vasoconstriction through  $\alpha$ -receptor stimulation. Oral

**Table 5. Pharmacologic Agents for Allergic Rhinitis Management**

Medication	Pediatric Dosing	Adolescent and Adult Dosing
<b>First-Generation Antihistamines</b>		
Brompheniramine	2–5 years: 1 mg PO every 4–6 hours 6–11 years: 2 mg PO every 4–6 hours	≥ 12 years: 4 mg PO every 4–6 hours
Chlorpheniramine maleate	2–5 years: 1 mg PO every 4–6 hours 6–11 years: 2 mg PO every 4–6 hours (not to exceed 12 mg/day) or extended release: 8 mg PO every 12 hours Alternative dosing: 0.35 mg/kg/day PO divided every 4–6 hours	≥ 12 years: 4 mg PO every 4–6 hours or extended release: 8–12 mg PO every 12 hours; not to exceed 24 mg/day
Clemastine fumarate (Tavist)	< 6 years: 0.11–0.34 mg PO every 8–12 hours, not to exceed 1.34 mg/day 6–11 years: 0.34–0.67 mg PO every 12 hours, not to exceed 4.02 mg/day	≥ 12 years: 0.67–1.34 mg PO every 8–12 hours, not to exceed 8.04 mg/day
Diphenhydramine (Benadryl)	2–5 years: 6.25 mg PO/IM/IV every 4–6 hours, not to exceed 37.5 mg/day 6–11 years: 12.5–25 mg PO/IM/IV every 4–6 hours, not to exceed 150 mg/day Alternative dosing: 1 mg/kg PO/IM/IV every 4–6 hours, up to 50 mg/dose	≥ 12 years: 25–50 mg PO/IM/IV every 4–6 hours, not to exceed 300 mg/day
<b>Second-Generation Antihistamines</b>		
Cetirizine (Zyrtec)	6–12 months: 2.5 mg PO once daily 12 months–5 years: 2.5 mg PO every 12–24 hours	≥ 6 years: 5 mg PO every 12–24 hours or 10 mg PO once daily
Desloratadine (Clarinex)	6–11 months: 1 mg PO once daily 1–5 years: 1.25 mg PO once daily 6–11 years: 2.5 mg PO once daily	≥ 12 years: 5 mg PO once daily
Fexofenadine (Allegra)	6–23 months: 15 mg PO every 12 hours 2–11 years: 30 mg PO every 12 hours	≥ 12 years: 60 mg PO every 12 hours or 180 mg PO once daily
Levocetirizine (Xyzal)	6 months–5 years: 1.25 mg PO once daily 6–11 years: 2.5 mg PO once daily	≥ 12 years: 5 mg PO once daily
Loratadine (Claritin)	2–5 years: 5 mg PO daily	≥ 6 years: 10 mg PO once daily
<b>Oral Decongestants</b>		
Pseudoephedrine (Sudafed)	Not recommended for children < 2 years 2–5 years: 15 mg PO every 6 hours, not to exceed 60 mg/day 6–12 years: 30 mg PO every 6 hours, not to exceed 120 mg/day	≥ 12 years: 60 mg PO every 6 hours as needed or extended release: 120 mg PO every 12 hours or 240 mg PO once daily
Phenylephrine (Sudafed PE)	4–6 years: 2.5 mg PO every 4 hours, not to exceed 15 mg/day 7–12 years: 5 mg PO every 4 hours, not to exceed 30 mg/day	≥ 12 years: 10 mg PO every 4 hours, not to exceed 60 mg/day
<b>Topical Decongestants</b>		
Naphazoline 0.05% (AK-Con)	6–12 years: 1 drop or spray in each nostril every 6 hours as needed Therapy should not exceed 3–5 days.	≥ 12 years: 1 or 2 drops or sprays in each nostril every 3–6 hours as needed Therapy should not exceed 3–5 days.
Phenylephrine (Little Noses, Sinex)	0.16% solution: ≥ 6–11 months: 1 or 2 drops in each nostril every 3 hours as needed 0.125% solution: 1–5 years: 2 or 3 drops in each nostril every 4 hours as needed 0.25% solution: 6–11 years: 2 or 3 drops in each nostril every 4 hours as needed Therapy should not exceed 3–5 days.	0.25% to 0.5% solution: ≥ 12 years: 2 or 3 drops or 1 or 2 sprays in each nostril every 4 hours as needed Therapy should not exceed 3–5 days.

*(Continued)*

**Table 5. Pharmacologic Agents for Allergic Rhinitis Management** *(Continued)*

Medication	Pediatric Dosing	Adolescent and Adult Dosing
Oxymetazoline 0.05% (Afrin)	≥ 6 years: 2 or 3 drops or sprays in each nostril every 12 hours Therapy should not exceed 3–5 days.	
Xylometazoline 0.1% (Sinusal)	≥ 12 years: 2 or 3 drops into each nostril every 8–10 hours as needed Therapy should not exceed 3–5 days.	
<b>Nasal Corticosteroids</b>		
Beclomethasone (Beconase AQ) 42 mcg/spray	≥ 6 years: 1 or 2 sprays in each nostril every 12 hours After symptoms are controlled, titrate to lowest effective dose.	
Budesonide (Rhinocort Aqua) 32 mcg/spray	6–11 years: 1 or 2 sprays in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.	≥ 12 years: 1–4 sprays in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.
Ciclesonide (Omnaris) 50 mcg/spray	> 6 years: 2 sprays in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.	
Fluticasone propionate (Flonase) 50 mcg/spray	≥ 4 years: 1 or 2 sprays in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.	Adult: 2 sprays in each nostril once daily Alternative dosing: 1 spray in each nostril every 12 hours After symptoms are controlled, titrate to lowest effective dose.
Fluticasone furoate (Veramyst) 27.5 mcg/spray	≥ 2 years: 1 or 2 sprays in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.	
Flunisolide (Nasarel) 29 mcg/spray	6–14 years: 1 spray in each nostril every 8–24 hours Alternative dosing: 2 sprays in each nostril every 12 hours, not to exceed 4 sprays/nostril/day After symptoms are controlled, titrate to lowest effective dose.	≥ 15 years: 2 sprays in each nostril every 8–12 hours, not to exceed 8 sprays/nostril/day After symptoms are controlled, titrate to lowest effective dose.
Mometasone (Nasonex) 50 mcg/spray	2–11 years: 1 spray in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.	≥ 12 years: 2 sprays in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.
Triamcinolone (Nasacort AQ) 55 mcg/spray	2–5 years: 1 spray in each nostril once daily 6–11 years: 1 or 2 sprays in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.	≥ 12 years: 1 or 2 sprays in each nostril once daily After symptoms are controlled, titrate to lowest effective dose.
<b>Nasal Antihistamine</b>		
Azelastine (Astelin) 0.1% intranasal solution	5–11 years: 1 spray in each nostril every 12 hours	≥ 12 years: 1 or 2 sprays in each nostril every 12 hours
Olopatadine (Patanase) 6% intranasal solution	6–11 years: 1 spray in each nostril every 12 hours	≥ 12 years: 2 sprays in each nostril every 12 hours
<b>Nasal Mast Cell Stabilizer</b>		
Cromolyn (NasalCrom)	≥ 2 years: 1 spray in each nostril every 6–8 hours	
<b>Nasal Anticholinergic</b>		
Ipratropium (Atrovent) 0.03%, 0.06%	0.03%: ≥ 6 years: 2 sprays in each nostril every 8–12 hours 0.06%: ≥ 5 years: 2 sprays in each nostril every 6–8 hours	

Medication	Pediatric Dosing	Adolescent and Adult Dosing
<b>Ophthalmic Antihistamines</b>		
Azelastine (Optivar) 0.05% solution	≥ 3 years: 1 drop into each affected eye every 12 hours	
Emedastine (Emadine) 0.05% solution	≥ 3 years: 1 drop into each affected eye up to four times/day	
<b>Ophthalmic Antihistamines/Decongestant Combinations</b>		
Antazoline 0.05% + naphazoline 0.05% (Vasocon-A) solution	≥ 6 years: 1–2 drops into affected eye(s) as needed, not to exceed four times/day	
Pheniramine 0.3% + naphazoline 0.025% (Naphcon-A) solution	≥ 6 years: 1 or 2 drops into affected eye(s) as needed, not to exceed four times/day	
<b>Ophthalmic Antihistamine/Mast Cell Stabilizers</b>		
Ketotifen (Zaditor) 0.025% solution	≥ 3 years: 1 drop into lower conjunctival sac of affected eye(s) twice daily at an interval of 8–12 hours	
Olopatadine 0.1% (Patanol) solution	≥ 3 years: 1 drop into each affected eye twice daily at an interval of 6–8 hours	
Olopatadine 0.2% (Pataday) solution	≥ 3 years: 1 drop into each affected eye once daily	
<b>Ophthalmic Mast Cell Stabilizers</b>		
Cromolyn (Crolom) 4% solution	≥ 4 years: 1 or 2 drops in affected eye(s) every 4–6 hours	
Lodoxamide (Alomide) 0.1% solution	≥ 2 years: 1 or 2 drops in affected eye(s) every 6 hours for up to 3 months	
Nedocromil (Alocril) 2% solution	≥ 3 years: 1 or 2 drops in affected eye(s) every 12 hours	
Pemirolast (Alamast) 0.1% solution	≥ 3 years: 1 or 2 drops in affected eye(s) every 6 hours	
<b>Ophthalmic Nonsteroidal Anti-inflammatory Drugs (NSAIDs)</b>		
Ketorolac (Acular) 0.5% solution	≥ 3 years: 1 drop in affected eye(s) every 6 hours	
<b>Leukotriene Inhibitors</b>		
Montelukast (Singulair)	6 months–5 years: 4 mg PO once daily 6–14 years: 5 mg PO once daily	≥ 15 years: 10 mg PO once daily

IM = intramuscularly; IV = intravenously; PO = orally.  
Adapted from References 44–52.

decongestants are widely available over-the-counter both as single agents and combined with antihistamines (Table 5). Because of significant adverse effects (e.g., insomnia, agitation, urinary retention), they are recommended only for the temporary relief of nasal obstruction (References 37, 43). Topical decongestants generally have fewer adverse effects than oral agents, but topical agents should not be used for more than 5 days. Therapy extending beyond 5 days can result in rebound congestion and overall worsening of symptoms.

Mast cell stabilizers are available over-the-counter (as cromolyn nasal spray) and by prescription (as several ophthalmic solutions). They are most effective if initiated before the start of allergen exposure and may take up to 2–4 weeks for full effectiveness if begun after symptoms develop. Their efficacy is less than that of INCSs or antihistamines; they may therefore be an option for children who cannot tolerate these other therapies. In addition, they have an excellent safety profile, causing mainly local irritation; however, their frequent dosing (Table 5) limits their practicality in children.

**Table 6.** Bioavailability of Intra-nasal Corticosteroids

Medication	Bioavailability (%)
Beclomethasone	44
Fluticasone propionate	< 2
Flunisolide	50
Triamcinolone	< 1
Mometasone	< 0.1
Ciclesonide	< 1
Budesonide	34
Fluticasone furoate	< 1

Montelukast (Singulair) is the only leukotriene inhibitor approved for treating AR (Table 5). Leukotriene inhibitors are competitive antagonists that prevent the binding of cysteinyl leukotrienes (proinflammatory mediators released by eosinophils and mast cells) to the CysLT<sub>1</sub> receptor, thus inhibiting inflammatory reactions in the upper respiratory passageways. Some evidence suggests that leukotriene inhibitors are as efficacious as H<sub>1</sub>-antihistamines for relieving nasal symptoms, although less so than INCSs (References 43, 63). They may carry an additional benefit in patients with asthma because they also inhibit airway smooth muscle contraction. Montelukast is generally well tolerated with minimal adverse effects. Its safety in children is well supported, with most adverse effects reported as mild headache, ear infection, and nausea (Reference 56). However, leukotriene inhibitors carry a considerable drug cost, and they are not recommended over an H<sub>1</sub>-antihistamine. Some benefit may occur in patients with concomitant asthma, but the role of leukotriene inhibitors in AR has yet to be defined (Reference 43).

Ophthalmic therapies are excellent options for patients with conjunctivitis symptoms (Table 5). They act locally, often with minimal adverse effects aside from local irritation. These are excellent options for children with symptoms limited to the eye area.

Ipratropium (Atrovent) is an anticholinergic agent that relieves rhinorrhea (Table 5). When applied topically, it has an antisecretory effect but does not offer relief for other symptoms. Because ipratropium is a topical agent, it has a minimal adverse effect profile, with the most common adverse effects being epistaxis and nasal dryness.

Immunotherapy should be reserved for patients with severe symptoms not well controlled under standard therapy. It consists of subcutaneous injections or sublingual tablets of diluted allergen extracts given at frequent intervals and increasing in concentration during

the course of therapy. Over time, the patient's immune system becomes tolerant of the allergens and stops producing hypersensitivity reactions.

Although well established in adults, the efficacy and safety of immunotherapy is controversial in the pediatric population (Reference 13). Immunotherapy can result in life-threatening anaphylactic reactions, requiring that most treatments be administered in an office setting with an adequate observation period. The ARIA guidelines set the same indications for immunotherapy in both children 5 years or older and adults: patients with symptoms induced predominantly by allergen exposure, patients with a prolonged season or with symptoms induced by succeeding pollen seasons, patients with rhinitis and symptoms from the lower airways during peak allergen exposure, patients in whom antihistamines and moderate-dose topical glucocorticoids insufficiently control symptoms, patients who do not want to be on constant or long-term pharmacotherapy, and patients in whom pharmacotherapy induces undesirable adverse effects (Reference 37). It is important to weigh the benefits and risks of immunotherapy before therapy is initiated. Immunotherapy is a long-term, costly investment; a typical course involves one or two treatments per week for 8–12 weeks and then every 4 weeks for 3–5 years.

A new agent in the treatment of AR, omalizumab (Xolair), is a monoclonal antibody that binds to circulating IgE. The IgE-omalizumab complex cannot interact with mast cells or basophils, thus inhibiting IgE-mediated allergic reactions. Currently, omalizumab has only been studied for AR in adults, but it shows significant efficacy in treating nasal symptoms and improving quality of life. U.S. Food and Drug Administration approval is only for patients 12 years or older. Omalizumab carries a black box warning for potentially life-threatening allergic reactions after any dose, even if there is no history of a reaction. Because of its significant cost and potentially life-threatening allergic reactions, omalizumab should be reserved for patients 12 years or older who have not adequately responded to other AR treatments. More research is required before recommendations can be made for infants and children.

### Food Allergies

The goals for managing food allergies are primarily to minimize the effect on quality of life and reduce anxiety. The best treatment is prevention, and children and their parents should receive instruction on the importance of avoiding allergens. Referral to an allergist can assist in specifically identifying the offending food(s), which can help prevent an overly restrictive diet. Consulting with a nutritionist may also help ensure adequate nutrition in conjunction with the dietary limitations.

The focus of pharmacologic treatment is purely symptomatic management (diphenhydramine for hives, for example) because no recommended pharmacologic treatment currently exists for preventing food allergies. Food-induced anaphylactic reactions should be treated as a life-threatening emergency in which treatment is initiated as quickly as possible. The treatment of anaphylaxis is discussed later.

## Drug Allergies

The goal of treating allergic drug reactions is symptomatic management. Oral antihistamines can be used for treating cutaneous pruritus and rashes. Topical corticosteroids are an option if the reaction is localized to a small area. Topical steroids should not be used over extensive areas, particularly in children, because of the risk of significant systemic absorption.

Anaphylaxis triggered by any drug should be treated as outlined in the Treatment of Anaphylaxis section that follows. The offending drug should be discontinued immediately. For non-life-threatening reactions, the benefits and risks should be considered before discontinuing the medication.

Ultimately, when a clinician is deciding whether to use an agent to which a patient has a documented or suspected allergy, it is best to consider the severity of the previous reaction, the specific symptoms present during the previous reaction, and the timing of the reaction relative to the trigger exposure. Delayed cutaneous reactions, especially to antibiotics, have a low probability of recurring on rechallenge (References 64, 65).

## Anaphylaxis

Promptly initiating treatment is vital to minimizing anaphylactic-related morbidity and preventing death (References 30, 31, 66). If possible, the allergic trigger should be avoided or discontinued as quickly as possible. The primary goal should always be to restore and maintain airway, breathing, and circulation, although the emphasis in this chapter will be on treatments specific to anaphylaxis.

It is also important to consider the possibility of a biphasic anaphylactic reaction. This occurs in up to 20% of anaphylactic cases and can be as severe as the initial reaction (Reference 18). The patient will appear to have recovered from the initial episode and suddenly develop a second acute episode of bronchospasm that does not respond as well to initial therapies. Thus, it is important to observe patients before discharge for at least 4–6 hours with moderate reactions and for up to 8–24 hours with severe refractory reactions (References 67–69).

Epinephrine is well supported as the primary pharmacologic intervention for treating anaphylaxis and should be administered as soon as anaphylaxis is

suspected (Table 7) (References 28, 67, 68). Despite strong evidence in favor of using epinephrine, other evidence suggests that this treatment goes vastly underused in both the community and emergency settings, with less than one-half of all anaphylactic cases receiving an epinephrine intramuscular injection (Reference 70). An optimal window for epinephrine administration has not been studied; however, delaying epinephrine treatment may be severely detrimental because the lack of prompt treatment with epinephrine is a major risk factor for anaphylactic-related death (References 30, 31, 66). It is worth noting that delayed epinephrine administration is likely to offer some benefit over no administration, so epinephrine should be given as soon as it becomes available.

Epinephrine's action during anaphylaxis is 3-fold: it is an  $\alpha_1$ -agonist causing increased blood pressure and decreased vascular permeability by vasoconstriction of vascular smooth muscle, a  $\beta_1$ -agonist causing increased inotropic and chronotropic effects (increased heart rate and cardiac contractility), and a  $\beta_2$ -agonist resulting in bronchodilation (References 71, 72). Administering intramuscular epinephrine to the anterior lateral thigh is preferred because of its more rapid absorption and attainment of higher peaks compared with subcutaneous injections (References 67, 73). Subcutaneous injection has slow absorption because of local vasoconstriction (Reference 67). Intravenous administration carries a high risk of dosing errors, particularly in children; is not practical in most community settings; and is generally not recommended except when intramuscular epinephrine is ineffective or in an acute care setting with continuous cardiac monitoring (References 67, 74). Epinephrine 1:1000 is dosed at 0.01 mg/kg intravenously/intramuscularly, up to 0.3 mg in children and 0.5 mg in older children and adults. Autoinjectors for intramuscular administration are commercially available in 0.15-mg and 0.3-mg doses. Children who weigh 10–25 kg should receive 0.15 mg, and 0.3 mg is indicated for children weighing 25 kg or more (Reference 34). Several doses may be necessary in severe reactions and can be given every 5–15 minutes, as necessary (References 24, 67). Patient education on using an autoinjector is discussed later in the Patient Education section.

Although  $\beta$ -blocker use is uncommon in the pediatric population, a patient's response to epinephrine could theoretically be reduced if he or she is concomitantly taking  $\beta$ -blockers (References 67, 75). Although largely unsupported in the literature, the use of glucagon in children could be useful if epinephrine is having a reduced effect in a patient known to be using a  $\beta$ -blocker. At high doses, glucagon is thought to produce a positive cardiac inotropic effect independent of  $\beta$ -receptors. The recommended dose in children is a 20- to 30-mcg/kg bolus dose up to a maximum of 1 mg administered

**Table 7. Management of Anaphylaxis**

<b>First-line Therapies</b>	
Epinephrine IM (autoinjector or 1:1000 solution)	10–25 kg: 0.15 mg IM autoinjector > 25 kg: 0.3 mg IM autoinjector <i>Alternative: 0.01 mg/kg/dose, maximal dose: 0.5 mg/dose</i> May repeat every 5–15 minutes as needed
<b>Adjunctive Therapies</b>	
Fluid resuscitation	10–20 mL/kg
Supine position with lower extremities elevated	
Supplemental oxygen	
Glucagon	IV bolus: 20–30 mcg/kg over 5 minutes, maximal dose: 1 mg over 5 minutes ≥ 12 years: 1–5 mg May follow with a continuous IV infusion of 5–15 mcg/minute
<b>H<sub>1</sub>-antihistamines</b>	
Diphenhydramine	1–2 mg/kg/dose PO/IM/IV every 4–6 hours, up to 50-mg/dose
Chlorpheniramine	2–5 years: 1 mg PO every 4–6 hours 6–11 years: 2 mg PO every 4–6 hours ≥ 12 years: 4 mg PO every 4–6 hours
Cetirizine	6–12 months: 2.5 mg PO once daily 12 months–5 years: 2.5 mg PO every 12–24 hours > 6 years: 5 mg PO every 12–24 hours or 10 mg PO once daily
Levocetirizine	6 months–5 years: 1.25 mg PO once daily 6–11 years: 2.5 mg PO once daily ≥ 12 years: 5 mg PO once daily
Loratadine	2–5 years: 5 mg PO daily ≥ 6 years: 10 mg PO once daily
Desloratadine	6–11 months: 1 mg PO once daily 1–5 years: 1.25 mg PO once daily 6–11 years: 2.5 mg PO once daily ≥ 12 years: 5 mg PO once daily
Fexofenadine	6–23 months: 15 mg PO every 12 hours 2–11 years: 30 mg PO every 12 hours ≥ 12 years: 60 mg PO every 12 hours or 180 mg PO once daily
<b>H<sub>2</sub> Antihistamines</b>	
Ranitidine	1–2 mg/kg/dose PO/IV, maximum 150 mg
<b>Short-Acting β-Agonist</b>	
Albuterol nebulized solution	≤ 11 years: 0.15 mg/kg every 20 minutes × 3 doses; then 0.15–0.3 mg/kg every 1–4 hours, maximum 10 mg/dose ≥ 12 years: 2.5–5 mg every 20 minutes × 3 doses; then 2.5–10 mg every 1–4 hours <i>Alternative: 0.5 mg/kg/hour continuous nebulization (Adults: 10–15 mg/hour)</i>
Albuterol MDI	4–8 puffs every 20 minutes × 3 doses; then every 1–4 hours as needed (same dosing for adults)
<b>Glucocorticoids</b>	
Prednisone	1 mg/kg PO, maximum dose: 80 mg
Methylprednisolone	1 mg/kg IV, maximum dose: 80 mg

H<sub>1</sub> = histamine-1; H<sub>2</sub> = histamine-2; IM = intramuscular; IV = intravenous; MDI = metered dose inhaler; PO = oral.  
Adapted from Reference 24.

intravenously over 5 minutes, followed by a continuous infusion of 5–15 mcg/minute titrated to clinical effect (Reference 67). Vomiting is a frequent adverse effect, so the airway should be secured before administration.

Aggressive fluid resuscitation (10–20 mL/kg) with a crystalloid intravenous solution such as 0.9% saline or lactated Ringer's solution may be required to support cardiovascular function if initial doses of epinephrine are ineffective. Other vasopressors, such as dopamine or norepinephrine, may be required if fluid resuscitation and epinephrine are inadequate. Patients should be placed in a supine position with legs raised to maximize blood flow to vital organs (References 28, 67). Supplemental oxygen may also be of use to patients experiencing respiratory symptoms and wheezing. Endotracheal intubation should be employed if the patient is unable to maintain a patent airway.

The H<sub>1</sub>-antihistamines are the most commonly used pharmacologic intervention for anaphylaxis, but they are not effective as a primary therapy (Reference 70). These agents have a much slower onset of action than epinephrine and do not affect the life-threatening cardiovascular or pulmonary symptoms of anaphylaxis. The H<sub>1</sub>-antihistamines should be used only as an adjuvant therapy for the relief of anaphylactic-related cutaneous and nasal symptoms (e.g., urticarial, flushing, rhinorrhea). Some evidence exists that H<sub>1</sub>- and H<sub>2</sub>-antihistamines given together are more effective at treating the cutaneous symptoms of anaphylaxis versus H<sub>1</sub>-antihistamines alone (References 24, 67, 75). For dosing information on various antihistamines, refer to Table 7.

Inhaled short-acting  $\beta$ -agonists such as albuterol may be used as an adjunct to epinephrine for bronchospasm. However, their efficacy for anaphylaxis is not well supported, and delivery may be impaired in severe reactions.

Glucocorticoids have not been evaluated for use in anaphylactic reactions. Because of their usefulness in other allergic reactions (drug-mediated and AR), however, they are commonly used in treating acute anaphylaxis. Some evidence suggests they help prevent a biphasic reaction, although the evidence is minimal (References 30, 76).

### Desensitization

Patients may require treatment with a medication known to induce anaphylaxis. Desensitization can be performed by gradually exposing the patient to small doses of the medication according to a strict protocol. The protocol must be started from the beginning if a dose is missed. The full dose of the medication must be given upon completing the protocol; otherwise, it must be repeated. Ultimately, this desensitization allows the temporary administration of necessary medication with few adverse effects. For initial desensitization, patients must be monitored in an inpatient setting with

intravenous access and cardiopulmonary monitoring. Often, after the initial desensitization, patients can be desensitized in an outpatient setting. These protocols are commonly used for patients with cystic fibrosis who are colonized with several drug-resistant organisms for whom maximizing antibiotic choices through desensitization is often the only choice.

### Patient Education

For patients who have experienced severe allergic reactions, prevention education for future episodes must be discussed with each patient and caregiver, including day care staff, grandparents, teachers, coaches, and babysitters. This includes a prescription for self-injectable epinephrine and instructions on its use. All patients should have action plans in place at school and extracurricular events. Precautions must be taken to avoid known allergens, and caretakers of children should be aware of this importance.

For patients being treated for milder allergic reactions, education regarding prevention is also vital. For severe reactions, both the child and his or her caregivers should take precautions to avoid known triggers. Even children with a history of only mild allergic reactions should be given a prescription for an epinephrine autoinjector because most severe reactions occur in children with no history of allergy.

Proper education is critical for appropriate and accurate use of an epinephrine autoinjector. Children and their parents should be counseled not to delay injection if anaphylaxis is suspected because delayed injections are associated with worse outcomes. The commercially available autoinjectors are designed to work through clothing, so clothing removal is unnecessary before administration. Doses should only be injected into the outer thigh, never into the buttock. In addition, most of the liquid stays in the autoinjector after administration; thus, even if a decreased amount is not visible, patients should be assured they received the correct dose. It is also important to counsel patients never to put thumbs, fingers, or hands over the orange tip of the autoinjector because accidental injection might occur. If the patient does accidentally inject the liquid into the hands or feet, immediate medical attention should be sought because this may result in local vasoconstriction and loss of blood flow to the affected extremity. Box 3 provides instructions for using an epinephrine autoinjector.

The importance of seeking immediate medical attention should also be stressed, as should the fact that the epinephrine injection is not a replacement for medical evaluation and treatment. Medical attention or 9-1-1 notification should be sought immediately after epinephrine is administered. The patient should bring

### Box 3. Instructions for use of an epinephrine autoinjector.

- Flip open the yellow cap of the Epi-Pen or green cap of the Epi-Pen Jr. of the carrier tube.
- Remove the autoinjector from the carrier tube.
- Form a fist around the unit with the orange end pointed downward.
- Pull off the blue safety release. (Do NOT remove the blue safety release until ready to use.)
- Hold the orange tip near the outer thigh.
- Swing and FIRMLY PUSH the orange tip against the outer thigh until a click is heard. The unit should be at a 90 degree angle to the outer thigh.
- Hold FIRMLY against the thigh for about 10 seconds.
- Remove unit from thigh (the orange tip will extend to cover the needle).
- Massage injection area for 10 seconds.

Adapted from Reference 77.

the used autoinjector to the emergency department and alert the medical providers that he or she received a dose of epinephrine.

Patients receiving a prescription or over-the-counter recommendation for a nasal spray should be counseled on appropriate technique. Proper technique can help maximize efficacy and minimize local irritation and adverse effects. Sprays should always be primed before first use or if stored unused for more than 1 week. Patients should blow their noses, if possible, before use. If considerable crusting or mucous is present, patients should be encouraged to use a saline nasal spray or irrigation before using the medication. This will allow a maximum application of spray to the nasal membranes. Sprays should always be directed away from the nasal septum to avoid the risk of perforation and irritation. The patient should breathe gently inward through the nostril after each spray and out through the mouth. Nasal applicators should be wiped clean after use and recapped. Adults should assist young children who may have difficulty with these steps.

### CONCLUSIONS

Diagnosing AR, drug allergies, and food allergies involves a combination of history and laboratory testing. Drug and food allergies can be managed through recognizing and avoiding triggers. Although AR may be managed through avoiding allergens, it often requires pharmacologic intervention. Pharmacologic treatment of AR should be selected on the basis of a child's specific symptoms and optimized for quality of life. FGA or SGA are first-line agents for the treatment of mild, intermittent allergic rhinitis. INCS should be given to patients with moderate to severe or persistent rhinitis with FGA or SGA added if needed. Other pharmacologic agents may be added to treat specific symptoms

as need arises (e.g. ophthalmic agents, nasal decongestants). Finding the most effective combination while minimizing the adverse effects of therapies can be challenging because so many effective pharmacologic options are available for physicians and patients to consider.

The pharmacologic treatment of anaphylaxis is difficult to study in a standardized manner. It is unethical to conduct a placebo-controlled trial of epinephrine administration and dosing; thus, we will continue to use the guidelines established from years of clinical experience. It is important to remember that anaphylaxis is a potentially fatal reaction that may occur within minutes of drug or allergen exposure. Medical treatment should be sought immediately if anaphylaxis is suspected. Intramuscular epinephrine should be administered as soon as possible as prompt delivery results in a dramatic improvement in symptoms and reduced morbidity. In the acute care setting, additional measures such as fluid resuscitation and vasopressor use may be required. Antihistamines (first or second generation) should never be considered a first line agent for anaphylaxis treatment as they have no effect on the life-threatening cardiovascular or pulmonary symptoms. Finally, providing education about avoiding triggers is very important in all allergic diseases, as is ensuring that patients have medications such as epinephrine available and instructions on their proper use.

# CHAPTER 47

## PEDIATRIC ANEMIA

Teresa V. Lewis, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. Compare and contrast the pathophysiology of anemia among the different pediatric populations.
2. Describe special concerns that exist in treating anemia in various pediatric patient populations.
3. Review recommendations for preventing, treating, and monitoring anemia in pediatric patients based on laboratory values.
4. Recommend appropriate drug therapy for correction of microcytic and macrocytic anemia in children.
5. Recognize and manage adverse drug reactions in the treatment of pediatric anemias.

### ABBREVIATIONS IN THIS CHAPTER

AAP	American Academy of Pediatrics
CHr	Reticulocyte hemoglobin content
CKD	Chronic kidney disease
DFE	Dietary folate equivalent
EP	Erythrocyte protoporphyrin
IDA	Iron-deficiency anemia
KDOQI	Kidney Disease Outcomes Quality Initiative
MCV	Mean corpuscular volume
RBC	Red blood cell
TSAT	Transferrin saturation

### INTRODUCTION

Anemia is defined by the World Health Organization (WHO) as a hemoglobin concentration that is 2 SDs or more below the mean value for children of the same age and sex who live at the same altitude. Concomitantly, there is an impaired capacity to transport oxygen (References 1, 2). The Kidney Disease Outcomes Quality Initiative (*KDOQI*) workgroup defines anemia as a hemoglobin value less than 12 g/dL in male patients and less than 11 g/dL in premenopausal women and prepubertal patients (Reference 3).

Children, especially infants and preschool children, are at increased risk of morbidity and mortality related to anemia. Anemia that occurs in the fetal period can lead to low birth weight, which is a strong predictor of infant mortality (Reference 4). During the first year

of life, rapid growth and a concomitant increase in the number of red blood cells (RBCs) can bring about a marked decline in hemoglobin concentration (Reference 5). Anemia during peak growth periods can have adverse consequences on neurocognitive development (Reference 6). In addition, data evaluating anemia in developing countries suggest that concomitant illnesses with anemia and malaria infection increase the risk of death in children and that the highest mortality risk occurs in the very young (Reference 4).

Anemia is usually caused by nutritional deficiencies in iron, folate, and/or vitamin B<sub>12</sub>. Severe inflammation, chronic kidney disease (CKD), or other chronic illnesses can lead to anemia (Reference 7). Deficiencies in vitamin A or copper and exposure to lead can also contribute to the development of anemia. Genetic mutations that are associated with impaired erythropoiesis can also cause anemia. Examples include thalassemia, sickle cell trait, and Fanconi anemia (Reference 1). This chapter will discuss anemia caused by deficiencies in folate, vitamin B<sub>12</sub>, and iron as well as anemia associated with CKD. The chapter will address the implications of persistent anemia as it pertains to a child's health and describe approaches to the clinical management of the condition.

### EPIDEMIOLOGY

Data from the WHO Vitamin and Mineral Nutrition Information System for 1993–2005 showed that 24.8% of the world's population is anemic. The most anemia cases were found among women and young children. Children younger than 5 years had the highest prevalence of anemia at 47.4%, whereas 25.4% of children 5 years or older were reported to be anemic (Reference 7). In the United States, the overall prevalence of anemia has been declining and is much lower than that of the world's population, with all-cause anemia among infants and children being around 3.6%.

Globally, iron-deficiency anemia (IDA) is the most common type of anemia (Reference 1). The prevalence of IDA in the United States has not changed for more than 2 decades. Young children, adolescent girls, and pregnant women continue to have a higher prevalence of IDA than all other age groups (References 8–10). Iron deficiency was reported in 9% of toddlers between 1 and 2 years of age and in 9% to 11% of adolescent girls and women of childbearing age in the National Health

and Nutrition Examination Survey (NHANES) 1988–1994. Iron-deficiency anemia was found in 3% of toddlers and in 2% to 5% of adolescent girls and women of childbearing age (Reference 9). In NHANES 1999–2000, the prevalence of iron deficiency among American children 1–3 years of age was 8%. Risk factors in children for iron deficiency include being of Hispanic ethnicity, being of younger age, and being overweight (Reference 10).

Pediatric epidemiologic data for folate and vitamin B<sub>12</sub> deficiencies are limited because infants and children are typically not screened for these deficiencies. Folate deficiency among children in Western societies is rare. Its prevalence in American children 4 years and older has decreased from 15.5% to 0.5%. Girls between 12 and 19 years of age are at highest risk of folate deficiency (Reference 11). Data for vitamin B<sub>12</sub> deficiency among infants and children are lacking. However, one study of newborn screening programs in the United States estimated the incidence of neonatal B<sub>12</sub> deficiency to be 0.88 per 100,000 newborns (Reference 7).

## PATHOPHYSIOLOGY OF ANEMIA

The primary function of erythrocytes is to deliver oxygen. Old erythrocytes are replaced by new erythrocytes daily. The average life cycle of a normal RBC is 120 days. The erythrocyte life span seen in neonates is about one-half of this duration at 60–90 days (Reference 12). The process by which new RBCs are formed is called erythropoiesis. Multipotential stem cells undergo two stages to become RBCs, but only one stage is responsive to erythropoietin. This is the stem-and-progenitor cell stage (Reference 12). During erythropoiesis, multipotential stem cells in the bone marrow transform into erythroid progenitor cells. Receptors for erythropoietin are located on the erythroid progenitor cells. Erythropoietin causes differentiation and proliferation of the erythrocyte progenitors to produce billions of new erythrocytes daily (References 12, 13).

Erythropoietin is produced primarily in specialized interstitial cells in the renal cortex (Reference 3). It is also produced, to a lesser extent, by the liver (References 12, 13). Transient blood loss, hemolysis, or anemia leads to a decreased number of circulating RBCs and decreased oxygen delivery to tissues. One source of blood loss that is often not accounted for is frequent phlebotomy. Children are at increased risk of anemia from phlebotomy because of their small body size and small total blood volume (Reference 14). Excessive blood loss from laboratory testing is the leading cause of anemia in critically ill neonates (Reference 15).

The kidneys are extremely sensitive to changes in oxygen supply. Under normal conditions, the body has a basal rate of erythropoietin release. Normal plasma concentration for males ranges from 1 mIU/mL to 21.9 mIU/mL and is 1.2–20.5 mIU/mL for females (Reference 16). Tissue hypoxia leads to an exponential increase in the amount of erythropoietin released. This leads to more erythrocyte progenitors surviving during the stem-and-progenitor cell stage. Erythrocyte production increases, permitting enhanced delivery of oxygen to tissues (Reference 13). When blood is replenished or hypoxia is corrected, a negative feedback signal is created to decrease the release of erythropoietin to baseline concentrations (Reference 13).

Healthy term neonates are born with adequate iron stores for about 4 months of postnatal growth (Reference 17). The hemoglobin content of cord blood in a term infant ranges from 13.7 g/dL to 20.1 g/dL (Reference 18). Cord blood hemoglobin of less than 12.5 g/dL is suggestive of fetal anemia (Reference 4). During the first few days after birth, erythropoiesis is maintained at a low level. Between 9 and 29 days of life, a rapid decline in hemoglobin is observed. This event correlates with an increase in erythropoiesis. The number of bone marrow erythroid cells observed at day 29 of life is more than double the amount seen at day 9 of life. After 29 days of life, erythropoiesis is sustained so that, by day 59 of life, the marrow erythroid cell count reaches 22,000 per cubic millimeter (almost 8 times the value seen at day 9 of life). Erythropoiesis is then adjusted to maintain a constant hemoglobin value of 11–12 g/dL (Reference 5).

In anemic patients, one or more factors that affect the sequence of events required for erythropoiesis may fail. Adequate concentrations of iron, folate, and vitamin B<sub>12</sub> are required to maintain active erythropoiesis. A deficiency in iron, folate, and vitamin B<sub>12</sub> can lead to decreased hemoglobin and erythrocyte production, thus causing decreased oxygen delivery to tissues (Reference 3). Folate and vitamin B<sub>12</sub> are involved in the proliferation and differentiation of immature erythrocytes. They are required for the DNA synthesis that accompanies the production of new erythrocytes (Reference 13). In the presence of kidney disease, erythropoietin production may be impaired. Abnormal hematopoietic tissue can lead to impaired responses to erythropoietin. This contributes to impaired RBC formation (References 3, 17).

## Clinical Features and Complications

Children who have anemia may be asymptomatic; however, even with mild anemia, the oxygen transport capacity of the blood is reduced. This can lead to lethargy and decreased physical endurance. Often, the clinical presentation of symptoms is related to the root cause of anemia. Common symptoms of anemia include irritability, lethargy, weakness, tachycardia, and pallor.

Anemic infants may be irritable and have poor oral intake. Severe anemia can lead to impaired growth and development. Decreased attention span has also been reported in children. Serious symptoms include arrhythmia, heart failure, and stroke (Reference 19).

## Laboratory Data

### Hemoglobin

Hemoglobin testing is the standard surrogate for iron deficiency because of its low cost. However, this test fails to identify individuals with mild iron deficiency. Hemoglobin changes typically do not occur until the late stages of iron deficiency. A diagnosis of iron deficiency is made when iron deficiency is severe enough to cause anemia (Reference 20).

The mean and reference range of hemoglobin in newborns is 16.8 (13.7–20.1) g/dL for both males and females (Reference 18). Neonates born to mothers living in high altitudes typically have higher hemoglobin values. Beginning at around 22 weeks, a 0.64% increase in hematocrit and a 0.21 g/dL increase in hemoglobin have been observed for every week's advance in gestational age. Those born between 35 and 42 weeks' gestational age were found to have a mean hemoglobin value

of 18 g/dL (Reference 21). Age-specific mean hemoglobin cutoff values for defining anemia in children are listed in Table 1 (Reference 22).

### Mean Corpuscular Volume

The type of anemia is often classified by RBC size. Mean corpuscular volume (MCV) is the average size of erythrocytes. Red blood cell size in children varies with age. Thus, it is important to consider physiologic changes in the overall assessment of anemia. Several conditions may cause increases in MCV. A value greater than 100 fL suggests the presence of macrocytic anemia. Macrocytic anemia can sometimes be megaloblastic, with folate deficiency and vitamin B<sub>12</sub> deficiency being the primary causes (Reference 23).

Around one-third of patients with IDA have a normal MCV (Reference 24). Mean corpuscular volume concentrations typically do not drop below normal range early in iron deficiency. Rather, changes are seen after long-standing deficiency (Reference 3). A peripheral blood smear will provide valuable information regarding the morphology of RBCs and assist with diagnosis (Reference 18). Age-specific mean MCV cutoff values for defining microcytic anemia in children are listed in Table 1 (Reference 22).

### Total Reticulocyte Count

The total reticulocyte count is an indirect marker of erythropoietic activity. It helps distinguish anemia caused by hypoproduction versus anemia caused by increased RBC destruction. A low reticulocyte count may suggest an impaired production of RBCs, whereas a sustained high reticulocyte count may indicate active blood loss or increased RBC destruction (Reference 19). During the maturation process, reticulocytes exist in the bone marrow for 3 days before entering the circulation. Once they leave the bone marrow, they spend a day in the peripheral blood before becoming mature erythrocytes. During severe anemia, reticulocytes are released early into the peripheral blood. Early release into the circulation shortens their maturation time in the bone marrow but prolongs the time it takes for the cell to mature in the bloodstream (Reference 3).

### Screening

The American Academy of Pediatrics (AAP) recommends routine screening for anemia in all children between 9 and 12 months of age. Additional screening is recommended between 1 and 5 years of age for children with risk factors for IDA. These include lower socioeconomic status, Hispanic ethnicity, history of prematurity or low birth weight, lead exposure, being exclusively breastfed beyond 4 months of age, and having inadequate dietary iron intake (References 7, 25).

**Table 1.** Laboratory Cutoff Values for IDA (Reference 22)

Age	Laboratory Cutoff Value
<b>Hemoglobin</b>	
6 months to < 2 years	11 g/dL
2 to < 5 years	11.1 g/dL
5 to < 8 years	11.5 g/dL
8 to < 12 years	11.9 g/dL
Boys 12 to < 15 years	12.5 g/dL
Girls 12 to < 15 years	11.8 g/dL
Boys 15 to < 18 years	13.3 g/dL
Girls 15 to < 18 years	12 g/dL
<b>MCV</b>	
1–2 years	< 77 fL
3–5 years	< 79 fL
6–11 years	< 80 fL
12–15 years	< 82 fL
> 15 years	< 85 fL

IDA = iron-deficiency anemia; MCV = mean corpuscular volume.

Initial laboratory testing should include hemoglobin, hematocrit, and red cell indices as well as a white blood cell count and differential, platelet count, reticulocyte count, and examination of the peripheral blood smear. The need for additional laboratory studies is dictated by the patient's history, the physical examination, and the results of this initial testing (Reference 18).

Normal laboratory values in children vary with age. Some laboratory values differ slightly between the male sex and female sex. Therefore, it is important to compare individual results with population-based mean concentrations observed in children of the same age and sex.

## MACROCYTIC ANEMIA

### Pathogenesis

Folate is a water-soluble compound found in plant and animal tissues. Humans are entirely dependent on dietary sources for this nutrient. Primary sources are raw green leafy vegetables, dried cooked beans, and fortified cereals. Animal sources include the liver and kidney (Reference 26). Cooking causes folate loss; however, the extent of loss depends on the type of food and cooking method (Reference 27).

Vitamin B<sub>12</sub> is found in animal tissue. Therefore, a diet that is strictly vegetarian without the presence of dairy or eggs does not provide a sufficient amount of vitamin B<sub>12</sub>. Vitamin B<sub>12</sub> deficiency and anemia can also result from autoimmune pernicious anemia or from malabsorption after gastric bypass surgery (Reference 7). Pregnant women who adhere to a strictly vegetarian diet or who have had gastric bypass surgery are at risk of vitamin B<sub>12</sub> deficiency, and they place their fetus at risk of deficiency as well. Adults can withstand long-term vitamin B<sub>12</sub> deficiency without significant physiologic impairment because reserves can last 3–5 years. In contrast, infants have limited hepatic reserves of this nutrient and thus are sensitive to vitamin B<sub>12</sub> deficiency (Reference 28).

Folate and vitamin B<sub>12</sub> are essential nutrients that are vitally important in DNA production. Anemia can occur with a deficiency in either vitamin, but a deficiency in one will alter the metabolism of the other (Reference 28). Interference with DNA synthesis can cause abnormal cell division. Rapidly dividing cells are most affected by impaired DNA synthesis. There is an abundance of large and immature erythroblasts and myeloblasts. These cells are collectively called megaloblasts (Reference 13). Anemia that is caused by a deficiency in either nutrient is called megaloblastic anemia. Folate and/or vitamin B<sub>12</sub> deficiency anemia can lead to impaired DNA synthesis and increased rates of hematopoietic cell death. The mechanism for this cell death has not been identified. Data from animal models suggest that proerythroblasts undergo programmed cell death

before differentiating into reticulocytes. Because these cells are unable to mature before undergoing apoptosis, erythropoiesis under these circumstances is deemed ineffective (Reference 13).

## Clinical Features and Complications

### Folate

Folate is critically important in children because of its role in nucleic acid synthesis. Deficiency during gestation can adversely affect cell replication and growth. Neural tube defects of the fetus (e.g., anencephaly, encephalocele, and spina bifida cystica) are well-documented consequences of maternal folate deficiency, although the mechanism by which this occurs is not known (Reference 29). No similar strong correlations between maternal folate deficiencies have occurred with other adverse fetal or neonatal outcomes. It has been suggested that maternal folate deficiency increases the risk of certain conditions such as abruptio placentae, preeclampsia, spontaneous abortion, preterm delivery, and low birth weight. Mothers who had megaloblastic anemia while pregnant have a markedly high prevalence of abruptio placentae (Reference 30).

Milk is an important dietary source of folate during the first year of life. Most commercial infant formulas are fortified with folic acid (References 31–34). Human breast milk also contains sufficient concentrations of folate (50 mcg/L) for nursing infants (Reference 35). The vitamin is excreted into breast milk in a constant manner, and it is provided to the infant at the expense of maternal stores. Thus, breastfeeding women are at increased risk of folate deficiency and require additional folate (References 30, 36, 37). Infants who are solely fed goat's milk are at risk of folate deficiency and anemia because this type of milk is naturally low in folate content (6 mcg/L). Children with anemia from folate deficiency may present with pallor, lethargy, and failure to thrive (References 35, 38).

### Vitamin B<sub>12</sub>

Infants fed milk from mothers with adequate vitamin B<sub>12</sub> status are not at risk of developing vitamin B<sub>12</sub> deficiency. Vitamin B<sub>12</sub> composition of breast milk from mothers of term infants is highest in colostrum (0.49 mcg/L). Mature breast milk contains about 0.23 mcg of vitamin B<sub>12</sub> per liter (Reference 39). Breastfed infants of mothers with vitamin B<sub>12</sub> deficiency are at risk of severe developmental abnormalities, failure to thrive, and anemia (Reference 36). The mothers may not have clinical symptoms of vitamin B<sub>12</sub> deficiency, but their infants may develop demyelination lesions. These infants do not have megaloblastic anemia but will present with failure to thrive and have neurologic deficits (Reference 30). These infants may be irritable and have abnormal

reflexes and feeding difficulties. Prolonged vitamin B<sub>12</sub> deficiency can lead to irreversible neurologic damage (Reference 7). If left untreated, almost all patients who have this anemia will eventually develop some nervous system involvement before death occurs. Vitamin B<sub>12</sub> deficiency lasting more than 3 months will lead to the development of central nervous system lesions. This type of damage is irreversible (Reference 40).

## Prevention

### Folate

Dietary folates (from natural sources) are found in a conjugated form in food. This factor contributes to the decreased bioavailability of the nutrient (Reference 41). Dietary folates are also prone to degradation from cooking. Spinach and broccoli have been reported to retain less than one-half the amount of folate after they are boiled (49% and 44%, respectively). The extent of nutrient loss depends on the type of food and the cooking method used (Reference 27).

In 1998, the U.S. Food and Drug Administration (FDA) mandated the fortification of cereal products with 140 mcg of folic acid per 100 g of cereal/grain product. This mandate was targeted toward women of childbearing age to prevent neural tube defects. However, children who consume these products also benefit from folic acid fortification (Reference 42).

The Institute of Medicine provides recommendations for adequate intake and recommended daily allowances (RDAs) of dietary folate. The term *dietary folate equivalent* (DFE) is used to describe the RDA of folate. One microgram of DFE (i.e., natural food folate) is equal to 0.6 mcg of folic acid from fortified foods (Reference 37). When a patient takes folic acid in the form of a tablet supplement, the presence of food will affect the bioavailability of the drug (Reference 41).

One microgram of DFE equals 0.5 mcg of folic acid if taken on an empty stomach. However, if the supplement is taken with food, then 1 microgram DFE equals 0.6 mcg of folic acid. The RDA for specified age groups is provided in Table 2 (References 3, 37, 43).

Pregnant and breastfeeding women may increase their folic acid intake through supplements. Supplementation with 400 mcg of folic acid daily in pregnancy in addition to dietary folate intake minimizes the risk of neural tube defects (Reference 37). Lactating mothers require an additional 300 mcg of folic acid daily to maintain adequate serum folate concentrations (Reference 30).

### Vitamin B<sub>12</sub>

The best strategy to prevent vitamin B<sub>12</sub> deficiency is to encourage individuals to consume an adequate amount of the vitamin in their diet. Foods with the highest vitamin B<sub>12</sub> content include beef, liver, beef by-products (e.g., blood, bone, edible fats, organs), clams, turkey, and chicken. Beef liver and beef-containing variety meats may contain up to 70.66 mcg of vitamin B<sub>12</sub> per 3 oz (Reference 26). Fortified foods and oral supplements may be an alternative source of vitamin B<sub>12</sub> (Reference 44). Fortified ready-to-eat cereals contain up to 6 mcg of vitamin B<sub>12</sub> per serving (Reference 26). The ideal dose of vitamin B<sub>12</sub> for supplementation has not been established. Recommended daily allowances for specified age groups are provided in Table 2 (References 3, 37, 43).

## Diagnosis

### MCV and Peripheral Smear

An MCV greater than 100 fL is a sensitive hematologic marker for folate and vitamin B<sub>12</sub> deficiency. A peripheral blood smear should be included in the initial workup. The presence of macroovalocytes and hypersegmented neutrophils indicates the presence of megaloblastic anemia (Reference 23).

**Table 2.** Recommended Daily Allowance (References 3, 37, 43)

Age (years unless specified)	Folate (mcg) <sup>a</sup>	Vitamin B <sub>12</sub> (mcg)	Iron <sup>b</sup> (mg)	Ascorbic Acid (mg)
0–6 months	65 <sup>c</sup> (9.4 mcg/kg)	0.4 <sup>c</sup> (0.05 mcg/kg)	0.27 mg/day <sup>c</sup>	40 <sup>c</sup>
7–12 months	80 <sup>c</sup> (8.8 mcg/kg)	0.5 <sup>c</sup> (0.05 mcg/kg)	11	50 <sup>c</sup>
1–3	150	0.9	7	15
4–8	200	1.2	10	25
9–13 (males)	300	1.8	8	45
9–13 (females)	300	1.8	8	45
14–18 (males)	400	2.4	11	75
14–18 (females)	400	2.4	15	65

<sup>a</sup>Amount listed as dietary folate equivalents (DFEs).

<sup>b</sup>Elemental iron.

<sup>c</sup>Listed as recommendations for adequate intake.

### Folate and Vitamin B<sub>12</sub>

Folate and vitamin B<sub>12</sub> assessments may be performed by direct vitamin assays or indirectly by surrogate biochemical markers. Direct assays include serum folate, RBC folate concentrations, and serum vitamin B<sub>12</sub>. Serum folate readily detects deficiency. It is primarily a reflection of short-term folate balance and is subject to diurnal and prandial variations. Red blood cell folate is a more stable value that more accurately reflects average body folate when that particular population of RBCs was produced (References 45, 46).

Surrogate markers reflect the metabolic function of each vitamin. These markers include homocysteine and methylmalonic acid. They may be used to distinguish between folate and vitamin B<sub>12</sub> deficiency. Homocysteine is associated with folate and vitamin B<sub>12</sub> status, and methylmalonic acid is more specific for vitamin B<sub>12</sub>. Homocysteine is a sulfur-containing amino acid that is present in the body. The breakdown of homocysteine requires the presence of both folate and vitamin B<sub>12</sub>. Deficiency of either vitamin will lead to increased homocysteine concentrations (References 45, 46). Only vitamin B<sub>12</sub> deficiency is associated with an elevation in methylmalonic acid concentration. Changes in homocysteine and/or methylmalonic acid are not specific to folic acid or vitamin B<sub>12</sub> deficiencies. Other diseases (e.g., renal failure, hypothyroidism) may also cause an increase in homocysteine and/or methylmalonic acid (References 45, 46). Laboratory values in these patients must be cautiously interpreted. Direct measurement of vitamin B<sub>12</sub> and/or folate in conjunction with surrogate markers may provide a better diagnosis for deficiency. Table 3 provides reference ranges for these laboratory values (References 47, 48).

### Schilling Test

The Schilling test is used to identify malabsorption of vitamin B<sub>12</sub>. Fasting patients are given a 1-mcg dose of radioactively labeled synthetic cyanocobalamin. Urine is collected during a 24-hour period. Individuals with malabsorption will have lower concentrations of radioactivity in their urine. This test is rarely used because of the high rate of indeterminate results (References 46, 49). Individuals may have normal test results even if malabsorption of dietary cobalamin is present. Inadequate urine collection is a considerable cause of error. In addition, individuals with renal insufficiency may have delayed excretion of the radioactively labeled cobalamin, thus providing an inaccurate interpretation of the test results (Reference 49).

### Treatment

#### Folate

Oxidative cleavage of dietary folate from cooking creates degradation products that are not active and cannot be converted by the body to active folate. Folate

deficiency is treated with folic acid. Folic acid is a synthetic vitamin that is a fully oxidized molecule, and it is more stable than dietary folate. Bioavailability of the synthetic formulation is twice the amount seen with dietary folate (Reference 44). Absorption of folic acid is better at smaller doses. High doses cause oversaturation of GI folate transport pathways, resulting in inefficient absorption (Reference 44). Folic acid is relatively well tolerated, and it may be given orally, intramuscularly, intravenously, or subcutaneously. The injectable form of folic acid is available as sodium folate. Dosage recommendations are 100 mcg/day for infants and 300 mcg/day for children younger than 4 years. Those older than 4 years are given a typical adult dose of 400 mcg/day (Reference 50). An extemporaneously prepared formulation can also be prepared (Reference 50).

### Vitamin B<sub>12</sub>

Vitamin B<sub>12</sub> deficiency in children in the United States is not common; therefore, cobalamin supplementation is seldom used in this population. When supplementation is required, cyanocobalamin given as intramuscular or subcutaneous injections is the preferred route of administration for pediatric patients. The dose used for children with vitamin B<sub>12</sub> deficiency is not well established. A starting dose of 0.2 mcg/kg can be used. This dose is given for 2 days and then changed to 1000 mcg/day for the next 5 days. The dosing interval is then extended to weekly administration at a dose of 100 mcg/week.

**Table 3.** Reference Values for Folate and Vitamin B<sub>12</sub> Assays and Surrogate Markers (References 47, 48)

Direct Vitamin Assays	Reference Range
<b>Serum vitamin B<sub>12</sub></b>	
Newborn	160–1300 pg/mL
Child	200–835 pg/mL
<b>Serum Folate</b>	
Newborn	16–72 ng/mL
Child	4–20 ng/mL
<b>RBC folate</b>	
Newborn	150–200 ng/mL
Infant	74–995 ng/mL
2–16 years old	Greater than 160 ng/mL
Older than 16 years	140–628 ng/mL
<b>Surrogate Markers</b>	
Serum homocysteine	4.6–8.1 micromol/L
Methylmalonic acid	0.05–0.26 micromol/L

RBC = red blood cell.

Treatment spans 1 month. Children who have malabsorptive conditions may require long-term cobalamin therapy. Cobalamin may be given in doses of 100 mcg on a monthly basis. An alternative regimen is 100 mcg/day given for 10–15 days, followed by 100 mcg given once or twice a week for several months. Cyanocobalamin given orally is not recommended because absorption by this route is variable. An intranasal formulation is also available; however, it is not FDA approved for use in children at this time (References 51–53).

### Monitoring

All patients should have a baseline complete blood cell count for hemoglobin and MCV measurements, together with a peripheral blood smear. Vitamin B<sub>12</sub> and folate levels can provide the distinction between folate deficiency and vitamin B<sub>12</sub> deficiency. Folate therapy should be continued for at least 3–4 weeks until a definite hematologic response is observed (Reference 23). Vitamin B<sub>12</sub> concentrations and a complete blood cell count should be performed 1 month after the start of cyanocobalamin and every 3–6 months thereafter to determine treatment efficacy (References 52, 53). Once therapy is initiated, it may take 1–4 months to achieve complete recovery of hematologic indices.

Serum potassium and a complete blood cell count are particularly important during the initial treatment of vitamin B<sub>12</sub> deficiency. Laboratory values should be observed closely during the first 48 hours of treatment. When treating patients with severe vitamin B<sub>12</sub> deficiency, hypokalemia requiring replacement therapy and thrombocytosis may develop. Hypokalemia is caused by an intracellular shift of potassium after correction of anemia. The condition can be severe and fatal (References 52, 53).

## MICROCYTIC ANEMIA

### Pathogenesis

Iron is an essential cofactor for many different cellular processes. It is acquired from dietary sources either as heme or non-heme iron. Heme iron (Fe<sup>2+</sup>) is primarily from animal sources as hemoglobin and myoglobin. It is well absorbed by the gastrointestinal (GI) tract. Non-heme iron (Fe<sup>3+</sup>) is free iron and is found in foods such as spinach, beans, enriched cereals, and whole grains (Reference 26). This form of iron is not as efficiently absorbed. For iron to be absorbed, ferric iron (Fe<sup>3+</sup>) must be reduced by brush border ferrireductases in the GI tract to ferrous iron (Fe<sup>2+</sup>) (Reference 54).

Iron's ability to accept and donate electrons makes it a useful element biologically. This same characteristic gives iron the capacity to be toxic. Iron can catalyze a reaction that generates free radicals. These free radicals

can attack cellular membranes, proteins, and DNA. To prevent free radicals from forming, the body maintains a tight regulation of iron by sequestering most of it within proteins (Reference 54). It is incorporated into hemoglobin, myoglobin, and respiratory enzymes and is needed for oxygen transport (Reference 22).

Transport proteins tightly bind to iron and circulate it throughout the body. Transferrin is the main carrier of iron in the blood. Elemental iron bound to transferrin is a critical source of iron for developing erythroid cells within the bone marrow. Once inside the developing erythroid cell, the iron is cleaved off from transferrin and transported to the mitochondria, where it can be made available for incorporation into the heme molecule (Reference 55).

Most iron found in the body is bound to hemoglobin (Reference 22). Two hundred eighty million hemoglobin molecules are carried in one RBC. Hemoglobin is a tetrameric compound consisting of four polypeptide chains. Mature erythrocytes contain a heme group linked to each of the two alpha and two beta chains. Heme is composed of a porphyrin ring and an iron atom. The atom of iron is chelated at the center of the porphyrin ring. Heme readily binds with oxygen. The resulting oxyhemoglobin gives blood its characteristic red color (Reference 56). Iron found in hemoglobin functions as a carrier of oxygen to the tissues from the lungs (Reference 22).

Iron that is not readily used is complexed to ferritin and hemosiderin for storage within cells. Ferritin and hemosiderin are primarily located within the liver, bone marrow, spleen, and skeletal muscles. In healthy individuals, most stored iron is bound to ferritin (Reference 22).

The body efficiently regulates the processes of erythrocyte formation and destruction. When old RBCs are destroyed, the liberated iron is recycled for incorporation back into the hemoglobin. Under normal physiologic conditions, plasma iron concentrations are maintained in a relatively constant range. The balance between concentrations of iron available for incorporation into hemoglobin and those found in storage compartments is efficiently managed (Reference 57). Certain circumstances can tip this balance. Iron deficiency can cause hemoglobin synthesis to slow down and impair erythropoiesis. Fewer reticulocytes may be released by the bone marrow. The reticulocytes that are released are small with decreased hemoglobin concentration. Erythrocytes are described as hypochromic and microcytic.

Iron status has been described as a continuum. Individuals may have normal functional iron (e.g., bound to hemoglobin, myoglobin, and respiratory enzymes) with varying concentrations of transport and stored iron. Persistent iron deficiency may result in severe reductions in total body iron concentrations. Iron depletion exists when the amount of stored iron is reduced but the

amount of functional iron and transport iron is normal. The body may not have sufficient iron stores to mobilize if there is an increased need. With iron depletion, there are no physiologic impairments. Iron-deficient erythropoiesis may occur if the body continues to have a negative iron balance for a sufficient duration. The amount of iron absorbed by the GI tract is insufficient to replace the quantity that is lost, or the body is unable to meet the demands necessary for growth and function (Reference 22). In children, rapid growth can overwhelm the body's ability to maintain sufficient iron concentrations (Reference 54). Adolescent girls, similar to adult women, can become iron deficient because of regular blood loss during menstruation and limited dietary iron consumption (References 8, 58). Iron-deficient erythropoiesis is characterized by depleted iron stores and a reduced transport of iron. The concentration of functional iron is normal. The decreased concentrations of iron will lead to impaired hemoglobin and RBC production. Although iron deficiency is less severe, it still has the potential for causing physiologic impairment. Iron-deficiency anemia is a more severe form of iron deficiency in which functional, transport, and stored iron concentrations are all reduced. The lack of iron leads to an impaired production of hemoglobin, myoglobin, and respiratory enzymes. Red blood cell formation decreases, and organ systems can be adversely affected (Reference 22).

Risk factors for developing IDA in infants include premature birth, low birth weight, and prolonged stay in the neonatal intensive care unit. Preterm neonates possess lower total body iron than term neonates; however, the proportion of iron to body weight is similar between the two populations. The faster rate of postnatal growth experienced by infants who are born premature places them at risk of rapidly depleting iron stores compared with their term counterparts. In these infants, iron deficiency can develop by 2–3 months of age if adequate iron supplementation is not provided (Reference 59).

Infants who are exclusively breastfed and who do not receive iron supplementation are at increased risk of developing anemia (Reference 24). Babies who are not fed iron-fortified formula during the first year of life and those who have an early introduction of cow's milk are also at increased risk (Reference 24). Human breast milk and cow's milk have similarly low concentrations of elemental iron, about 0.5–1 mg/L (References 22, 60). However, human breast milk's bioavailability is around 50% compared with 10% with cow's milk (References 22, 59–62). High calcium and casein content of cow's milk can inhibit GI iron absorption (References 59, 61). In addition, early introduction of cow's milk during infancy can cause occult bleeding from the GI tract (References 62, 63). These factors can contribute to iron loss.

## Clinical Features and Complications

Women who are iron deficient early during pregnancy are at greater risk of having preterm delivery and of giving birth to babies with low birth weight (Reference 64). Data suggest that maternal IDA during the first half of pregnancy is associated with an increased risk of preterm delivery, despite correction of iron deficiency during the third trimester. Pregnant women who present with IDA at their first prenatal visit are more likely to give birth to a baby with low birth weight. The risk is 3 times greater if the woman is from a low-income household. The association between premature delivery and low birth weight has not been found with other types of maternal anemia (Reference 65).

Strong evidence supports the role of iron in neurologic development. Some data support the causality of IDA with poor cognitive, neurologic, and motor development. Infants with IDA have lower motor function scores than infants who do not have IDA (Reference 66). Some effects of IDA can be long lasting and irreversible (References 7, 67). Studies evaluating the long-term effects of IDA have reported lower IQ scores for children between 4 and 7 years of age if they had IDA during the first year. One follow-up study that evaluated 167 children from Costa Rica found that infants with severe and chronic IDA still had lower motor scores as well as lower achievement in math and writing in adolescence (Reference 6).

## Prevention

The Department of Health and Human Services Healthy People 2010 includes objectives for reducing iron deficiency to less than 5% for children 1–2 years of age, less than 1% for children 3–4 years of age, and less than 7% for females of childbearing age. The AAP has published guidance regarding the diagnosis and prevention of IDA. It is recommended that all preterm infants receive 2 mg of elemental iron per kilogram of body weight per day, the amount provided in iron-fortified formulas. This should be provided through 12 months of age. Preterm infants who are solely breastfed should be given oral iron supplementation by 1 month of age at a dose of 2 mg of elemental iron per kilogram per day. This therapy should be continued until the infant is weaned to iron-fortified formula or is able to consume foods that supply 2 mg/kg/day of elemental iron. Healthy term infants who are exclusively breastfed should receive 1 mg of elemental iron per kilogram per day orally starting at 4 months of age. Term infants who consume both breast milk and formula should be given 1 mg of elemental iron per kilogram per day orally starting at 4 months of age if breast milk intake comprises greater than 50% of the infant's total daily intake. For infants who are solely formula fed, iron-fortified

formulations are recommended until 12 months of age. These infants do not require additional iron supplementation. The use of cow's milk should be avoided until after 12 months of age (Reference 3). Recommended dietary intake of iron for specified age groups may be found in Table 2 (References 3, 37, 43).

Most dietary iron is available as ferric iron ( $\text{Fe}^{3+}$ ). This is primarily iron that is not bound to heme. Only ferrous iron ( $\text{Fe}^{2+}$ ) is absorbed in the duodenum and jejunum. Brush border ferrereductases in the GI tract reduce ferric iron to ferrous iron so that dietary iron may be absorbed (References 68, 69). Reducing substances such as ascorbic acid facilitates the conversion of ferric iron to ferrous iron, enhancing GI absorption (Reference 70). In addition, ascorbic acid is reported to have chelating properties that bind polyphenol (e.g., tannic acid) and phytates (e.g., bran, cereals), which inhibit iron absorption (Reference 71). Ingesting foods that are rich in ascorbic acid increases the absorption of non-heme iron from the diet, and its effects are more pronounced when the meal contains inhibitors of iron absorption (Reference 70).

Synthetic ascorbic acid has the same effect of improving dietary iron absorption as that found in foods (References 70, 71). For most people, taking ascorbic acid as a supplement to improve the absorption of dietary iron is unnecessary. Dietary sources of ascorbic acid are preferred. Health care professionals should advise patients and caregivers regarding RDA values if they are posed with questions about supplement use. The RDA for ascorbic acid may be found in Table 2 (References 3, 37, 43).

## Diagnosis

### Iron Status

Hemoglobin alone may fail to identify children at risk of developing anemia because it does not detect iron deficiency in individuals with normal-range hemoglobin values (Reference 7). Iron status tests should be used to confirm iron deficiency and guide the use of iron therapy. The iron profile typically consists of measures of serum iron concentration, total iron-binding capacity, transferrin saturation (TSAT), and serum soluble transferrin receptor. Serum iron concentration is the total amount of iron found in the serum. Total iron-binding capacity reflects the availability of iron-binding sites on transferrin. Transferrin saturation is serum iron divided by total iron-binding capacity. The value reflects the extent to which transferrin has "vacant" iron-binding sites. The *KDOQI* workgroups have defined absolute iron deficiency as a TSAT less than 20% (Reference 3). A serum soluble transferrin receptor assay measures the

expression of soluble transferrin receptors. The serum soluble transferrin receptor concentration is reciprocally related to the iron supply and increases markedly in the presence of iron deficiency (Reference 72).

### Ferritin

Ferritin is an indicator of iron stores status. It provides insight about whether iron stores are adequate or insufficient. Low serum ferritin is highly diagnostic for iron deficiency. In the absence of comorbidities, a ferritin value of 15 ng/mL or less indicates the absence of iron stores in children older than 6 months (References 22, 73). Individuals who have anemia from chronic disease may have normal or elevated serum ferritin, which is reflective of increased iron storage and retention in the reticuloendothelial system. Increased ferritin may also be caused by activation of the immune response (Reference 73). The lower limit for serum ferritin is defined by the *KDOQI* workgroup as 200 ng/mL for individuals on hemodialysis and 100 ng/mL for those with CKD not on hemodialysis (Reference 3).

### Limitations to Serum Iron, TSAT, and Serum Ferritin Concentration

Serum iron, TSAT, and serum ferritin concentrations may be affected by factors unrelated to iron. Diurnal variations have been observed with serum iron and TSAT. High estrogen or progesterone states (e.g., with pregnancy, oral contraceptive use) are associated with increased TSAT values. Inflammatory states cause elevations in serum ferritin (Reference 26). Iron-deficient individuals on hemodialysis or chronically ill patients can present with high serum ferritin concentrations. The presence of malnutrition, chronic infection, or inflammation can cause serum ferritin values to be elevated (Reference 3).

### Treatment

If iron supplementation is required, oral administration is the treatment of choice. Intravenously administered iron may be considered in patients who have disease states associated with malabsorption of the mineral (References 74, 75). The ferrous salt form is often used in therapy because it is most readily absorbed, although only 10% to 35% of an oral dose of ferrous sulfate is absorbed by the GI tract. The percentage of iron that is absorbed by the GI tract increases to 80% to 95% during iron deficiency (Reference 19).

Most commercially available products for oral administration are supplied as ferrous iron, and several different salt forms are on the market. Each salt form has a varying amount of elemental iron, but the extent

of iron absorption is relatively the same for all formulations. Table 4 and Table 5 provide details of elemental iron content for single-ingredient oral iron preparations and multivitamins (References 76–80).

For infants and children with mild to moderate anemia, elemental iron at a dose of 3 mg/kg given once daily or divided into two doses is recommended. Severe IDA is treated with elemental iron 4–6 mg/kg/day, usually given in three divided doses (Reference 76). Liquid oral iron preparations are preferred for infants and young children because they are unable to swallow tablets. This formulation may also be preferred for certain individuals who are unable to adequately absorb iron tablets because of poor dissolution of the film coating (Reference 81). Caution should be taken when dosing liquid iron preparations to young children because elemental iron concentrations vary among different products. Close attention should be given to interpreting the iron content because some preparations provide details in the form of milligrams of the iron salt, whereas other preparations provide iron content as milligrams

of elemental iron. Several preparations provide details of iron content both as elemental iron and as the iron salt. Misinterpreting this information can lead to dosing errors. It is especially important to be aware of these issues when substituting one liquid preparation for another (see Table 4) (References 76–79).

Ideally, oral iron supplements should be taken on an empty stomach; however, this may not be possible because of the GI distress that occurs in some individuals with this therapy. Gastrointestinal distress is a common adverse effect of oral iron, and it is the most common reason for therapy nonadherence. Symptoms with a greater than 10% occurrence rate include abdominal pain, epigastric pain, nausea, vomiting, and constipation. Adequate daily fluid intake should be encouraged to alleviate constipation. Stool softeners may also be considered. Diarrhea may occur, but to a lesser extent (Reference 76–78). Administering the drug with meals may reduce GI symptoms but may decrease the extent of drug absorption. Alternatively, giving smaller doses more often may be tried. Carbonyl iron, polysaccharide iron complex, or delayed-release formulations may

**Table 4.** Iron Content of Select Single-Ingredient Pediatric Oral Supplements (References 76-79)

Drug	Percent Elemental Iron	Dosage Strength
<b>Single-Ingredient Product</b>		
Ferrous gluconate (Fergon)	11.2	240-mg tablet (elemental iron 27 mg)
Ferrous fumarate (Ferro-Sequels)	33.3	150-mg tablet (elemental iron 50 mg)
Ferrous sulfate, enteric-coated tablets	20	324-mg tablet (elemental iron 65 mg)
Ferrous sulfate, exsiccated tablets (Feosol)	32.5	200-mg tablet (elemental iron 65 mg)
Ferrous sulfate, extended-release tablets	32.1	140-mg tablet (elemental iron 45 mg)
Ferrous sulfate, slow-release tablets (Slow FE)	31.7	142-mg tablet (elemental iron 45 mg)
Ferrous sulfate, elixir	20	220 mg/5 mL (elemental iron 44 mg/5 mL)
Ferrous sulfate, liquid	20	300 mg/5 mL (elemental iron 60 mg/5 mL)
Ferrous sulfate, liquid drops (Fer-In-Sol)	20	75 mg/mL (elemental iron 15 mg/mL)
Ferrous sulfate, suspension (MyKidz Iron 10)	20	75 mg/1.5 mL (elemental iron 15 mg/1.5 mL)
Polysaccharide iron complex, capsules (various manufacturers)	100	Elemental iron 150 mg per capsule

have fewer GI effects (References 69, 74). Carbonyl iron is a pure form of iron that can be found in certain pediatric multivitamin formulations such as chewable tablets or as a gummy. This form of iron is more slowly absorbed and has a higher bioavailability than ferrous sulfate. It also has a better safety profile than ferrous sulfate. The estimated median lethal dose (LD<sub>50</sub>) of ferrous sulfate is 250 mg of ferrous iron per kilogram of body weight (References 82). Toxicity studies in animals estimate the lethal dose at which no deaths occurred (LD<sub>0</sub>) for carbonyl iron to be 10,000–15,000 mg of iron per kilogram of body weight (References 82, 83). To extrapolate these data to humans, a 10-kg child would have only consumed around one-third of the LD<sub>0</sub> if the child ingested 63 carbonyl iron capsules,

each containing 600 mg (Reference 83). Fatal outcomes have arisen from children ingesting 30 to 40 ferrous sulfate 325 mg tablets and there have been reported deaths with very young children consuming as few as five tablets (Reference 82). Caution should still be taken with carbonyl iron because an accidental overdose can occur. Polysaccharide iron complex is available as an elixir or tablet for use in children 6 years and older (Reference 79). Enteric-coated preparations, which delay the dissolution of iron until it reaches the intestinal tract, may be considered for older children who are able to swallow tablets. Enteric-coated preparations may have lower bioavailability than film-coated preparations and oral solutions. This should be considered when changing products (Reference 84).

**Table 5.** Vitamin B, Folic Acid, and Elemental Iron Content of Select Multi-ingredient Pediatric Oral Supplements (Reference 80)

Drug	Percent Elemental Iron	Dosage Strength	Folic Acid	Vitamin B <sub>12</sub>
Centrum Kids Complete (Carbonyl iron)	100	Elemental iron 18 mg per tablet	400 mcg per tablet	6 mcg per tablet
Flintstones Gummies Complete	-	-	100 mcg per each gummy	1.5 mcg per each gummy
Flintstones Complete Chewables (Ferrous fumarate)	100	Elemental iron 18 mg per tablet	400 mcg per tablet	6 mcg per tablet
Flintstones with Iron Chewables (Ferrous fumarate)	100	Elemental iron 15 mg per tablet	300 mcg per tablet	4.5 mcg per tablet
L'il Critters Gummy Vites	-	-	130 mcg per each gummy	3 mcg per each gummy
L'il Critters Omega-3 Gummy Fish	-	-	-	-

Additional adverse effects associated with oral iron supplements that may be of concern to patients and caregivers are urine discoloration and dark stools. Tooth discoloration observed in individuals taking liquid iron preparations is superficial and not permanent. Diluting the oral liquid with water or juice and giving the supplement through a straw can minimize contact of the solution with teeth. Proper oral hygiene can remove and prevent tooth discoloration (Reference 76).

### Monitoring

Assessing hemoglobin changes in combination with a reticulocyte count may be useful in determining treatment response to anemia because changes in the reticulocyte count can be seen in the early stages of erythropoiesis. A hemoglobin increase of 1 g/dL should occur every 2–3 weeks after therapy initiation. Some individuals may require up to 4 months of therapy for iron status to return to therapeutic range once hemoglobin has been corrected (Reference 81). Hemoglobin values that increase by more than 1 g/dL or absolute reticulocyte counts that increase by more than 100,000 cells/mm<sup>3</sup> (100 × 10<sup>6</sup>/L) after 4 weeks of therapy indicate the patient is responding to therapy (References 19, 73).

## ANEMIA OF CKD

### Pathogenesis

Anemia in CKD is common and often occurs early. The cause of anemia may be erythropoietin deficiency; however, there may be other causes such as iron deficiency. Individuals on dialysis therapy have the highest risk of anemia secondary to regular blood loss to the dialysis circuit after each dialysis session. The use of anticoagulation associated with dialysis therapy increases the risk of GI bleeds, and frequent phlebotomy can contribute to blood loss and anemia.

### Clinical Features and Complications

In general, complications seen in patients with CKD are similar to those in patients with IDA. Having CKD and anemia can decrease a patient's quality of life. These individuals have increased risk of target organ damage. Impaired oxygen delivery increases the workload of the heart. Over time, this could lead to ventricular hypertrophy and poor cardiac output (Reference 85).

### Diagnosis

The KDOQI anemia workgroup recommends a complete blood cell count, TSAT, and serum ferritin for initial assessment of anemia in all children with a diagnosis of CKD. Hemoglobin values should be measured at least annually, and more frequent monitoring may be needed for those at higher risk of anemia. This includes

children who have a greater disease burden, those who have an unstable clinical course, or those who have had a previous decrease in hemoglobin concentration. A diagnosis of anemia should be made when the observed hemoglobin value is lower than the 5th percentile of normal when adjusted for age and sex (Reference 2).

### *Erythropoietin Concentration*

Erythropoietin is a glycosylated protein that weighs around 30,500 Da (Reference 13). The clinical utility of this laboratory test is limited. It is not routinely useful to differentiate erythropoietin deficiency from other types of anemia (Reference 2). In addition, erythropoietin levels are only useful when evaluating individuals with a hemoglobin value less than 10 g/dL. This is because erythropoietin concentrations are typically within normal range in patients having hemoglobin values higher than 10 g/dL (Reference 73).

### *Erythrocyte Protoporphyrin*

Erythrocyte protoporphyrin (EP) is the immediate precursor of hemoglobin. It increases when insufficient iron is available for hemoglobin production. Erythrocyte protoporphyrin is more sensitive and is at least as specific for detecting IDA as hemoglobin and serum ferritin. This makes EP a useful screening tool for detecting earlier stages of iron deficiency (Reference 20). Early detection is important in children because of the developmental consequences associated with IDA. A whole-blood EP value of 35 mcg/dL or greater suggests decreased hemoglobin production and iron deficiency (References 86, 87). Erythrocyte protoporphyrin is not widely used at this time. Compared with hemoglobin, EP is a more expensive and complicated test to perform.

### *Reticulocyte Hemoglobin Content*

Reticulocyte hemoglobin content (CHr) quantifies the amount of hemoglobin found in reticulocytes. This is another test of adequacy of iron for erythropoiesis. It is a direct measure of iron that is incorporated into newly formed RBCs. Because reticulocytes are typically 1–2 days old, this laboratory parameter reflects immediate availability of iron. Many studies have shown that CHr is effective for the early detection of iron-restricted erythropoiesis in adults who received epoetin therapy. The KDOQI recommends targeting CHr greater than 29 pg/cell as an alternative to TSAT for adult hemodialysis patients with anemia (Reference 88). Reticulocyte hemoglobin content is not widely used in children at this time, and pediatric data are limited. A study comparing the performance of laboratory parameters in 210 children (mean [SD] age, 2.7 [2.0] years) who

underwent lead screening found that CHr was the only significant predictor of iron deficiency. A CHr of 26 pg/cell or less was the optimal cutoff value for detecting iron deficiency (Reference 89).

### Treatment

The goal of iron therapy is to avoid storage iron depletion, prevent iron-deficient erythropoiesis, and achieve and maintain erythropoiesis (Reference 3). For patients on hemodialysis, sufficient iron should be given to maintain a serum ferritin above 200 ng/mL and TSAT above 20%. For patients who have CKD not requiring dialysis or those who require peritoneal dialysis, serum ferritin should be maintained above 100 ng/mL and TSAT above 20% (Reference 3).

Although the absorption of oral iron may be slow, it remains an effective therapy and is preferred for children with anemia of CKD who are not on dialysis and children who are on peritoneal dialysis. The recommended dose of elemental iron is 2–3 mg/kg/day up to 6 mg/kg/day (maximum 150–300 mg of elemental iron per day) given in two or three divided doses. To optimize GI absorption, doses of oral iron preparations should be taken at least 2 hours before or 1 hour after ingesting any calcium-containing phosphate binders (Reference 2). There are several reasons why an individual may not respond to oral iron supplementation. Therapy nonadherence, impaired GI absorption of iron, inflammation, and chronic bleeding can all contribute to therapy unresponsiveness. Most data supporting the use of intravenous iron are found in the dialysis patient population. Red blood cell transfusions are necessary if patients are symptomatic after experiencing acute bleeding, acute hemolysis, or blood loss from surgery (Reference 3).

### Intravenous Iron

Injectable iron therapy is generally reserved for when oral therapy has failed. However, it is the preferred route of administration for treating anemia in children on hemodialysis therapy. Current intravenous iron preparations consist of iron complexed to a carbohydrate moiety. In the body, the reticuloendothelial cells separate the iron from the iron-carbohydrate complex (Reference 90). The iron is then available for binding to transferrin for transport throughout the body. It may be incorporated into the body's total iron stores, or it may be used for hemoglobin synthesis (Reference 90).

No adequately powered studies exist that directly compare efficacy between parenteral iron preparations. Hypersensitivity reactions can occur with all injectable iron preparations; however, they are more pronounced

with iron dextran. Iron toxicity can be detrimental in both acute and chronic situations. Care should be taken to monitor for iron overload in patients with predisposing conditions.

### Iron Dextran

Iron dextran is an older formulation of parenteral iron. It is ferric hydroxide complexed with polymerized dextran. In comparative studies, iron dextran showed higher rates of adverse events than newer parenteral iron preparations. Use of this iron preparation is associated with increased risk of hypersensitivity reactions. Iron dextran should generally not be given to infants in the first 4 months of life. Before iron dextran is administered, all patients should receive an intravenous test dose of 0.5 mL (25 mg) (Reference 91). Cases have been documented in which patients tolerated a test dose but then experienced a hypersensitivity reaction with treatment doses. Caution should be taken to maintain an administration rate below 50 mg/minute when giving treatment doses. The dosage calculation for intravenous infusion in an iron-deficient patient is described below (Reference 91).

Calculation of iron dextran dose for children 5–15 kg is as follows (Reference 91):

$$\text{dose (mL)} = 0.0442 [\text{desired hemoglobin (g/dL)} - \text{observed hemoglobin (g/dL)}] \times W + (0.26 \times W)$$

where W = weight in kg.

$$\text{weight in kg} = \frac{\text{weight (lb)}}{2.2}$$

### Iron Sucrose (Iron Saccharate)

Iron sucrose is an aqueous complex of iron hydroxide in sucrose. It can be given undiluted by slow intravenous push or as an intravenous infusion. Iron sucrose is not FDA approved for use in children; however, it is prescribed. The pediatric dose for correcting iron status in hemodialysis-dependent patients is 1 mg/kg/dose per dialysis session. The maximum single dose is 100 mg. The suggested maintenance dose is 0.3 mg/kg/dose given at each dialysis session (Reference 92). Iron sucrose has been successfully administered to adult patients with sensitivity to iron dextran and does not require a test dose before administration (References 2, 93). Safety data related to the use of iron sucrose in children are limited. A retrospective study involving eight individuals who received at least one dose of iron sucrose reported no serious adverse events (Reference 2).

### *Ferric Gluconate*

Ferric gluconate is a sodium ferric gluconate complex in sucrose. Ferric gluconate is FDA approved for use in children 6 years and older undergoing hemodialysis and receiving epoetin therapy (Reference 94). The recommended pediatric regimen is 1.5 mg/kg/dose of elemental iron at each dialysis session for eight doses total. The maximum single dose is 125 mg. A slow infusion rate is recommended over 60 minutes (Reference 94). Hypersensitivity reactions are rare (Reference 93). In a trial involving children who received eight intravenous doses of ferric gluconate, no child developed an allergic or anaphylactic reaction during the immediate treatment. One child who was given a 1.5-mg/kg dose developed an isolated episode of mild nausea, vomiting, and diarrhea (Reference 2).

### *Ferumoxytol*

Ferumoxytol is the newest parenteral iron preparation on the market. It is a superparamagnetic iron oxide coated with a low-molecular-weight semisynthetic carbohydrate. The safety and efficacy of ferumoxytol use in children have not been established (Reference 95).

### **Recombinant Human Epoetin**

Epoetin is often used to stimulate erythropoiesis in patients with renal dysfunction. Most of the available data for use in children involve short-acting agents such as epoetin alfa (Reference 3). Because of convenience, subcutaneous administration is favored. Observational trials of children suggest that administering short-acting epoetin subcutaneously is more efficacious than using the intravenous route (Reference 3).

Information derived from registry data suggests that a higher starting dose of a short-acting epoetin is required for hemodialysis patients, compared with peritoneal dialysis patients, to achieve target hemoglobin values of 11–12 g/dL. The mean dose of short-acting epoetin for children on hemodialysis is 300 units/kg/week compared with 225 units/kg/week for peritoneal dialysis patients. Young children require higher doses per kilogram of body weight than older children. Infants on average require 350 units/kg/week. Those between 2 and 5 years of age and 6 and 12 years of age require slightly lower doses (about 275 units/kg/week and 250 units/kg/week, respectively). Children older than 12 years need around 200 units/kg/week (Reference 3).

Pediatric studies involving long-acting epoetin (darbepoetin alfa) are limited. One small study involving children on hemodialysis therapy proposed a dose conversion of 0.5 mcg of darbepoetin alfa for every 200 units of erythropoietin alfa (Reference 3).

In children with CKD who are not receiving dialysis, the mean dose of short-acting erythropoietin alfa required to maintain target hemoglobin values between 11.5 g/dL and 13.5 g/dL is 133 units/kg/week. The dose range is 75–300 units/kg/week. Darbepoetin alfa at a dose of 0.45 mcg/kg/week showed similar efficacy (Reference 3).

Up to 10% of patients with CKD have a poor response to epoetin therapy. Hyporesponsiveness to epoetin therapy is defined as persistently low hemoglobin (less than 10 g/dL), despite treatment with clinically appropriate doses (Reference 3). Clinicians should rule out nonadherence and verify that the patient has sufficient iron available for erythropoiesis. Transferrin saturation percent should be greater than 20%, and serum ferritin should be higher than 100 ng/mL. Other potential causes of hyporesponsiveness include infection, inflammation, and inefficient dialysis. It is believed that uremia is associated with increased release of proinflammatory cytokines in the bone marrow. Chronic inflammation can lead to impaired erythropoiesis (Reference 96).

Blood pressure should be assessed because hypertension in children receiving epoetin is an important concern. One pediatric study involving children 4 months to 21 years of age who received low or high doses of epoetin found that epoetin treatment was associated with a significant increase in diastolic blood pressure compared with baseline. Thrombotic events have also been reported in children receiving epoetin (Reference 2).

### **Monitoring**

An increase in the reticulocyte count is not observed for at least 4–7 days after starting therapy. A decision about the effectiveness of treatment should not be made for 3–4 weeks after treatment initiation (References 20, 81). Erythropoietic response to iron replacement is considered appropriate if the hemoglobin concentration increases by at least 2 g/dL or reaches normal values within 4 weeks of treatment. The 2 g/dL increase can be reached by intravenous iron therapy within 2–4 weeks (Reference 3). The hemoglobin target for all children with anemia of CKD is 11–12 g/dL (References 2, 88). The monitoring interval is extended to every 1–3 months once the patient has achieved a stable iron dose. More frequent monitoring is required for individuals who have experienced recent bleeding, for postsurgical or hospitalized patients, or for those who are hyporesponsive to epoetin (Reference 3). Erythropoietin concentrations have also been used to evaluate a patient's responsiveness to epoetin therapy (Reference 73).

Monitoring intervals are the same for individuals who receive oral iron, intravenous iron, or intravenous iron with epoetin. Recommendations for epoetin dose increases and decreases vary among different expert panels. According to the European Paediatric

Peritoneal Dialysis Working Group, a minimally acceptable increase in hemoglobin value is 0.66 g/dL per month. Other panels such as KDOQI recommend hemoglobin increases between 1 g/dL and 2 g/dL per month. Epoetin dosage adjustments should be considered for children who have a greater than 0.5 g/dL increase per week in hemoglobin to avoid exceeding the target value (Reference 2). It is also recommended to decrease the epoetin dose rather than hold or discontinue the medication when hemoglobin is above target range (References 2, 3). The ideal approach to therapy is to decrease the dose if hemoglobin is elevated (References 2, 3, 88).

Iron status tests should be performed monthly during initial treatment with epoetin. Serum ferritin should be maintained above 100 ng/mL, and TSAT should be above 20% during epoetin treatment. The monitoring interval for assessing iron status may be extended to every 3 months for children who are on a stable epoetin dose or for those who are on hemodialysis and are not receiving epoetin therapy (Reference 2).

## CONCLUSIONS

Anemia is commonly caused by iron, folate, and/or vitamin B<sub>12</sub> nutritional deficiencies. Severe inflammation, CKD, or other chronic illnesses can also cause anemia. Rapid growth and development, together with decreased stores of certain nutrients compared with adults, contribute to increased risk of anemia in children.

Mild cases of anemia can still have effects on oxygen transport capacity of the blood and may produce symptoms such as irritability, lethargy, and decreased physical endurance. Additional symptoms vary and pertain to the cause of anemia. For example, folate deficiency in pregnant women can lead to neural tube defects in the fetus, vitamin B<sub>12</sub> deficiency is associated with neurologic damage, and iron deficiency is associated with poor cognitive and motor development.

Early detection of deficiency and prevention of anemia are essential. In the United States, fortifying foods is one measure taken to prevent nutritional deficiencies. Many laboratory assays are available; however, hemoglobin is currently the standard laboratory assessment for detecting and monitoring anemia.

Pediatric cases of folate and/or vitamin B<sub>12</sub> anemia in the United States are rare. If treatment is required, folic acid is available in oral and injectable dosage forms. The dosing strategy is the same for all formulations. Vitamin B<sub>12</sub> deficiency may be treated with cyanocobalamin given intramuscularly or subcutaneously. Individuals with severe vitamin B<sub>12</sub> deficiency could develop profound

and potentially fatal hypokalemia. It is important to closely monitor patients during the first 48 hours after initiating therapy, and potassium replacement should be available for use if the need arises.

Iron deficiency is the most common form of nutritional deficiency worldwide. In the United States, the prevalence of iron deficiency among young children is of concern. The AAP has published guidelines detailing measures that should be taken to detect and prevent IDA in infants and young children. Oral iron is the therapy of choice for treating iron deficiency and IDA. Gastrointestinal adverse effects from oral therapy can contribute to nonadherence. Giving iron in smaller doses or with food can help alleviate GI effects.

Anemia of CKD may be caused by IDA in combination with erythropoietin deficiency. This type of anemia can occur early in CKD, and it can decrease a child's quality of life. Long-standing anemia can lead to ventricular hypertrophy and cardiac dysfunction. Oral iron is the therapy of choice; however, intravenous iron may be necessary. Children with malabsorptive disorders may benefit from intravenous iron, and those receiving dialysis often require intravenous iron therapy. If intravenous iron is needed, newer formulations (e.g., ferric gluconate and iron saccharate) are preferred because of their better adverse effect profile compared with iron dextran. Epoetin is also commonly used to treat anemia of CKD. Most data for use in children involve the short-acting formulation, epoetin alfa. Children who require epoetin should have a baseline iron profile to ensure adequate iron status before starting epoetin. Hemoglobin, while on epoetin therapy, should not exceed 13 g/dL.

Although untreated anemia of all types may result in considerable organ dysfunction, it is reassuring that early detection and treatment can prevent these complications. Preventive medicine, instead of reactive medicine, should be the gold standard.

# CHAPTER 48

## ANTICOAGULATION

Brady S. Moffett, Pharm.D., MPH

### LEARNING OBJECTIVES

1. Understand the epidemiology and pathophysiology of pediatric thrombosis, including common risk factors for thrombosis.
2. Understand the pharmacology and therapeutics of antithrombotic agents including unfractionated heparin, warfarin, low-molecular-weight heparin, and direct thrombin inhibitors.
3. Know how to monitor pediatric patients receiving anticoagulant medications for the treatment and prevention of thrombosis.

### ABBREVIATIONS IN THIS CHAPTER

ACT	Activated clotting time
Anti-Xa	Antifactor Xa
aPTT	Activated partial thromboplastin time
DVT	Deep venous thrombosis
HIT	Heparin-induced thrombocytopenia
INR	International normalized ratio
PE	Pulmonary embolism
UFH	Unfractionated heparin

### INTRODUCTION

This chapter will review the epidemiology and etiology of thrombosis in the pediatric population and will focus on the pharmacologic treatment and prophylaxis of thrombosis in pediatric patients. Because anticoagulant agents are used in a wide variety of practice settings, this chapter must be limited to indications that are common to pediatric patients, but also outside the purview of other disease states that are covered in separate chapters of this book (e.g., prophylaxis of thrombosis in patients with cancer or heart disease). Other patient populations that receive anticoagulants, but that will not be covered in this chapter, include patients undergoing hemodialysis, patients in the cardiac catheterization laboratory, and patients in the operating room (including those undergoing cardiopulmonary bypass). Primarily, this chapter will focus on thromboses that occur within the vasculature (deep venous thrombosis [DVT], arterial thrombosis, pulmonary embolism

[PE], ischemic stroke) and intravascular catheter patency in the pediatric population. The intention is that a review of these areas, with a focus on the available pharmacotherapy data for them, will cover most pediatric pharmacist-patient interactions.

### DEEP VENOUS THROMBOSIS

The epidemiology of pediatric DVT is markedly different from that of adult DVT. Most adult DVTs occur in the lower extremities, whereas pediatric DVTs often occur in both the upper and lower extremities. Unlike in adults, the etiology of pediatric DVT is rarely idiopathic because pediatric patients have a lower thrombotic potential compared with adults owing to their decreased concentrations of plasma procoagulant factors, decreased thrombotic potential of the vascular endothelium, and increased inhibition of thrombin by alpha-2 macroglobulin (References 1, 2).

The incidence of pediatric DVT has been increasing. In 2000, an incidence of 5.3 per 10,000 pediatric hospital admissions was noted, which has subsequently increased to a current incidence as high as 58 per 10,000 pediatric hospital admissions (References 1–4). In general, infants and adolescents have the highest incidence of DVT (Reference 4). Central venous catheters are the primary underlying factor for developing a DVT, particularly in younger and critically ill children, and account for most DVTs in the upper parts of the vasculature. Other factors include sepsis, nephrotic syndrome, malignancy, surgery, congenital heart disease (with or without prosthetic materials), antiphospholipid antibody syndrome, L-asparaginase therapy, and congenital or acquired prothrombotic conditions. Adolescent females also have a higher risk of developing a DVT, presumably because of oral contraceptive use (References 1–5).

Many pediatric patients with a DVT are asymptomatic (References 2, 6). Patients with symptoms note pain, discoloration, and swelling in the area distal to the DVT. Catheter-related DVTs are often initially noticed when the catheter begins to malfunction or when the thrombus becomes infected and no other source for infection in a patient can be found (References 1, 2, 6). Neonates may present with thrombocytopenia caused by thrombus consumption of platelets. D-dimer tests can be used to assist in the detection of a DVT, and Doppler ultrasonography is used often for detecting

extrathoracic DVTs. Echocardiography can be useful for identifying a thrombus within the vena cavae, and a computed tomography (CT) scan is often used for detecting a thrombus within the abdominal and pelvic regions (References 1, 2, 6).

Mortality rates for venous thromboembolism have been previously reported at 1% to 2%, but recently, they have been noted to be as high as 8% for a patient admitted with a DVT (References 2, 3, 6). Recurrence rates after resolution of initial DVT are high (9% to 21%), most likely because of underlying chronic conditions (Reference 5). Postthrombotic syndrome can occur in pediatric patients after resolution of a DVT in the leg; it consists of pain, swelling, altered skin pigmentation, and skin ulceration near the site of the DVT. The etiology of this condition is unclear, but symptoms are usually mild in children (References 2, 7).

Long-term anticoagulation is the primary therapy for treatment of pediatric DVT. For an outpatient with an uncomplicated DVT, use of enoxaparin or warfarin is typically indicated for 3–6 months (Reference 8). Laboratory monitoring (anti-Xa or INR) should occur at the beginning of therapy and regularly throughout therapy, especially in younger patients, to ensure the attainment of therapeutic concentrations. In particular, warfarin can be difficult to manage in infants and children (Reference 9). Patients with a large thrombus, evidence of progression of thrombus while on anticoagulant therapy, or a thrombus that completely occludes a vessel may require more than 6 months of therapy. Inpatients or critically ill patients with a DVT may be placed on unfractionated heparin (UFH) titrated to therapeutic aPTT or anti-Xa concentrations before the transition to enoxaparin or warfarin as the patient stabilizes. The choice of initial anticoagulant therapy can vary on the basis of patient characteristics and pathophysiology.

## PULMONARY EMBOLISM

Pulmonary embolism is a rare event in pediatric patients, with reported rates at less than 1 per 100,000 children per year (References 10, 11). However, this is likely an underestimation of the true incidence because most patients with a PE are asymptomatic unless the embolus is very large (Reference 12). In pediatric populations with risk factors, the percentage of patients who were asymptomatic but had PEs was as high as 50% (Reference 13). Risk factors for PE are similar to those for DVT, and the incidence of PE is likely increasing because of the increased use of central venous catheters (Reference 3).

As previously stated, most pediatric patients who present with a PE will be asymptomatic unless the PE is large (obstructing more than 50% of the pulmonary circulation). However, patients with preexisting

hemodynamic instability or decreased pulmonary blood flow may have symptoms even with small emboli. Primary symptoms include dyspnea, cough, hemoptysis, and chest pain (Reference 12). Patients may also have a concurrent DVT at another location in the body. Increased pulmonary vascular resistance caused by an embolus may lead to elevated right ventricular pressures or tricuspid regurgitation. Ventilation and perfusion mismatch may occur, and patient arterial oxygen saturation may decrease. Ventilated patients may have a sudden increase in oxygen requirements. Arrhythmias and even sudden death have occurred in pediatric patients with a PE. A D-dimer test can be useful for determining an embolus. Diagnosis can be made by the use of noninvasive imaging, such as magnetic resonance imaging (MRI), CT scan, ventilation perfusion lung scanning, or pulmonary angiography. However, the data for use of these modalities are primarily extrapolated from adult experience (Reference 12).

The goal of therapy is to eradicate the PE and prevent the recurrence or propagation of the embolus. Nonpharmacologic therapies for PE include surgical embolectomy and interventional procedures. Surgical procedures can have substantial associated morbidity (Reference 14). Catheter-based techniques can minimize morbidity, but they should only be performed by clinicians with experience and in centers that can offer this therapy (Reference 15).

Choice of pharmacologic therapy for PE will be based on the acuity of the patient and the size of the embolus. Unfractionated heparin is often the first-line agent for acute treatment of PE in children. If a patient is experiencing hemodynamic compromise, the use of alteplase for thrombolysis is an option, but definitive recommendations for the use of alteplase in pediatric patients are unavailable because of the small number of patient cases that have been reported (References 16–20). Use of alteplase for PE in a pediatric patient should be evaluated on a case-by-case basis because morbidity from hemorrhage can be high. For longer-term therapy, enoxaparin or warfarin can be used, depending on patient factors and preferences. Patients will often be treated for at least 6 months after receiving a diagnosis of a PE, but the optimal treatment duration in pediatric patients is currently unknown (Reference 8).

## ARTERIAL THROMBOSIS

Arterial thrombosis is a rare but potentially devastating condition. Primarily, the thrombosis occurs because of indwelling arterial catheters or after cardiac catheterization at the arterial access point of catheter insertion (References 21, 22). Damage to the endothelium of the artery, resulting in inflammation and clotting cascade activation, is the primary pathophysiology for arterial

thrombosis (Reference 8). Younger patients who have had arterial catheters indwelling for extended periods are at the greatest risk of arterial thrombosis (Reference 23). In addition, if the patient did not have a prophylactic infusion of UFH through the arterial catheter, he or she is at increased risk of thrombosis. Septic patients or patients with underlying coagulopathies with indwelling catheters are also at increased risk of arterial thrombosis (References 8, 22, 24, 25).

Patients with an arterial thrombosis will typically present with an acute loss of circulation to the affected limb or region. Doppler ultrasonography for detection of pulses distal to the thrombus can be useful to assess the clinical severity of the thrombus. Contrast angiography is the gold standard for assessing arterial thrombosis, but it is difficult to perform in young children (Reference 26).

If possible, the first step for treatment of arterial thrombosis is to remove the offending catheter. Non-pharmacologic treatment of arterial thrombosis is typically reserved for life- or limb-threatening conditions. Thrombectomy, either surgically or interventionally can be performed for large thrombi. Devices to mechanically destroy a thrombus have also been used. However, these devices have the disadvantage of potentially causing trauma to the vessel wall and are sometimes unable to extract free-floating thrombus (Reference 27).

Pharmacologic therapy is instituted on the basis of the severity of arterial blockage. Unfractionated heparin or enoxaparin is typically a first-line agent for arterial thrombus that is not immediately life or limb threatening (References 26, 28). Alteplase has been used in emergency cases for the dissolution of an arterial thrombus (Reference 29). The use of alteplase has a high bleeding risk, and caution should be exercised in patients with the potential for hemorrhage, such as premature infants, patients who have undergone recent major surgery, or patients with baseline bleeding disorders (Reference 8).

## ISCHEMIC STROKE

Acute ischemic stroke is uncommon in infants and children, with an incidence ranging from 2 to 8 per 100,000 children per year in the United States. Morbidity is very high in patients who have had an ischemic stroke, with as many as 70% of patients having a persistent neurologic deficit. Risk factors for ischemic stroke include cardiovascular disease (congenital or acquired), vasculopathies, sickle cell disease, and other coagulopathies (References 30, 31). However, about 30% of the children presenting with an ischemic stroke have no identifiable risk factors (References 32, 33).

Pediatric patients with an ischemic stroke will present with monoparesis or hemiparesis, vision changes, numbness, ataxia, headache, seizures, and/or altered mental status. These signs and symptoms will vary depending on the age of the child and any other comorbid conditions that are present (References 30–34).

Initial medical management of the pediatric patient with ischemic stroke includes maintaining airway, breathing, and circulation and performing hematologic studies to evaluate for baseline coagulopathies. Use of brain CT or MRI can be useful to identify whether the stroke is ischemic or hemorrhagic, but the choice of modality must be evaluated on a case-by-case basis (Reference 35). Monitoring of blood pressure and maintenance of blood glucose are also important parameters to evaluate because patients with ischemic stroke may have worse outcomes with hypotension or hyperglycemia (References 36, 37). Surgical or interventional procedures may be an option, but there are limited data to routinely recommend their use in pediatric patients. Dysregulation of body temperature has been noted, and acetaminophen should be used to decrease temperature in patients with fever (References 36, 37). Seizures are common in patients with ischemic stroke; fosphenytoin and levetiracetam have both been used in this subset of patients (Reference 37).

Anticoagulation therapy for pediatric patients can be quite varied, and no current standard for treatment of ischemic stroke exists. A recent survey of centers that care for patients with acute ischemic stroke showed almost equal use of antiplatelet therapy and anticoagulation in pediatric patients with acute ischemic stroke, with a smaller percentage using both (Reference 36). Unfractionated heparin or enoxaparin has traditionally been a first-line treatment option, with enoxaparin more traditionally used in the post-acute stroke period (Reference 38). Warfarin can be used as long-term therapy for stroke after the acute period. Antiplatelet therapy for acute ischemic stroke can also be quite varied, but traditionally, it has consisted of aspirin in the acute and chronic periods. In addition, clopidogrel and dipyridamole can be used, but limited data are associated with the use of either of these agents in the acute or chronic period in pediatric patients (References 39, 40). Duration and intensity of chronic therapy will largely depend on the etiology for the stroke and any underlying comorbidities that place the patient at increased risk of future events.

## MAINTENANCE OF ARTERIAL OR VENOUS CATHETER PATENCY

The previous section of this chapter focused on the treatment of thromboembolism within the various vascular structures of the body. As previously mentioned, the main cause of thromboembolism in pediatric patients is the presence of an indwelling venous or arterial catheter. To prevent thromboembolism and maintain these catheters in working order, prophylaxis is often necessary. For patients who have developed a thrombus at the tip of a catheter, treatment may be necessary to prevent the removal or replacement of the catheter.

In the hospital setting, several different techniques have been employed to prevent catheter-related thrombosis. Because of the wide variety of patients, UFH concentrations, use of bolus or continuous-infusion regimens, and catheter size and type, definitive recommendations for prophylaxis are currently unavailable. The use of UFH is not inconsequential because adverse events can occur even with the routine flushing of catheters (References 41–44). Using UFH as a bolus to flush central venous catheters has been shown to decrease the incidence of patient thromboembolism and the incidence of catheter replacement in pediatric patients compared with normal saline flushes. However, other studies have shown that low-dose UFH as a continuous infusion or bolus does not increase the time of patency compared with normal saline for central venous catheters in neonates (References 45–47). Other methods of preventing catheter-related thrombosis have also had unclear results. Routine low-dose anticoagulation of critically ill pediatric patients (not directed through the catheter) has not shown a benefit (Reference 41). A recent Cochrane Review suggests that using a low concentration of UFH as a continuous infusion through a central venous catheter in neonates prevents thrombosis (Reference 48). Reports of using heparin-bonded catheters have shown promise in preventing thromboembolism in pediatric patients, but this reduction may be the result of prevention of infection, not a direct anticoagulant effect (References 49–54). In the outpatient setting, prevention of catheter-related thrombosis has been evaluated in patients receiving warfarin and long-term total parenteral nutrition (Reference 55). Reviews of the literature have shown that more powerful study designs are necessary to obtain a definitive answer for the optimal regimen for prophylaxis of arterial and venous catheters (References 56–58).

Alteplase has been the most frequently studied agent for the treatment of catheter occlusions in pediatric patients, with many reports showing safety and efficacy in clearing catheter occlusions (References 59–66). In addition, interventional catheter-directed thrombolytic therapy with alteplase has been shown to be successful in clearing catheter occlusions compared with direct instillation of alteplase into the affected catheter (References 67, 68).

## PHARMACOLOGY

### Aspirin

Aspirin mediates antiplatelet effects by irreversibly acetylating cyclooxygenase-1, thereby decreasing the amount of thromboxane A<sub>2</sub> generated. A decrease in thromboxane A<sub>2</sub> leads to decreased platelet aggregation (References 69, 70). Absorption is primarily in the stomach and small intestines, with greater absorption

in the small intestines for enteric-coated formulations (Reference 69). Peak serum concentrations for non-enteric-coated or non-delayed-release aspirin formulations occur about 1–2 hours after oral ingestion. Aspirin is primarily hepatically metabolized and renally eliminated as unchanged drug or as metabolites and is dialyzable (Reference 69). Aspirin dosing in pediatric patients, which is not well defined, is often rounded to the nearest ¼ tablet due to unavailability of a commercially produced suspension (Table 1).

Adverse events with aspirin include bleeding caused by the lack of platelet aggregation, and enteric-coated formulations have been developed primarily to avoid gastrointestinal bleeding (Reference 69). Reye syndrome, a form of noninflammatory hepatic encephalopathy, has been linked to aspirin therapy in patients with viral illness. Historically, patients younger than 18 years have been advised not to take salicylate-containing products if they have a viral illness, to avoid the development of Reye syndrome (Reference 71). However, data supporting the link between aspirin use, viral illness, and Reye syndrome are weak, and the true etiology of Reye syndrome likely has a strong genetic component and is multifactorial (Reference 71).

### Dipyridamole

Dipyridamole inhibits platelet aggregation by decreasing phosphodiesterase, which results in an increase in cyclic adenosine monophosphate (cAMP). This increase in cAMP decreases platelet aggregation and may cause mild vasodilation. Prostacyclin release may also be induced by dipyridamole, which can also decrease platelet aggregation and cause arterial vasodilation (References 69, 72). Few data are available regarding the pharmacokinetics of dipyridamole in pediatric patients, and most dosing has been extrapolated from adult data (References 73–76) (Table 1). Dipyridamole is primarily hepatically metabolized and, when administered enterally, has slow and variable absorption from the gut.

Adverse events with dipyridamole include bleeding, caused by antiplatelet effects, and events related to vasodilation, such as syncope, dizziness, and hypotension. Bleeding risk may increase with the concomitant use of other antiplatelet or anticoagulant agents (References 69, 72). Data are limited for an accurate portrayal of the adverse events of dipyridamole in the pediatric population, and patients should be monitored closely for adverse events.

### Clopidogrel

Use of clopidogrel in the pediatric population is a relatively new phenomenon. However, more pediatric patients are being prescribed clopidogrel for a wide variety of indications, and dosing methods are being refined

**Table 1.** Dosing and Monitoring of Commonly Used Anticoagulant and Antiplatelet Agents in Pediatric Patients (References 69, 72)

Medication	Dosing and Administration	Suggested Monitoring Parameters
Abciximab (ReoPro)	<p>Infants, children, adolescents: Treatment: Bolus IV: 0.25 mg/kg/dose Continuous IV infusion: 0.125 mcg/kg/minute</p>	aPTT; PT; fibrinogen; platelet count; bleeding
Alteplase (Activase, Cathflo)	<p>Infants, children, adolescents: Treatment of systemic thrombus: Continuous IV infusion: 0.1–0.6 mg/kg/hour for 6 hours Note: UFH infusion is typically continued during alteplase infusion to prevent rethrombosis.</p> <p>Treatment of catheter thrombus: (low dose) Continuous IV infusion: 0.01–0.05 mg/kg/hour</p> <p>Catheter clearance: Dose: 0.5–2 mg in 1–3 mL of normal saline instilled into the catheter and aspirated after a 1- to 2-hour dwell time. Do not infuse into patient.</p>	aPTT; anti-Xa; plasminogen; fibrinogen; bleeding
Argatroban	<p>Infants, children, adolescents: Treatment: Continuous IV infusion: 1.75 mcg/kg/hour</p> <p>Dose may need to be reduced in patients with hepatic dysfunction.</p>	aPTT; platelet count; bleeding; serum creatinine; liver function
Aspirin	<p>Prophylaxis: Infants, children, adolescents: Oral: 1–5 mg/kg/day once daily; maximum 81 mg/day</p> <p>Kawasaki disease: Infants, children, adolescents: Oral: 80–100 mg/kg/day divided four times/day for 14 days, or until defervescence. Then 3–5 mg/kg/day once daily</p>	Platelet count; bleeding
Bivalirudin (Angiomax)	<p>Infants, children, adolescents: Treatment: Bolus IV: 0.75 mg/kg/dose Continuous IV infusion: 1.75 mg/kg/hour</p>	aPTT; ACT; platelet count; serum creatinine; bleeding
Clopidogrel (Plavix)	<p>Treatment, prophylaxis: Infants &lt; 24 months: Oral: 0.2 mg/kg/dose once daily</p> <p>Children &gt; 2 years: Oral: 1 mg/kg/dose once daily; maximum 75 mg once daily</p>	Platelet count; bleeding
Dipyridamole (Persantine)	<p>Treatment, prophylaxis: Infants, children, adolescents: Oral: 3–6 mg/kg/day divided three times day; maximum: 400 mg/day</p>	Platelet count; bleeding
Enoxaparin (Lovenox)	<p>Treatment: subcutaneous: Preterm neonates: 2 mg/kg/dose twice daily Term neonates: 1.7 mg/kg/dose twice daily Infants 1 to &lt; 2 months: 1.5 mg/kg/dose twice daily Children &gt; 2 months: 1 mg/kg/dose twice daily Adolescents and adults: 1 mg/kg/dose twice daily</p> <p>Prophylaxis: subcutaneous: Neonates, infants, and children: 0.75 mg/kg/dose twice daily Adolescents and adults: 0.5 mg/kg/dose twice daily</p>	<p>Anti-Xa; platelet count; serum creatinine; bleeding</p> <p>Goal anti-Xa concentrations for treatment of thrombus are typically 0.5–1 unit/mL and should be drawn 4–6 hours after a dose.</p>

(continued)

**Table 1. Dosing and Monitoring of Commonly Used Anticoagulant and Antiplatelet Agents in Pediatric Patients (References 69, 72) (continued)**

Medication	Dosing and Administration	Suggested Monitoring Parameters
	Prophylaxis for adolescents and adults may be a standard dose (40 mg subcutaneously) and can depend on indication for prophylaxis.	
	Injection sites should be rotated (abdomen, thigh, upper arm) to prevent injection site bruising and lipomas.	
Unfractionated heparin	Treatment of venous or arterial thrombus:  Infants $\leq$ 1 year starting dose: Bolus IV: 75 units/kg/dose Continuous-infusion IV: 28 units/kg/hour  Children > 1 year starting dose: Bolus IV: 75 units/kg/dose Continuous IV infusion: 20 units/kg/hour  Adolescents and adults, starting dose: Bolus IV: 80 units/kg/dose (maximum 5000 units) Continuous IV infusion: 18 units/kg/hour  Maintenance of catheter patency: Arterial: neonates: 5 units/mL infused at 1 mL/hour Infants and children: 1 unit/mL infused at 1 mL/hour  Venous: Neonates: 10 units/mL as a bolus flush Infants and children: 10–100 units/mL as a bolus flush	aPTT; anti-Xa; platelet count; bleeding; thrombosis; serum creatinine  Infusions should be titrated to a therapeutic aPTT or anti-Xa values, which may be institution-specific. aPTT values are typically calibrated to achieve an anti-Xa concentration of 0.35–0.7 unit/mL.  UFH use to maintain catheter patency will vary on the basis of patient- and institution-related factors. Caution should be warranted to ensure that young patients do not receive therapeutic doses of UFH from several flushes or infusions.
Warfarin (Coumadin)	Treatment, prophylaxis: Infants, children, adolescents: Starting dose: oral: 0.2 mg/kg/dose; maximum 5 mg/day Note: Loading doses of > 5 mg are generally not recommended.  Patients with drug interactions, Fontan, or hepatic disease: Starting dose: oral: 0.1 mg/kg/dose  Usual therapeutic doses: Infants < 1 year: 0.34 mg/kg/day Children 1–12 years: 0.15–0.19 mg/kg/day Adolescents: 0.14 mg/kg/day	PT; INR; bleeding; thrombosis; dietary intake of vitamin K; drug-drug interactions  Dose should be titrated to goal INR value for the patient.

ACT = activated clotting time; anti-Xa = antifactor Xa; aPTT = activated partial prothrombin time; INR = international normalized ratio; IV = intravenous; PT = prothrombin time; UFH = unfractionated heparin.

(References 77, 78) (Table 1). A formulation for a suspension of clopidogrel has recently been published that will allow greater ease of administration to younger patients (Reference 79). Clopidogrel is extensively hepatically metabolized into an active thiol compound, which irreversibly binds to the P2Y<sub>12</sub> platelet receptors and prevents activation of the glycoprotein IIb/IIIa platelet-binding complex. The metabolism of clopidogrel involves cytochrome P450 (CYP) enzymes, particularly CYP 2C19 and 3A4. Therefore, not all patients who receive clopidogrel will have the same degree of platelet inhibition because of the variability in patient enzyme expression and the subsequent variation in the transformation of clopidogrel into an active form (Reference 80). Clinically, the implications of patient pharmacogenomic variability and therapeutic outcomes with clopidogrel are

unknown. In addition, drug interactions play a role in the efficacy of clopidogrel platelet inhibition. Concomitant use of proton pump inhibitors with clopidogrel has been identified as a potentially significant drug interaction in both adults and children (References 81, 82). The exact clinical implications of this interaction have not yet been elucidated. Practitioners should be aware of the potential for significant drug interactions with clopidogrel and other medications that are metabolized or are substrates for the CYP family of enzymes.

### Warfarin

Warfarin has been widely used in both adult and pediatric patients for many years. The reader is encouraged to review current guidelines for warfarin therapy in the latest *CHEST* supplement (Reference 8).

Anticoagulation is achieved by inhibition of vitamin K epoxide reductase, which is responsible for converting the vitamin K–dependent clotting factors (II, VII, IX, X) to active forms. Warfarin also inhibits the anticoagulant proteins C and S.

Warfarin dosing in pediatric patients is on a milligram per kilogram basis, with reductions in dose for drug interactions or disease states (Reference 9) (Table 1). Because of the varying half-lives of the vitamin K–dependent clotting factors, the full effect of warfarin will typically not be seen until after 5–7 days of therapy. Dosing algorithms or guidelines and, more recently, pharmacogenomic testing can assist with identifying appropriate warfarin doses for therapeutic effect (References 83, 84). Therapy with warfarin in pediatric patients has been traditionally difficult to manage. The international normalized ratio (INR) is used to monitor warfarin therapy, but most pediatric goal INR ranges have been extrapolated from adult data. Variation in INR values is high in pediatric patients, and close monitoring is warranted (References 9, 85–88). Age, concomitant medications, disease state, nutritional status, and pharmacogenetic profiles of patients have been shown to alter dosing regimens of warfarin in pediatric patients (References 9, 89–91). Younger patients often require higher warfarin doses per kilogram of body weight to achieve therapeutic INR values (References 9, 89–91) (Table 1). The effect of vitamin K supplementation in diets as well as enteral feeding formulas or breastfeeding should be considered when evaluating warfarin therapy in pediatric patients (Reference 9).

Significant morbidity associated with warfarin therapy has driven the development of methods to improve warfarin dosing and monitoring. The use of standardized guidelines, health care provider and family education programs, computerized algorithms, and home INR monitoring are examples of interventions used to improve warfarin dosing and monitoring (References 84, 86, 92–100). Drug interactions play a role in the morbidity of patients taking warfarin, and pediatric patients likely have an exposure to interacting medications that is different from adult patients receiving warfarin (References 101, 102). Overall, a multidisciplinary approach to the management of warfarin therapy, with close monitoring, is ideal to maximize efficacy and minimize patient morbidity.

Pharmacogenomic testing has recently come to the forefront as a method for improving warfarin dosing and identifying patients at risk of warfarin-related morbidity (References 83, 103–106). Polymorphisms in *CYP2C9* have been shown to affect a patient's response to warfarin therapy (Reference 107). Specifically, Asian patients have been shown to require lower doses of warfarin because of the underexpression of *VKORC1* (Reference 108). Currently, no data are available to

guide pharmacogenomic dosing of warfarin specifically in pediatric patients (Reference 90). In addition, factors other than pharmacogenomics may better explain the variation in warfarin dose in the pediatric patient population (Reference 103). Adverse events with warfarin primarily consist of bleeding complications, with other complications (thrombosis, “purple toe syndrome”) occurring rarely (Reference 9). Studies evaluating the outpatient management of warfarin in pediatric patients have reported the incidence of bleeding caused by warfarin at around 0.5% per patient-year, although this rate can vary because of differing management strategies (References 9, 73, 89, 109). Guidelines for the reversal of warfarin therapy have been published, and reversal can be accomplished with the administration of enteral or intravenous vitamin K (Reference 8) (Table 2). Severe bleeding events may require the administration of blood products or recombinant clotting factors (References 8, 110). Routine administration of vitamin K for the management of elevated INR values without bleeding symptoms is discouraged. Holding warfarin therapy for a period is often as effective as administering reversal agents and prevents resistance to warfarin when therapy is reinitiated (Reference 111).

### Unfractionated Heparin

Unfractionated heparin (UFH) is a glycosaminoglycan that potentiates the action of antithrombin III on thrombin (factor II) to inhibit the conversion of fibrinogen to fibrin, which leads to decreased formation of thrombi. Unfractionated heparin also releases tissue factor pathway inhibitor, which has antithrombotic effects (Reference 112). In addition, UFH inhibits the activated factors IX, X, XI, and XII and plasmin. Metabolism of UFH is thought to occur by the reticulo-endothelial system, but it may have a small degree of elimination by renal routes (Reference 112).

Dosing of UFH is often dependent on laboratory monitoring parameters, patient factors, and pathophysiology (Table 1). Primarily, UFH is given as an intravenous continuous infusion for the treatment of thrombi, with loading doses given as a bolus. The subcutaneous route has been used for DVT prophylaxis in adults, but it is not typically recommended in children. Continuous infusions of UFH are dosed as units per kilogram per hour, with neonates requiring larger per kilogram doses compared with older children and adults, likely because of differences in heparin-protein-binding characteristics (References 69, 112, 113) (Table 1). Obese patients have been noted to require lower doses of UFH, but dose adjustment before therapy initiation for obesity is not routinely recommended (Reference 114). For patency of intravenous or intra-arterial catheters, UFH is usually administered at a constant continuous infusion through the catheter, with no dose adjustment on

**Table 2.** Reversal of Supratherapeutic Anticoagulant Effect (References 1, 4)

Anticoagulant	Laboratory Values	Clinical Evidence of Bleeding	Reversal Agent and Dosing
Low-molecular-weight heparin (enoxaparin)	Elevated aPTT or anti-Xa	Dependent on patient scenario—clinical evidence of bleeding not necessary to administer reversal agents	Protamine sulfate  Dose for correction of enoxaparin overdose is 1 mg of protamine per 1 mg of enoxaparin. Additional doses of 0.5 mg of protamine per 1 mg can be administered at 2- to 4-hour intervals if necessary.
Unfractionated heparin	Elevated aPTT or anti-Xa	Dependent on patient scenario—clinical evidence of bleeding not necessary to administer reversal agents	Protamine sulfate  Dose for immediate correction of UFH overdose is 1–1.5 mg of protamine per 100 units of UFH, with a maximum of 50 mg.  UFH is rapidly eliminated, and protamine dose should be decreased on the basis of the time after UFH administration.
Warfarin	INR < 5	No evidence of bleeding	Hold doses – no reversal agent necessary
	INR ≥ 5 and < 9	No factors for increased bleeding risk and no evidence of bleeding	Hold doses – no reversal agent necessary
	INR ≥ 9	Factors that increase risk of bleeding but no evidence of bleeding	Hold doses – administer enteral vitamin K at 1–2.5 mg/dose daily until INR is within normal limits.
		No bleeding	Hold doses – administer enteral vitamin K at 2.5–5 mg/dose daily until INR is within normal limits.
Any INR value	Serious or life-threatening bleeding	Hold doses – administer intravenous vitamin K, fresh frozen plasma, cryoprecipitate.  Recombinant factor VIIa (10–100 mcg/kg/ dose) may also be used. Lower doses are initially preferred.	

anti-Xa = antifactor Xa; aPTT = activated partial thromboplastin time; INR = international normalized ratio; UFH = unfractionated heparin.

the basis of laboratory parameters (Reference 8). Bolus doses of UFH can be used to flush intravenous catheters (Reference 8). Caution should be exercised and institutional safety policies developed when using UFH for various indications in the inpatient setting. Serious errors have occurred because of several concentrations of commercially available UFH.

Laboratory monitoring of UFH can vary markedly depending on patient care setting and availability of tests (Table 1). Traditionally, the activated partial thromboplastin time (aPTT) has been the standard for laboratory measurement of therapeutic effect of UFH. The aPTT is titrated to an antifactor Xa (anti-Xa) concentration of 0.3–0.7 unit/mL (chromogenic assay). Antifactor Xa concentration monitoring in pediatric patients is used in some institutions, but it is not routinely available because of cost and labor (References 112, 113, 115–120). The activated clotting time (ACT) is used when heparin concentrations are high, as in patients in the cardiac catheterization laboratory or

patients on cardiopulmonary bypass or extracorporeal membrane oxygenation. Overall, the ideal laboratory monitoring parameter for UFH in pediatric patients is unclear. The use of the aPTT or the ACT for children has not been shown to correlate well with anti-Xa concentrations (References 115, 116, 119–121). Finally, there have been no data to correlate beneficial outcomes with the achievement of goal aPTT values in pediatric patients (Reference 112).

Primary adverse events with UFH are bleeding and heparin-induced thrombocytopenia (HIT). Bleeding rates in pediatric patients receiving UFH are high (ranging from 1% to 56% of patients), but they are difficult to interpret because of the variety of definitions used and the relative paucity of data (Reference 112). Nonetheless, bleeding is a common adverse event in pediatric patients receiving UFH, and neonates or critically ill children may be at a greater risk of hemorrhage. Clinically significant hemorrhage can be treated with protamine sulfate and by discontinuing the UFH infusion (Table 2).

Heparin-induced thrombocytopenia type II is an immune-mediated reaction to platelets, whereas HIT type I is a much milder form of thrombocytopenia that is not immune mediated. Heparin-induced thrombocytopenia type II is characterized by a greater than 50% decrease in platelets and/or a new thrombotic event after the initiation of UFH, typically 5–14 days after starting (Reference 122). Clinical confirmation of HIT type II can occur with laboratory testing (serotonin tests, platelet factor 4, ELISA [enzyme-linked immunoassay]); however, the sensitivity and specificity of these tests are often low, and the results can be inconclusive. The data for HIT type II in pediatric patients are scarce, but it is thought to occur at a much lower incidence than in adult patients (Reference 123). When a patient is given a diagnosis of HIT type II, removal of UFH from all sources, including flushes, must occur. A direct thrombin inhibitor can be used, if anticoagulant therapy is necessary. However, low-molecular-weight heparins should not be used because of a high incidence of cross-reactivity (Reference 124).

Finally, osteoporosis has been noted as a potential adverse event in patients who are receiving prolonged therapy with UFH (Reference 125). It is recommended that long-term therapy with UFH be avoided to minimize the risk of osteoporosis (Reference 112).

### Low-Molecular-Weight Heparin

The primary low-molecular-weight heparin used in pediatric patients is enoxaparin. Other low-molecular-weight heparins, such as dalteparin and tinzaparin; have limited data for use in pediatric patients (References 126, 127). Enoxaparin primarily inhibits factor X and, to a lesser degree, factor II, by potentiating the action of antithrombin III on those factors. Factor X is inhibited to a 4 times greater extent than factor II. Enoxaparin is renally eliminated, with as much as 40% of the drug eliminated unchanged in the urine (References 69, 128–130). Enoxaparin has high bioavailability (about 100%) when administered subcutaneously (Reference 69).

Dosing of enoxaparin for treatment of thrombosis is on a milligram per kilogram basis for children (References 69, 128) (Table 1). An upper limit of dosing has not been determined, but morbidly obese patients may require empiric decreases in dose (References 131, 132). Dosage requirements to attain therapeutic concentrations decrease with age, with neonates requiring higher doses per kilogram than older children and adults (References 69, 128, 130, 133–139). However, the dose requirements for neonates and infants can vary widely (References 69, 128, 130, 133–139). Because enoxaparin is renally eliminated, patients with renal dysfunction or those who are undergoing dialysis should have doses adjusted on the basis of anti-Xa monitoring (Reference 69). To decrease the pain associated with

several injections, subcutaneous catheters have been used (References 133–136). The catheter can be placed subcutaneously and enoxaparin injected through the catheter, thus minimizing breaks into the skin. Dilutions of enoxaparin made from commercially available concentrations and the use of insulin syringes have been proposed to ensure adequate delivery of small volumes for subcutaneous injection (References 140, 141).

Antifactor Xa monitoring is not typically indicated for adult patients without significant comorbidities or in adult patients who receive enoxaparin for DVT prophylaxis. Patients with renal dysfunction, pregnancy, or obesity should have concentrations monitored because all of these can affect the attainment of therapeutic concentrations (Reference 69). In addition, pediatric patients should have anti-Xa concentrations monitored because of the wide range of dosing, particularly in neonates and infants, to achieve therapeutic concentrations and minimize bleeding risk (References 128, 136, 137). An anti-Xa concentration of 0.5–1 unit/mL drawn 4–6 hours after a dose at steady state is generally considered a therapeutic concentration, although there are limited pediatric data confirming the efficacy of this range (References 142, 143) (Table 1).

Bleeding has been associated with enoxaparin use, but at a much lower rate than with UFH. Hematoma development at the site of subcutaneous injection has been noted to occur, and appropriate administration techniques can minimize this adverse event (References 141, 144). Protamine sulfate can be used to reverse the effects of enoxaparin (References 69, 145) (Table 2). Heparin-induced thrombocytopenia has been noted with enoxaparin, but at a lower incidence than with UFH (Reference 69). However, low-molecular-weight heparins should not be used in patients who have developed HIT type II while receiving UFH.

### Alteplase

Alteplase is a recombinant form of serine protease that activates the conversion of plasminogen to plasmin within a fibrin clot. The plasmin degrades the fibrin and other procoagulant materials into soluble materials, thereby reducing the fibrin thrombus. Adult data suggest that alteplase has a very short half-life (from a few minutes to an hour) and that it is primarily hepatically metabolized. Few pharmacokinetic data are available to guide alteplase dosing in pediatric patients (Reference 69).

Alteplase dosing for the treatment of a thrombus in pediatric patients is controversial. High- and low-dose regimens have been reported (References 68, 69, 146–161) (Table 1). The clinical condition of the patient, size and location of the thrombus, and comfort of the practitioner in using alteplase may all be factors that determine the regimen chosen.

When administered systemically, alteplase is often given as an adjunct to continuous-infusion UFH therapy to prevent the re-formation of thrombus after lysis. Patient platelet counts, plasminogen levels, fibrinogen levels, aPTT, and anti-Xa levels should be monitored during the course of alteplase therapy. Patients should be monitored for signs and symptoms of bleeding, and they should be evaluated for bleeding risks before therapy is initiated.

When alteplase is used to clear an occluded arterial or venous catheter, standard doses and concentrations are often instilled into the occluded catheter, with lower doses/concentrations administered to younger patients. The alteplase is instilled into the catheter, left to dwell for about 2 hours, and then aspirated from the catheter and not given to the patient (Reference 69). Laboratory monitoring is not indicated when alteplase is used in this situation.

### ABCIXIMAB

Abciximab is an intravenous glycoprotein IIb/IIIa platelet inhibitor, used commonly in adult patients undergoing interventional cardiac catheterization procedures (Reference 162). Abciximab, which is given as a continuous infusion, is a potent, long-term, platelet inhibitor (Reference 69). Half-life in adults has been reported at about 30 minutes (Reference 69). Bleeding is the primary potential adverse event.

Pediatric data are limited to the use of abciximab in patients with Kawasaki disease (to prevent coronary remodeling) and a case report of its use to prevent thrombus on a device placed in the cardiac catheterization laboratory (References 163–166) (Table 1). Future reports on the use of abciximab in pediatric patients are needed before routine use can be recommended.

### BIVALIRUDIN

Bivalirudin is an intravenous direct thrombin inhibitor, with an immediate onset of action and a half-life of about 25 minutes in adults (Reference 72). The primary reported adverse events have been bleeding and hypotension in adults. The dose should be reduced for patients with kidney dysfunction to prevent accumulation of the drug (Reference 72) (Table 1). Therapy should be monitored using the ACT, particularly in areas where that test is the standard of care (i.e., cardiac catheterization laboratory).

Bivalirudin has shown promise in pediatric patients as an alternative to UFH in patients with HIT or other coagulopathies (References 122, 167–171). Dosing of bivalirudin in pediatric patients appears to be similar to that of adult patients, with good evidence of efficacy in treating thrombi (References 172, 173) (Table 1).

### ARGATROBAN

Argatroban is an intravenous direct thrombin inhibitor with a fast onset of action and a short half-life after the continuous infusion is discontinued (Reference 69). About 20% of the drug is eliminated through the urine unchanged, but no empiric adjustment for kidney dysfunction is currently recommended (Reference 69). A dose adjustment for severe hepatic dysfunction is recommended (Reference 69). A considerable body of literature in pediatric patients has been reported, and pharmacokinetic studies have been performed (References 174–176). It has been noted that critically ill pediatric patients have a lower clearance (up to 50% lower) than a relatively healthy adult patient; these patients may therefore require dose adjustments accordingly (Reference 174).

The literature for pediatric patients has primarily been in the form of case reports or series of patients with HIT requiring mechanical circulatory support (References 177–183) (Table 1). Other reports have shown its use in pediatric patients in the cardiac catheterization laboratory (Reference 184). Higher-goal INR values must be used when changing a patient from argatroban to warfarin because argatroban will elevate INR values (Reference 69). In this scenario, argatroban should typically not be discontinued until the INR value is greater than 4 (Reference 69). Argatroban therapy should be monitored with aPTT, in general, or with ACT if being used in the cardiac catheterization laboratory, in patients on extracorporeal membrane oxygenation, or during cardiopulmonary bypass (Reference 69). Specific monitoring strategies for pediatric patients may vary with institutional practices and patient pathophysiologies.

### FUTURE DIRECTIONS

Agents such as clopidogrel are coming to the forefront of therapy for treatment and prevention of thromboembolism in pediatric patients (References 39, 77, 185). As more experience is gathered, the ability to identify patients who will benefit the most from clopidogrel will be easier. Other agents such as dabigatran, an oral direct thrombin inhibitor, may be used more when clinical trials delineating pharmacokinetic and pharmacodynamic parameters in pediatric patients are completed (References 186, 187). Rivaroxaban, an oral direct factor Xa inhibitor, may also be used more in pediatric patients in the future (Reference 188).

### CONCLUSIONS

Anticoagulation of pediatric patients is challenging and requires expert knowledge. Pharmacists who care for pediatric patients should not only understand the pharmacology of anticoagulant and antiplatelet agents in infants and children, but also be aware of the limitations in the data for their use.

# CHAPTER 49

## HEMOPHILIA A AND B

Heidi Trinkman, Pharm.D.

### LEARNING OBJECTIVES

1. Discuss the differences between hemophilia A and B with respect to incidence and treatment options.
2. Describe inhibitors and their impact on therapy.
3. Identify complications associated with hemophilia and treatment of hemophilia.

### ABBREVIATIONS IN THIS CHAPTER

aPCCs	Activated prothrombin complex concentrates
BU	Bethesda unit
FVIII	Factor VIII
FIX	Factor IX
ICH	Intracranial hemorrhage
ITI	Immune tolerance induction
PCCs	Prothrombin complex concentrates
rFVIIa	Recombinant activated factor VII

### INTRODUCTION

Hemophilia A and B are genetic bleeding disorders that result from decreased or absent circulating levels of functional factor VIII (FVIII) or factor IX (FIX), respectively. This deficiency can ultimately lead to prolonged and excessive bleeding and result in poor-quality clot formation. Hemophilia A (also known as classic hemophilia) is more common and accounts for 80% to 85% of cases or 1 in 5,000–10,000 males. Hemophilia B (also known as Christmas disease, named for the first patient identified) constitutes the remaining 15% to 20% of cases or 1 in 30,000–50,000 males (References 1–3). Hemophilia A and B occur in all ethnic groups.

### Etiology

Both hemophilia A and B are genetically inherited X-linked recessive disorders primarily expressed in males. Women have two X chromosomes; therefore, if one is affected, the other carries the information for normal factor production, and the woman does not exhibit signs or symptoms of the disease. Any female children from a mother who is a carrier have a 50% chance of also being a carrier for the disease. Any male children have a 50% chance of receiving the affected X chromosome

resulting in hemophilia. Every female child from a father with hemophilia will be a carrier for the disease. Despite the genetic inheritance of hemophilia, about one-third of patients with newly diagnosed hemophilia have no family history of the disease, indicating a spontaneous genetic mutation (Reference 1).

The FVIII and FIX genes are located on the long arm of the X chromosome. These genes are very long and complex, representing around 0.1% of the X chromosome. Many mutations have been identified, including gene deletions, stop codon abnormalities, frameshift mutations, and inversion mutations. The inversion of intron 22 is the most common mutation found in hemophilia A (about 50%) and can be identified using Southern blot analysis (Reference 1). Independent mutations account for greater than 95% of all families with severe or moderate hemophilia B. Missense mutations are the most common mutations in patients with hemophilia B, accounting for 60% of FIX defects (Reference 4). Knowledge of the gene mutations may be used for determining carrier status and prenatal assessment. Major alterations to either gene will lead to a more severe disease compared with minor defects. Mutations in the 5' promoter region can result in the hemophilia B Leiden phenotype, which is characterized by very low levels of FIX activity at birth and through childhood but increases in adolescence to greater than 60% after puberty in response to androgens (Reference 1).

Acquired hemophilia is an autoimmune disease targeting FVIII and is very uncommon in children. The production of autoantibodies leads to FVIII proteolysis, thus increasing plasma clearance (Reference 5). Bleeding complications, which present similarly to classic hemophilia, are unpredictable. Fifty percent of cases occur spontaneously, whereas 10% occur postpartum within 3 months of delivery (Reference 5). Autoantibodies can be transferred to the neonate across the placenta, which can result in clinically significant bleeding. The incidence of acquired hemophilia is equally distributed between men and women. Outcomes are generally better in children because of the quicker resolution of autoantibodies in cases secondary to infections or antibiotic use (Reference 5).

### Pathophysiology

Both FVIII and FIX are crucial for normal thrombin formation. The classic representation of hemostasis is through activation of factor X by factor VII and tissue-activating factor. However, recent studies suggest that

FIX plays a role in this activation sequence. Through the intrinsic pathway, activated FIX complexes with activated FVIII, calcium, and phosphatidylserine on the membrane surface to generate activated factor X. The activation of factor X initiates the common pathway of the coagulation cascade, leading to normal thrombin and fibrin generation (Reference 4). A deficiency of FVIII or FIX results in delayed formation of a clot caused by a lack of normal thrombin and fibrin production (Figure 1). The resulting clots are friable, and re-bleeding is common. About 50% of patients with hemophilia B produce a nonfunctional FIX protein, whereas the rest of patients lack production of the protein entirely.

## DIAGNOSIS

Mothers with known familial hemophilia may have sons tested with a cord blood FVIII or FIX activity assay obtained at the time of delivery because neither FVIII nor FIX crosses the placenta. Prenatal testing may be performed using chorionic villus sampling or amniocentesis (Reference 1). These invasive techniques are not without risk to the mother and the fetus and should be discussed with the parents before the procedure.

About one-third of patients with a new diagnosis have no known family members with the disease. Children with signs of bleeding that are suggestive of hemophilia are evaluated further to make the diagnosis. These signs may include prolonged bleeding in newborns with circumcision or heel sticks, intracranial hemorrhage (ICH) or large cephalohematomas after difficult vaginal deliveries (e.g., use of forceps or vacuum extraction), or large raised bruising and/or an unusual number of bruises. Common laboratory parameters include a complete blood cell count, coagulation studies, and FVIII and FIX assays. Most patients with hemophilia have significantly prolonged partial thromboplastin time (PTT) (Reference 5). In general, the PTT is thought to be the most sensitive measure of defects in the intrinsic pathway of the coagulation cascade.

The severity of hemophilia is based on the patient's baseline circulating functional FVIII or FIX activity (Table 1). One unit is defined as the amount of factor found in 1 mL of normal plasma. Factor levels are often expressed as a percentage of activity. A level of 100% (1 IU/mL) is equal to the activity in 1 mL of normal plasma (Reference 4). For hemophilia A, around 70% of patients have the severe form of the disease. For hemophilia B, the prevalence of the severe form is around 50% (Reference 7). The diagnosis of mild hemophilia in a newborn may be delayed because vitamin K-dependent factors are reduced in this patient population and therefore would naturally have a slightly prolonged PTT (Reference 5).

## CLINICAL MANIFESTATIONS

The clinical manifestations of hemophilia A and B are all associated with bleeding. Patients with the severe form of the disease often have bleeding episodes from minor or unknown trauma. These children will often have spontaneous bleeding into muscle or joints from one to six times/month. If bleeding occurs in a closed space, such as a joint, cessation is aided by tamponade. In contrast, an open wound in which tamponade cannot occur may result in substantial blood loss (Reference 4). Patients with the moderate classification of the disease will not spontaneously bleed but can have significant bleeding with mild to moderate trauma. Those with only mild hemophilia may be undiagnosed for many years and have significant bleeding only with severe trauma or surgery (Reference 4). The significance of the bleeding will be determined by the location and severity of disease.

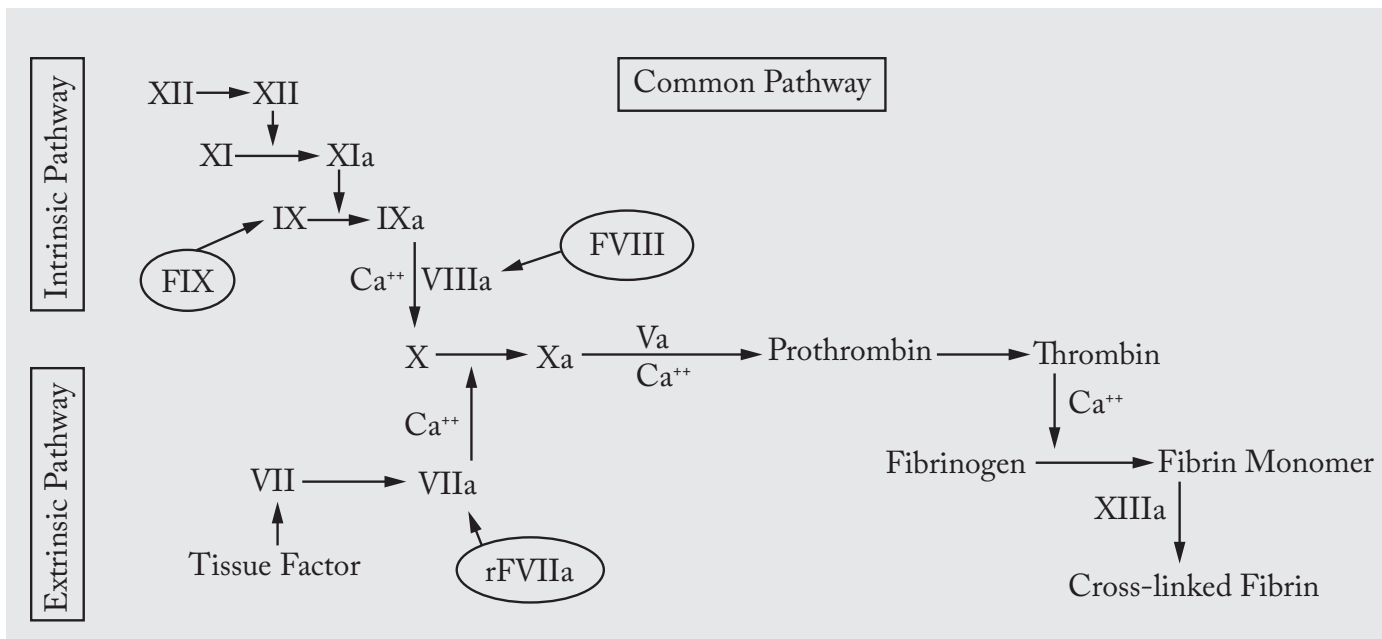

### Central Nervous System Bleeds

Bleeding into the central nervous system can be a life-threatening situation for a patient with hemophilia. Because FVIII and FIX do not cross the placenta, male infants with the severe form of the disease will

**Table 1.** Categorization of the Severity of Hemophilia

Severity	Clotting Factor Level % activity (IU/mL)	Bleeding Risk
Mild	5% to 40% (0.05–0.40)	Prolonged bleeding only with severe trauma or surgery
Moderate	1% to 5% (0.01–0.05)	Spontaneous bleeding is rare. Prolonged bleeding with trauma or surgery
Severe	< 1% (< 0.01)	Spontaneous bleeding

Created from Reference 6.

**Figure 1.** Clotting cascade and hemophilia factors.

FIX = factor IX; FVIII = factor VIII; rFVIIa = recombinant activated factor VII.

have either no or very little FVIII or FIX at birth. Babies who are born after a long, difficult labor, or after a vaginal delivery aided by the use of forceps or vacuum extraction, are at risk of developing large cephalohematomas or ICHs. The signs of ICH can include pallor, lethargy, neurologic deficits, unequal pupils, tense fontanelle, or vomiting. If the type of hemophilia is not known and FVIII or FIX assays are not immediately available, fresh frozen plasma should be administered at a dose of 10 mL/kg of body weight (Reference 1). In some reports, around 1% to 2% of neonates with hemophilia experience an ICH.

### Mucocutaneous/Soft Tissue Bleeds

In children without a family history of hemophilia, the disease is often diagnosed when the child begins to crawl or walk. Tongue and mouth ulcerations may occur around this time caused by the child's propensity for putting objects in his or her mouth. Soft tissue bruising is also more common during this first year of life, but it is often more alarming in appearance than clinically serious. If a diagnosis of hemophilia has not yet been made, these patients may be mistaken for child abuse victims. Around 30% of patients with hemophilia have bleeding with circumcision (Reference 5).

### Hemarthrosis

As a toddler starts to maintain an upright position and transitions to walking, more pressure is placed on the ankles, making them one of the more frequent bleeding sites. After the ankles, the knees are the most common

sites of joint bleeding. As the child ages, more bleeding will occur in the knees and elbows. When bleeding into a joint occurs, patients have described a sensation of tingling or warmth followed by increasing pain and decreased range of motion. In older children and adolescents, the risk of bleeding comes from sports-related activities and risk-taking behaviors. It usually takes 3–4 weeks for the blood to be reabsorbed from the joint and the fluid to be removed by the synovium (Reference 7).

When repeated bleeding occurs at a rate that does not allow this resolution back to baseline, the joint becomes a "target" for rebleeding, which is then identified as a "target" joint. These joints show a chronic inflammation of the synovium, which increases the volume of the joint. A new network of capillaries forms underneath the inflamed synovium to increase the blood flow for the removal of the breakdown products of the blood. The surface of the synovium becomes friable and irregular, increasing the likelihood of being caught in the sliding surfaces of the joint and causing more bleeding. This self-perpetuating process can lead to irreversible damage to the joint, resulting in loss of mobility, chronic pain, and ultimately destruction of the joint (Reference 7). Splinting and application of ice packs to the affected joint may provide some pain relief, but these are no substitute for factor replacement therapy (Reference 5). Medications such as aspirin and ibuprofen inhibit platelet function and can further hinder hemostasis in patients with hemophilia; therefore, these medications should be avoided. Early and aggressive management of these bleeds is the best approach for preventing the

bleed-synovitis-bleed cycle that characterizes a target joint. In patients with target joint bleeds that cannot be controlled with appropriate prophylactic factor administration, it may be necessary to remove the affected synovium, allowing a new, normal synovial layer to form within a few weeks. This can be accomplished through surgical removal of the affected synovium or through injection of a chemical, such as rifampin, or a radioactive agent, such as yttrium ( $^{90}\text{Y}$ ) (Reference 7).

### **Intramuscular Hemorrhage**

Muscle hematomas may be difficult to diagnose because the bleeds are generally deep within the tissue and not easily palpable. Some children with severe hemophilia may have excessive bleeding after intramuscular vaccinations. The bleeding occurs in the body of the muscle, causing the affected area to swell. Patients report a vague feeling of pain with motion. Bleeding into muscles is as serious as bleeding into joints. Repeated muscle bleeds can result in severe muscle contractures caused by fibrosis and atrophy. Muscle weakness is also a risk factor for joint bleeds, thus continuing the cycle of complications. Appropriate factor replacement is necessary to stop the bleed and reduce the size of the hematoma, whereas physical therapy can restore range of motion and prevent fibrosis of the muscle (Reference 5).

One muscle that is particularly worrisome for bleeding is the iliopsoas muscle. Symptoms may be vague, including lower abdominal or upper thigh pain, pain with passive extension of the thigh, and paresthesias below the inguinal ligament from femoral nerve compression. The clinical diagnosis should be confirmed with either ultrasonography or computed tomography (CT). Iliopsoas muscle hemorrhages can be life threatening because of the large amount of blood volume that can be lost into the retroperitoneal space.

Bleeding into other flexor muscles such as the calf or forearm can lead to a process called “compartment syndrome.” This is because of the limited space in the compartment where these muscles are located. When hemorrhage and swelling occur in this space, pressure compresses nerves and blood vessels that travel through the same compartment. This is manifested as paresthesias or numbness. Immediate factor replacement is indicated, and fasciotomy may be necessary if vascular supply and nerve function become compromised (Reference 8).

### **TREATMENT**

The fundamental treatment of both hemophilia A and B is replacement of the deficient factor. The first recorded successful treatment of hemophilia using a blood transfusion was in 1840 (Reference 1). Since then, the treatment has evolved from the infusion of pork or bovine plasma, which caused allergic responses and limited its

usefulness, to human pooled plasma products, which may expose the patient to transmission of bloodborne infectious risks such as hepatitis and human immunodeficiency virus (HIV), to our current practice of infusing safer, more pure factor concentrates produced through recombinant DNA technologies.

The improvements in replacement factors have made a dramatic impact on life expectancy for patients with hemophilia. The life expectancy before 1960 was a dismal 11 years for patients with severe hemophilia. From the 1960s to the early 1980s, this increased dramatically to about 60 years because of the development of replacement factors. During the 1980s, viral contamination of plasma-derived factor products became a problem. Many patients treated with these products became infected with HIV or hepatitis A, B, or C. The most serious of these was HIV, with 75% seroconversion in patients with severe hemophilia. In the United States, the mortality rates for patients with hemophilia tripled from 0.4 deaths per 1 million people (1979–1981) to 1.2 deaths per 1 million people (1987–1989). Acquired immunodeficiency syndrome (AIDS) accounted for 55% of all hemophilia deaths. With improved screening of donors, new purification methods, and recombinant factor production, much of this risk has been removed (References 9–11).

Despite these advances, apprehension remains as prions, such as Creutzfeldt-Jakob disease, emerge as a threat to patients with hemophilia who use blood- and plasma-derived products. Immunoaffinity and other chromatography techniques for preventing the transmission of prions are not well defined, and using pasteurization and solvent/detergent techniques is probably ineffective at preventing the transmission of these types of pathogens. In addition, other pathogens such as parvovirus B19 are resistant to many purification measures. The concern exists that there may be as-yet unidentified pathogens that can still be transmitted, even through highly purified products (Reference 12).

### **Early Therapies**

Fresh frozen plasma was the only product available to treat hemophilia B until the introduction of prothrombin complex concentrates (PCCs) and activated PCCs (aPCCs) in 1972 (Reference 2). PCCs contain only the factors themselves, whereas aPCCs contain the factors as well as other activating components that allow hemostasis to occur through the common coagulation pathway. These are intermediate-purity pooled plasma products containing FIX and a variety of other vitamin K-dependent clotting factors (II, VII, and X). Although these hemostatic agents are highly effective for both hemophilia A and B, the PCCs, especially the aPCCs, have been associated with thrombotic complications, such as disseminated intravascular coagulation and myocardial infarction (Reference 2). Factor eight inhibitor bypass

activity (FEIBA) is one of the most commonly used aPCCs currently on the market. It has been activated during the fractionation process to achieve increased amounts of activated FVII, FX, and thrombin (Reference 4). The simultaneous use of antifibrinolytic therapy should be avoided in patients receiving this product because of an increased risk of thrombosis.

### Factor Replacement Products

The cloning of the FVIII and FIX genes in the 1980s, combined with the explosion of recombinant technologies, led to the development of much safer, more consistent factor replacement products (Reference 13). Recently, newer techniques have been developed that allow recombinant FVIII (rFVIII) and recombinant FIX (rFIX) to be produced through a virtually plasma-free process. First-generation recombinant factor products employed viral removal or inactivation techniques, such as immunoaffinity or ion exchange chromatography (Reference 12). Second-generation recombinant factor products combined solvent/detergents and the use of ultra- or nano-filtration in their manufacturing process for the removal of enveloped viruses, such as HIV and hepatitis B and C (Reference 13). Third-generation recombinant factor products are manufactured through a process that is free of both human albumin and plasma (Table 2). Since 1999, rFIX has become the mainstay of therapy for hemophilia B.

### ADJUVANT THERAPIES

A nonpharmacologic adjuvant therapy for bleeds is easily remembered by the acronym RICE (rest, ice, compression, and elevation). Resting the joint or muscle associated with the bleed can be accomplished through splinting or the assistance of crutches or a wheelchair. Ice is helpful in reducing inflammation and causing

vasoconstriction and should be applied to the area with a towel or wrap. It is recommended to apply ice or an ice pack for 20 minutes every 4–6 hours until pain and swelling begin to decrease (Reference 14).

The role of desmopressin in the treatment of hemophilia A involves patients with the mild to moderate form of the disease. Desmopressin causes bound FVIII to be released into the systemic circulation, elevating the concentration available for coagulation. This can be a useful home treatment for mild bleeds. Unfortunately, many patients may experience tachyphylaxis (diminishing response) with frequently repeated dosing. This can occur after just a few doses; therefore, if the bleeding does not resolve after one or two doses, replacement of FVIII is indicated. Because of the potential for hyponatremia and water intoxication, fluids should be restricted for at least 12 hours after a desmopressin dose. Because of the difficulty in restricting fluids in very young children, this drug is not recommended for use in children younger than 2 years. Desmopressin can be administered intravenously, orally, or intranasally. The last form is most often used for home therapy for hemophilia A. The concentrated nasal spray desmopressin (Stimate) delivers 150 mcg per activation. One spray of this product (one nostril) is recommended for patients weighing less than 50 kg and two sprays (one in each nostril) for those weighing 50 kg or more (References 15, 16).

Antifibrinolytic agents may be used in combination with factor replacement to help maintain a clot that has formed. This is most often seen with bleeds that occur in the oral cavity because these tissues are rich in fibrinolytic materials. The two products currently used are aminocaproic acid and tranexamic acid. They should be started the evening before any planned invasive dentistry

**Table 2.** Comparison of Recombinant Factor VIII Products

Product	Generation	Producing Cell Line	Stabilizing Agent	Purification Method
Recombinate	First	Chinese hamster ovary	Human albumin	Immunoaffinity, ion exchange
Kogenate FS/ Helixate FS	Second	Baby hamster kidney	Sucrose	Immunoaffinity, ion exchange, solvent/ detergent, ultrafiltration

<sup>a</sup>When administering recombinant FIX, adjust dose by a factor of 1.2 for adults and 1.4 for children. CBC = complete blood cell count; FIX = factor IX; FVIII = factor VIII; hr = hour(s). Created from References 4, 15.

and be continued for 7–10 days. A mouthwash can also be made by mixing tranexamic acid with sterile water to make a 10% solution. This may be helpful after permanent tooth extractions (Reference 15).

### THERAPEUTIC APPROACHES

One approach to hemophilia treatment is the “on-demand” administration of replacement factors. Bleeding episodes are treated with factor replacement at a dose that is based on the bleeding site and the patient’s weight. The desired percent correction of factor activity varies by location of bleeding or procedure. The most severe bleeding associated with ICH or surgical procedures would require a 100% correction. The amount of FVIII product required to achieve this is calculated on the basis that 1 IU/kg will raise the serum FVIII activity by 2%. Using this formula, the desired dose of FVIII replacement can be determined: units of FVIII required = weight (kg) × desired level (%) × 0.5 (Reference 6). Because FIX binds to sites in the endothelium, more of the product is required to achieve the same rise in activity. Therefore, the amount of FIX product required to raise the activity to a desired level is twice that of the FVIII product: weight (kg) × desired level (%) × 1. The rFIX product requires a dose adjustment of 1.2 (for adults) to 1.4 (for children) international units/kg to raise the activity level by 1% (Reference 6). The frequency of dosing FVIII and FIX is influenced by their respective half-lives. Infused FVIII

has a half-life of between 3 and 6 hours during the initial equilibration with the extravascular spaces. The half-life then becomes closer to 12 hours. Dosing initially can be as frequent as every 8 hours until good hemostasis is achieved. The frequency can then be extended to every 12 hours, followed by every 24 hours as the patient recovers. The FIX product has a half-life of about 18–24 hours, allowing once-daily dosing except before surgery, when a twice-daily dose is required for the first day of the procedure (Reference 6). See Table 3 for common dosing goals. All factor products can be administered as rapid intravenous infusions over several minutes. Maximum infusion rates are specific to each product. Continuous infusion of FVIII is an approach that has been used in the treatment of moderate and severe bleeds. It has been shown that using a continuous infusion of factor after initial homeostasis is achieved can result in less overall factor consumption by avoiding the peaks and troughs associated with bolus dosing (Reference 17). An infusion rate of 2–3 IU/kg/hour can maintain an activity level of around 50% to 60% (Reference 4). Factor VIII levels should be monitored periodically to ensure goal levels are reached.

### THERAPEUTIC MONITORING

Most therapeutic monitoring of acute bleeding episodes is based on overall clinical response (Reference 18). The clinical monitoring of a patient with an acute bleed includes surrogate markers such as pain levels,

range of motion if the acute bleed is in a joint, swelling, and laboratory values such as hemoglobin. Although serum factor levels can be measured, the results can vary widely, and the clinical correlation is inconsistent. This is thought to be owing to the variable effect of FVIII on endogenous thrombin generation (Reference 19). The monitoring of factor VIII levels is warranted in the setting of surgical procedures. In some cases, homeostasis is achieved using a continuous infusion of factor product. Daily monitoring of factor levels during the continuous infusion is beneficial to ensure a consistent level of factor activity (Reference 20). Research continues into identifying the most appropriate surrogate marker for monitoring therapy. Parameters such as thrombin generation tests and endogenous thrombin potential are being studied to determine their degree of clinical correlation to outcomes (References 21, 22). If the patient is not clinically responding to adequate doses of factor replacement, serum should be sent for testing to determine whether an inhibitor is present.

### Prophylaxis

Another approach to therapy for hemophilia A and B is the prophylactic administration of factor concentrates. At present, there is no agreed-on definition for prophylactic therapy. The European Paediatric Network for Haemophilia Management has suggested several definitions based on the initiation of therapy. They describe primary prophylaxis as continuous therapy starting before 2 years of age (solely on the basis of age) or after the first episode of hemarthrosis and before 2 years of age. Secondary prophylaxis can be a long-term continuous treatment started after 2 years of age and two or more joint bleeds, or it can be an intermittent periodic treatment approach (Reference 23). The ultimate goal of primary prophylaxis is to prevent the formation of target joints and subsequent chronic arthropathy. Secondary prophylaxis is intended to prevent the progression of joint disease. It is important to remember that even one severe hemarthrosis is enough to start the cycle of bleeding and synovial hypertrophy that leads to the formation of a target joint (Reference 6). However, MRI examinations have shown that sometimes abnormalities have already occurred, even if there has been no clinically recognized hemarthrosis event. Prophylaxis is now recommended by the World Health Organization and the World Federation of Hemophilia (References 6, 14). Factor VIII 20–40 international units/kg every other day or three times/week is given to maintain FVIII levels above 0.01 IU/mL (1%) to prevent spontaneous bleeding in patients with severe hemophilia A (References 24, 25). A prophylactic dose for hemophilia

B would be FIX 25–40 international units/kg twice weekly because of the longer half-life (References 5, 6). The efficacy of this approach largely depends on the patient's adherence (Reference 26).

Until recently, primary prophylaxis was reserved for patients without inhibitors. Inhibitors are antibodies that can develop against the exogenously administered factor products, significantly decreasing their efficacy. A recent study compared on-demand therapy with prophylaxis using an aPCC (FEIBA) for patients with inhibitors. This prospective, randomized, crossover study was performed at 16 hemophilia treatment centers in Europe and the United States. A target dose of 85 units/kg was used for on-demand therapy as well as prophylaxis. The prophylaxis dose was administered on 3 nonconsecutive days weekly. The duration of on-demand therapy and prophylaxis was 6 months each, with a 3-month washout period in between. Twenty-six patients completed both study periods and were evaluable for the efficacy analysis. The overall reduction in bleeding was 84%, and the reduction in joint bleeds was 61%, with target joint bleeds reduced by 71% during the prophylactic period (Reference 27). These findings give clinical support to the use of bypassing agents for prophylaxis in children who develop inhibitors.

Despite the many studies establishing prophylaxis as a superior approach to treatment versus on-demand therapy, prophylaxis is not considered standard of practice by many institutions. The main deterrents continue to be cost and complications. The costs of prophylaxis versus those of on-demand therapy are difficult to quantify. The factor consumed during on-demand therapy tends to be one-third that consumed with the prophylactic approach (References 27, 28). However, when assessing the pharmacoeconomics of prophylaxis, it must be viewed from a long-term outcome perspective, including variables such as quality of life, potential benefits of avoiding hospitalizations and days lost from school or work, and prevention of long-term complications such as worsening joint disease and disability.

Another obstacle to prophylactic therapy is the need for venous access for factor administration. Peripheral venous access is preferred for the infusion of factor products; however, for patients receiving continuous prophylactic or immune tolerance induction (ITI) therapy, a central venous access device may be required. These are especially useful in infants and children whose small veins are difficult to access and who tend to be intolerant of frequent needlesticks. Central venous access devices are used in about 30% of children receiving prophylactic therapy and 90% of those receiving daily ITI (Reference 29). The biggest drawback to these devices is the risk of infection. A meta-analysis performed on 48 studies found a 44% incidence of infection in

patients with central venous access devices (Reference 30). These devices also require comprehensive education of the family/caregivers on proper aseptic technique as well as maintenance and monitoring of the central line.

## COMPLICATIONS OF THERAPY

A serious complication of hemophilia therapy is the formation of antibodies against FVIII and FIX. Inhibitors neutralize the procoagulant activity of FVIII and FIX, leading to the failure of routine factor replacement therapy. About 14% to 35% of patients with severe hemophilia A and up to 3% of patients with severe hemophilia B will develop inhibitors (References 2, 4, 31). Most inhibitor development occurs in patients with severe hemophilia around 1–2 years of age with about 9–12 treatments with factor product. The highest risk of developing inhibitors occurs within the first 50 exposures to FVIII, with the risk rapidly reducing after 200 treatment days (Reference 32). Risk factors for developing inhibitors include genetic factors such as the type of mutation on the FVIII or FIX gene, polymorphisms in genes that regulate the immune system, family history of inhibitors, and African heritage (References 33–36). Environmental risk factors for inhibitor development include intensive factor exposure caused by serious injury, surgery, or immunologic challenge such as infection or immunizations (Reference 37). In addition to the loss of therapeutic response to factor replacement, patients with hemophilia B with inhibitor development may experience anaphylaxis associated with FIX administration (Reference 38).

Inhibitors can be categorized into two groups: low responding and high responding. Inhibitors are measured by the Bethesda assay. One Bethesda unit (BU) is defined as the amount of inhibitor needed to inactivate 50% of FVIII or FIX in pooled normal plasma. Low-responding inhibitors are defined by a peak historical titer of less than 5 BU/mL, resulting in a very low or attenuated response to FVIII or FIX (Reference 6). Patients with low-responding inhibitors may still respond to factor replacement therapy at higher doses and/or more frequent dosing intervals. High-responding inhibitors are those with a titer greater than 5 BU/mL or a brisk anamnestic response to FVIII challenge. Patients can convert from low-responding inhibitors to high-responding inhibitors over time. All patients should be monitored for inhibitor formation every 6 months or in the setting of a decreased clinical or laboratory response to therapy (Reference 6).

Patients with high-responding inhibitors usually will not respond to FVIII or FIX replacement therapy even at high doses, and alternative approaches to treatment of acute bleeds must be used, such as recombinant activated factor VII (rFVIIa) (90 mcg/kg every 2–3

hours) or aPCCs (FEIBA 50–100 international units/kg every 6–12 hours) (References 39, 40). Recombinant activated FVII achieves homeostasis without requiring FVIII or FIX using the extrinsic coagulation pathway, binding to tissue factor at the site of injury, which then triggers coagulation through the common pathway. It can also cause activation of FIX and factor X on the surface of activated platelets (Reference 6).

Once an inhibitor has formed, ITI may be initiated in an attempt to decrease or eliminate the antibodies. Immune tolerance induction involves frequent, continuing exposure to the deficient clotting factor to achieve tolerance by antigen overload, resulting in restoration of normal factor replacement pharmacokinetics (PK) (Reference 2). This approach was first attempted in the 1970s and was achieved by the administration of high doses of FVIII (100–150 international units/kg) twice daily with the combination of aPCCs for control of acute bleeds. After a period of months to years, the FVIII antibodies were markedly reduced, and the dose could be decreased to a smaller daily dose or even administered every other day (Reference 5). A variety of different ITI regimens have been developed, some using varied doses of FVIII given less frequently and others combining the use of intravenous gammaglobulin and immunosuppressants (cyclophosphamide, rituximab) (Reference 39). Immune tolerance induction success rates are generally higher in patients with lower inhibitor titers (preferably less than 10 BU) at the initiation of therapy (References 40, 41). A meta-analysis of the North American Immune Tolerance Registry (NAITR) and the International Immune Tolerance Registry (IITR) determined that for patients with inhibitor titers less than 200 BU and pre-ITI titers less than 10 BU, FVIII dose did not affect ITI outcome. The IITR study protocol is presently comparing high-dose ITI (200 units/kg/day) with low-dose (50 units/kg three times/week). The data are undergoing final analysis (Reference 40). In patients with hemophilia A, ITI is unsuccessful in 30% to 50% of individuals. Immune tolerance induction in patients with hemophilia B is much less effective, with a high incidence of allergic reaction. Immune tolerance induction is demanding and expensive, exceeding \$1.2 million dollars for an average 5-year-old patient (Reference 42). The need for central venous access is another factor to consider when deciding whether to initiate ITI. However, the cost of successful ITI can decrease the overall lifetime cost of hemophilia therapy (References 6, 42, 43).

Some studies report better success rates for ITI in patients receiving plasma-derived factor products containing von Willebrand factor (VWF) (Reference 44), which is thought to be because of the role of VWF in FVIII function, stabilization, and immunogenicity. By VWF's binding to the C2 domain of FVIII, a

common site for inhibitor formation, epitope masking and decreased inhibitor activity may result. The use of VWF-containing products may also extend the plasma half-life of FVIII during ITI, thus increasing antigen presentation and possibly contributing to its overall success (Reference 44). If no response is seen after 2 years of ITI, the treatment approach is usually discontinued (Reference 6).

## FUTURE CONSIDERATIONS

Gene therapy for hemophilia A and B is being studied, but it is not yet available. Early success in animal models has been achieved; however, long-term maintenance of adequate clotting factors continues to be a problem (Reference 45). Current hemophilia research is focused in the areas of factor product improvement. One approach to improving factor products is through modification of the factor molecule to include polyethylene glycol (PEGylation). Polyethylene glycol can enhance the PK and pharmacodynamics (PD) of the factor product. These molecules would be less susceptible to proteolytic cleavage and degradation and would undergo slower clearance from the circulation, resulting in a longer half-life. Clinical studies are under way researching the possibility of PEGylation of rFVIII and rFVIIa. The PEGylation of rFIX has resulted in a product with an extended half-life, allowing once-weekly dosing (References 46–48). Another avenue of research is binding albumin to rFIX or rFVIIa to prolong half-life without increasing immunogenicity (Reference 49). Another mechanism for extending half-life has been created by fusing the Fc region of the immunoglobulin G to rFIX (rFIXFc) (Reference 50). Phase I studies have been concluded, and phase II/III studies are under way (References 45, 50).

Increasing the catalytic activity of a clotting factor may intensify its coagulation activity. Genetically engineered FIX molecules are under development. Intensifying the catalytic activity of a clotting factor may also improve the therapeutic index of gene therapy vectors for hemophilia B (References 51, 52). Bayer Healthcare is studying a “biosuperior” FVIIa molecule using a technology called DNA shuffling. This product has the ability to activate FX in the absence of tissue factor, resulting in a more potent product. Modifications were then made to improve its platelet targeting ability to make it less thrombogenic. Bayer also increased the number of *N*-glycosylations to prolong the half-life of the factor product. In animal studies, one candidate molecule (BAY866150) showed improved PK and PD parameters as well as an *in vitro* thrombin burst. A phase I study of patients with hemophilia A and B with inhibitors is planned (Reference 2).

## CONCLUSIONS

From the transfusion of blood products to the development of recombinant factors to the creation of genetic therapies, the treatment of hemophilia continues to evolve. It has changed from a childhood disease with early mortality to a chronically managed disease with a significantly improved life span. As the options for therapy continue to grow, the life span and quality of life continue to improve for patients affected by the disease.

It is essential that pharmacists take an active role in understanding the treatment regimens as well as the products available for managing hemophilia A and B. A complete understanding of the pathophysiology of the disease is also necessary to assist patients with supportive care both inside and outside the hospital setting. Important advances in hemophilia A and B therapies have occurred during the past 25 years, resulting in safer treatment options, better quality of life for patients, and, with improvements in gene therapy on the horizon, hope for a cure in the future.

# CHAPTER 50

## PEDIATRIC SICKLE CELL DISEASE

Tracy M. Hagemann, Pharm.D., FCCP, FPPAG

### LEARNING OBJECTIVES

1. Discuss the role of newborn screening in sickle cell disease (SCD).
2. List the signs and symptoms of SCD for infants, children, and adolescents.
3. Recognize the clinical characteristics associated with an acute sickle cell crisis.
4. Identify patients who require penicillin prophylaxis.
5. Explain the rationale for the use of hydroxyurea in pediatric patients with SCD.
6. Identify appropriate hydroxyurea regimens and monitoring parameters.
7. Discuss the risks and benefits of chronic transfusion therapy in patients with SCD.
8. Select appropriate empiric antimicrobial coverage in children with SCD who present with fever.
9. Develop a treatment plan for chelation therapy in pediatric patients receiving chronic transfusion therapy.
10. Create a treatment plan for children and adolescents with SCD who present with acute chest syndrome, priapism, and sickle cell crisis.
11. Devise a pain management plan for pediatric patients presenting with vaso-occlusive pain crisis.

### ABBREVIATIONS IN THIS CHAPTER

ACS	Acute chest syndrome
HbA	Normal adult hemoglobin
HbF	Fetal hemoglobin
HbS	Sickle hemoglobin
HbSC	Compound heterozygous (HbS and hemoglobin C)
HbSS	Homozygous form of SCD
HLA	Human leukocyte antigen
RBCs	Red blood cells
SCD	Sickle cell disease
SCT	Sickle cell trait

### INTRODUCTION

Sickle cell disease (SCD) is one of the most commonly inherited diseases in the United States, primarily affecting African Americans. About 2,000 confirmed cases are reported through neonatal screening in the United States each year (Reference 1). Although childhood morbidity and mortality have dramatically decreased because of standardized newborn screening, advances in preventive therapy, and acute complication management, children with SCD are often hospitalized, usually for severe pain, fever, or acute complications. Sickle cell disease is a chronic illness that can have a detrimental effect on a child's quality of life and, because of its unpredictability, can lead to interruptions in children's physical, family, and academic functioning, as well as in their emotional and social well-being (Reference 2). Most children with SCD will require several hospitalizations because of severe pain crises, and almost 1 in 10 will have a sickle-related stroke (Reference 3).

### Epidemiology and Nomenclature

Normal adult hemoglobin (HbA) is composed of two  $\alpha$ -globin chains and two  $\beta$ -globin chains. Sickle hemoglobin (HbS) occurs when valine is substituted for glutamic acid at position 6 of the  $\beta$ -polypeptide chain. Hemoglobin C (HbC) is another genetic variant that occurs when lysine is substituted for glutamic acid as the sixth amino acid in the beta chain. Changes in the  $\beta$ -globin chain are primarily responsible for the sickling of the red blood cells (RBCs); however, the  $\alpha$ -globin chain structure is identical in all forms (HbA, HbS, and HbC).

Sickle cell syndromes can be divided into two groups: SCD and sickle cell trait (SCT). Sickle cell trait is the heterozygous form of SCD in which the individual inherits one normal HbA gene and one HbS gene. Patients with SCT are usually asymptomatic or mildly symptomatic and are carriers of the sickle cell gene. Because *Plasmodium falciparum* cannot invade sickled RBCs easily, SCT is known to offer protection against clinical infections of malaria. Therefore, the sickle cell gene is more prevalent in tropical areas with a higher incidence of malaria. In the homozygous form of SCD (HbSS), also called *sickle cell anemia*, the patient inherits both abnormal genes, one from each parent. Compound heterozygous inheritance of HbS with

another mutation results in sickle cell hemoglobin C (HbSC) or one of two types of sickle cell  $\beta$ -thalassemia (HbS  $\beta^+$ thal and HbS  $\beta^0$ thal). Patients with HbSS and HbS  $\beta^0$ thal typically have a severer disease course than patients with other types because they do not have normal  $\beta$ -globin production (Reference 4).

Around 2 million people in the United States are carriers of the sickle cell gene. Most of them are of African ancestry, although those of Mediterranean and Middle Eastern descent may also have sickle cell mutations. More than 50,000 Americans have SCD, and for every 1 infant with SCD, 50 infants are identified as carriers. About 9% of African Americans carry the HbS gene. Homozygous HbS is the most common variant of SCD in the United States at 45%, followed by HbSC (25%), HbS  $\beta^+$ thal (8%), and HbS  $\beta^0$ thal (2%) (Reference 5).

### Pathophysiology

In the fetus, fetal hemoglobin (HbF) is the predominant oxygen transport protein, and at birth, it constitutes 60% to 90% of RBC hemoglobin. Fetal hemoglobin contains two gamma chains instead of beta chains; therefore, RBCs with HbF do not sickle. Before birth, HbF undergoes a conversion from gamma chains to beta chains, and after the child is born, only a few RBC clones remain to produce HbF. Infants with SCD typically have few symptoms of the disease until their HbF concentrations fall, usually by age 6 months. In an adult, RBCs contain less than 1% HbF (Reference 6).

Because of high hemoglobin concentrations, RBCs are extremely flexible. Both HbA and HbS have the same solubility when they are oxygenated, and HbS will carry the oxygen normally. As oxygen is unloaded from the cell, HbS solubility decreases, leading to valine binding to sites on adjacent globin chains. The deoxygenated HbS will begin to form a gel-like substance that distorts RBCs into the classic crescent or sickle shape. When HbS is re-oxygenated, the RBC will resume its normal shape, but as this sickle/unsickle process is repeated, membrane damage occurs, and the cell loses its flexibility as well as its potassium and water. This leads to dehydrated, dense sickled cells that cannot resume their original shape and remain sickled, even when oxygenated. Vaso-occlusion will occur as the blood becomes more viscous and as sickled RBCs adhere to the vascular endothelium, blocking small blood vessels and resulting in local tissue hypoxia. A normal RBC will have a life span of 100–120 days. An irreversibly sickled RBC lives only 10–20 days, leading to anemia, which is common in patients with SCD (Reference 7).

In addition to the local tissue damage from vaso-occlusive crises, sickled cells may obstruct the spleen, leading to functional asplenia and splenomegaly. Patients with SCD are at an increased risk of infections from encapsulated bacteria (e.g., *Streptococcus pneumoniae*) because of this effect on the spleen. They may also have coagulation abnormalities because of decreased levels of protein C, protein S, and antithrombin III, as well as increased thrombin generation and platelet aggregation (References 8, 9).

## CLINICAL PRESENTATION AND DIAGNOSIS

### Newborn Screening

Most infants with SCD appear healthy at birth and begin to exhibit symptoms only as their HbF concentrations decline during the first 6 months of life. Newer therapies and interventions have dramatically decreased morbidity in infants and children with SCD, so identifying these children before age 2 months is important. Neonatal screening for SCD is required in all 50 of the United States so that caregiver education can begin and care plans can be developed for these children. Screening is done by high-performance liquid chromatography or thin-layer isoelectric focusing, both of which have high sensitivity and specificity for SCT and SCD. All positive tests should be confirmed with a second test within 2 months. Because HbF is the primary hemoglobin in fetuses and the production of other hemoglobins (HbA, HgC, or HgS) does not occur until the last trimester of pregnancy, very premature neonates (those less than 28 weeks' gestation) may have false negatives (References 10, 11).

### Signs and Symptoms

Children with SCT are typically asymptomatic, although girls may have more frequent urinary tract infections (Reference 12). Because of RBC sickling in the renal medulla, patients with SCT may be unable to maximally concentrate their urine, leading to an increased risk of dehydration. Although microscopic hematuria is rare, patients with SCT may exhibit gross hematuria after very high-intensity exercise (Reference 13).

The most common signs and symptoms of SCD are pain and anemia, and they usually manifest early in childhood. In children with HbS, anemia is seen within 6 months of birth. Anemia is chronic and hemolytic with hemoglobin concentrations between 7 g/dL and 10 g/dL. These children typically tolerate the anemia well. Anemia may be complicated by megaloblastic changes caused by folate deficiency. As HbS concentrations increase, pain episodes increase, usually together with fever. Splenomegaly is common during the first

year of life, together with functional asplenia. The spleen becomes fibrotic and eventually shrinks, leading to an increased risk of infection with encapsulated bacteria. A painful splenic sequestration crisis may occur, in which the spleen undergoes a sudden enlargement caused by the pooling of many sickled RBCs. Infants may also present with dactylitis, also known as hand-foot syndrome, a painful swelling of the hands and feet (References 4, 10, 12, 14). Clinical presentation of SCD in children may differ depending on the age at symptom onset. Infants and younger children may present with dactylitis, pneumococcal sepsis, meningitis, severe anemia, acute chest syndrome (ACS), pallor, jaundice, or splenomegaly. Older children may exhibit anemia, aplastic crisis, ACS, splenomegaly or splenic sequestration, cholelithiasis, and severe or recurrent abdominal or musculoskeletal pain (Reference 12). Children with HbSC usually have a less severe presentation, with less frequent pain episodes and a mild anemia in which the hemoglobin is greater than 9 g/dL. These children may also exhibit splenomegaly that will persist into adulthood (References 4, 12, 14).

### Laboratory Diagnosis

Low hemoglobin counts (usually less than 10 g/dL) are common in patients with SCD. Red blood cell transfusions are not typically used unless hemoglobin falls below 7 g/dL and the patient is being treated for an acute complication such as ACS, a pain crisis, or an infection (Reference 12). Increased reticulocytes, platelets, and white blood cells are common findings in a complete blood cell count. Peripheral blood smears will show sickle cell forms (Reference 12).

### Course and Prognosis of Disease

#### *Growth and Development*

Decreases in growth velocity and growth delays during puberty are commonly seen in children with SCD. Children and adolescents with SCD may also be below average for both height and weight, although this is independently associated with decreased hemoglobin concentrations, increased total energy expenditures, and nutritional intake (Reference 15). In adolescents, puberty is slow in onset, and delayed sexual maturation is common.

#### *Morbidity and Mortality*

Morbidity and mortality in SCD are caused by complications of the disease. In the past, 50% of patients with SCD did not survive to adulthood. Recent reports suggest that 85% of children with SCD will survive to age 18 years because of improvements in comprehensive care and early screening and intervention (Reference 12). Median survival is about 42 years for males and

48 years for females (Reference 12). Children younger than 3 years are more likely to die of infectious causes. Children who have dactylitis before age 1 year, severe anemia in the second year of life (hemoglobin concentrations less than 7 g/dL), and signs of leukocytosis without the presence of infection have higher morbidity and mortality. Morbidity and mortality in later years are secondary to chronic complications such as repeated pain crises, anemia, ACS, kidney dysfunction, and cerebrovascular complications, including stroke and lung disease (References 12, 16, 17).

### *Complications*

Acute complications of SCD are unpredictable, and the rate and occurrence vary between patients. Because of functional asplenia, the risk of overwhelming sepsis from encapsulated microorganisms is high, especially from *S. pneumoniae*, *Haemophilus influenzae*, and *Salmonella* spp. Viral infections can also result in significant morbidity, especially from influenza and parvovirus B19 (References 12, 14, 18). By age 20, about 11% of patients with SCD will have had a stroke, with the highest incidence in children aged 2–5 years (Reference 19). Symptoms of stroke in children with SCD may include aphasia or dysphasia, hemiparesis, severe headache, cranial nerve palsy, seizures, stupor, and coma. Nonfocal signs, such as developmental delay and poor academic performance, may be indicative of ischemic central nervous system injury. The leading cause of death in patients with SCD is ACS. Any patient who shows a new infiltrate on chest radiography, together with symptoms of a lower respiratory tract infection and hypoxia, should be immediately treated. Acute chest syndrome may occur because of a patient's undergoing general anesthesia, during a patient's acute illness, or 2–3 days after a patient suffers a severe vaso-occlusive pain crisis. Early signs of ACS (e.g., cough, dyspnea, chest pain) should be immediately assessed and treated to prevent deterioration to respiratory failure. Priapism, a prolonged painful penile erection, is a common complication in males with SCD, occurring in 90% of males by age 18 years. Vaso-occlusive pain crises are the most common SCD crisis and are characterized by acute pain (often deep and throbbing) with tenderness, erythema, and swelling in the affected area. Recurrent acute pain crises can lead to bone, joint, and organ damage, as well as chronic pain. These acute crises may be precipitated by infection, dehydration, extreme changes in weather, and stress (References 12, 14). Aplastic crisis, usually caused by infection with parvovirus B19, occurs when there is a decrease in hemoglobin with an acute, rapid decrease in the patient's reticulocyte count, usually to less than 1% (Reference 12). Patients in acute aplastic crisis may present with severe pain, ACS, and splenic

sequestration. Splenic sequestration in young children may lead to an acutely enlarged spleen, together with a rapid drop in the patient's hemoglobin concentration leading to hypovolemia, shock, and death.

Chronic complications generally are a result of organ damage, affecting the heart, lung, brain, bones and joints, eyes, kidneys, and gallbladder. Although much more common in adult patients with SCD, children and adolescents with poorly managed disease or severe repeated acute complications may also begin to show these chronic complications (Table 1).

## TREATMENT

### Therapy Goals

The therapy goals for children and adolescents with SCD are to decrease complications and morbidity to improve quality of life. This requires a comprehensive multidisciplinary approach including medication, regular examinations, education of both patients and caregivers, and psychosocial support (Reference 12). Preteens and adolescents should be actively involved in the management of their disease. Medications are aimed at maintaining health through prophylactic measures and treating acute complications and crises as they arise.

### Preventive Therapy

#### Immunizations

All children with SCD should receive all routine immunizations recommended by the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention and the American Academy of

Pediatrics (see Pediatric Vaccines chapter). The impaired splenic function that develops in these children during childhood increases the risk of infection with encapsulated bacteria (e.g., *S. pneumoniae*, *H. influenzae*, *Salmonella* spp.). Children with SCD are up to 600 times more likely to suffer from invasive pneumococcal disease, especially if they are younger than 2 years (Reference 21). Vaccination with 13-valent pneumococcal vaccine and *H. influenzae* vaccine is crucial in this population, and it has significantly decreased morbidity and mortality in children younger than 2 years with SCD. Despite appropriate vaccination, some children with SCD will still have high rates of invasive pneumococcal disease. The 23-valent polysaccharide vaccine contains the most common pneumococcal isolates seen in older children and adults. All children older than 2 years should also receive the 23-valent vaccine, with the first dose separated from the last dose of the 13-valent vaccine by at least 2 months. A second dose of the 23-valent vaccine is recommended 5 years after the initial dose. In addition to pneumococcal vaccine, children with SCD older than 2 years who are scheduled for surgical splenectomy or who have functional asplenia should receive meningococcal vaccine. When the first dose of meningococcal vaccine is administered between age 2 and 6 years, a second dose of meningococcal conjugate vaccine is recommended 3 years after the initial dose (Reference 22).

#### Penicillin Prophylaxis

Despite appropriate vaccination against pneumococcal disease, available vaccines do not cover all serotypes of *S. pneumoniae*. The use of prophylactic penicillin has dramatically decreased mortality from invasive

**Table 1.** Systems Affected by Those with Sickle Cell Disease (References 4, 10, 12, 14, 20)

System	Complication
Cardiovascular	Myocardial infarction, anemia
Gastrointestinal	Acute hepatic ischemia, cholestasis, acute or chronic cholelithiasis, acute or chronic liver disease (caused by drug toxicity or hepatitis C contracted from transfusions)
Genitourinary	Priapism, infertility
Musculoskeletal	Acute pain crises, vaso-occlusive pain crises, chronic pain, bone infarcts, osteonecrosis, dactylitis, osteomyelitis, septic arthritis, growth delays
Neurologic	Transient ischemic attacks, silent ischemic lesions, stroke, neurocognitive compromise
Ocular	Eye vessel occlusion, proliferative sickle retinopathy
Pulmonary	Acute chest syndrome, hypoxemia
Renal	Hematuria, proteinuria, renal infarct, focal segmental glomerulosclerosis, renal medullary carcinoma, enuresis
Skin	Leg ulcers
Other	Delayed puberty, splenomegaly, infectious complications secondary to <i>H. influenzae</i> , <i>S. pneumoniae</i> , <i>Salmonella</i> , leukocytosis

pneumococcal infections in young children (Reference 12). All children with SCD should be initiated on prophylactic penicillin at age 2 months and continued until at least 5 years old (Reference 12). Penicillin V potassium 125 mg orally twice daily is given until age 3; then, the dose is increased to 250 mg orally twice daily until the child is at least 5 years old. Benzathine penicillin 600,000 units intramuscularly every 4 weeks beginning at age 6 months and continued to age 6 years is an option when adherence to the oral regimen is a concern. Penicillin-allergic children can receive erythromycin orally at 10 mg/kg twice daily (References 12, 14). Some children will develop invasive pneumococcal infections despite use of prophylactic penicillin. Penicillin prophylaxis should be continued indefinitely in any child who has a history of severe invasive pneumococcal infections and in those with functional or surgical asplenia. In these patients, the dose remains 250 mg orally twice daily (References 12, 14).

### ***Folic Acid Supplementation***

Folic acid supplementation is generally recommended in children with SCD who have chronic hemolysis. Infants should receive 0.1 mg orally once daily, and children aged 1–4 years should receive 0.3 mg orally once daily. Children older than 4 years and adolescents should receive 0.4–1 mg orally once daily (Reference 23).

### ***Hydroxyurea***

Hydroxyurea is a ribonucleotide reductase inhibitor that prevents DNA synthesis, increases HbF production, and decreases neutrophils in patients with SCD. It has also been shown to decrease RBC adhesion to the intravascular endothelium and increase concentrations of nitric oxide, which is a regulator involved in physiologic disturbances. Landmark studies in adults with SCD who received hydroxyurea showed a reduction in pain crises, hospitalization rates, RBC transfusions, ACS incidence, and mortality. The HbF concentrations increased, and hemolysis decreased (References 24, 25). Studies in children and adolescents with SCD have shown results similar to those found in the adult hydroxyurea trials, with no adverse effects on growth and development (References 12, 26, 27).

Hydroxyurea treatment should be considered in children and adolescents with SCD who have a history of frequent vaso-occlusive crises, severe symptomatic anemia, repeated history of ACS, or other history of severe vaso-occlusive complications (Reference 12). Hydroxyurea can be used in children as young as 6 months. The therapy goals with hydroxyurea are to reduce the number and severity of acute SCD complications, including pain crises, and to improve the patient's quality of life. Hydroxyurea dosing should be individualized on the basis of the patient's

HbF concentration and hematologic response. For children with SCD, initiate hydroxyurea at 15 mg/kg orally once daily, and increase in increments of 5 mg/kg every 12 weeks to a maximum dose of 35 mg/kg/day. Complete blood cell counts should be evaluated every 2 weeks during dose titration and then every 4–6 weeks once the dose is stabilized (Reference 28).

Children and adolescents receiving hydroxyurea should be closely monitored for both safety and efficacy. Mean corpuscular volume will increase as the concentration of HbF increases. If the mean corpuscular volume does not increase with hydroxyurea use, patients' bone marrow may be unable to respond, the dose may be inadequate, or patients may not be adherent to their therapy. Response to therapy can also be assessed by monitoring the HbF concentrations, which should increase 15% to 20%.

Although hydroxyurea is only commercially available in a solid oral dosage form as 200-, 300-, 400-, and 500-mg capsules, an extemporaneous suspension can be compounded for younger children. Patients on solid dosage forms should have their dose rounded to the nearest available capsule or combination of capsules. The most common adverse effect of hydroxyurea is mild to moderate neutropenia, and other reported effects include mild thrombocytopenia, severe anemia, rash, nail changes, and headaches. All adverse effects are reversible upon discontinuation of the product. If the hemoglobin concentration is less than 5 g/dL, the absolute neutrophil count is less than 2,000/mm<sup>3</sup>, or the reticulocyte count is less than 80,000/mm<sup>3</sup> when the hemoglobin concentration is less than 9 g/dL, then hydroxyurea should be discontinued until recovery of one or more of the cell counts. After recovery, hydroxyurea should be reinitiated at a daily dose 2.5 mg/kg less than the dose at which toxicity occurred. Hydroxyurea should then be titrated by 2.5 mg/kg every 12 weeks (References 28, 29). Hydroxyurea is teratogenic in high doses in animal studies, so female patients should be counseled to use effective contraception. Studies are evaluating hydroxyurea use in children with SCD who have suffered a stroke to reduce the need for chronic RBC transfusions and prevent end-organ damage in young children with SCD.

### ***Transfusion Therapy***

Transfusions are indicated in children and adolescents with SCD for acute exacerbations of anemia that require supplemental oxygen, acute severe vaso-occlusive crises including stroke, ACS, and acute multiorgan failure and in patients who are preparing for surgery involving general anesthesia or radiologic procedures requiring the use of ionic contrast. Hyperviscosity may occur if the hemoglobin concentration is increased to greater than 10–11 g/dL. Volume overload is a concern if the anemia is corrected too rapidly, which may lead to congestive heart failure (Reference 12).

Studies have shown that in children, the use of chronic RBC transfusions decreases stroke recurrence from 50% to 10% over 3 years (Reference 30). In addition, chronic transfusions are used in children and adolescents to reduce certain SCD complications such as vaso-occlusive pain crises and ACS. Without chronic transfusion therapy, up to 93% of children with SCD who have had a stroke will suffer a recurrence. Several transfusion methods have been used, including simple transfusion, exchange transfusion, and erythrocytapheresis. The goal of chronic transfusion therapy is to reduce erythropoiesis and maintain the HbS concentration at less than 30% of the total hemoglobin concentration (Reference 12). Depending on the HbS concentrations, transfusions are administered every 3–4 weeks. For secondary stroke prevention, studies have indicated that lifelong transfusions are required; stroke risk increases once the transfusions are discontinued (Reference 12). Children and adolescents who should be considered for chronic transfusion therapy are those with severe or recurrent ACS, recurrent priapism, debilitating chronic pain, chronic organ failure, transient ischemic attacks, abnormal transcranial Doppler studies, and intractable leg ulcers, as well as those with severe chronic anemia who also have heart failure.

Risks associated with transfusions include alloimmunization, hyperviscosity, viral transmission, volume overload, transfusion reactions, and iron overload. Alloimmunization can be minimized with leukocyte-reduced RBCs or human leukocyte antigen (HLA)-matched units. Although the risk of viral transmission through transfusion is low, all patients with SCD should be immunized against hepatitis B and should be monitored for hepatitis C and other bloodborne pathogens. Parvovirus is associated with aplastic crisis and may be present in 1 of every 40,000 units of RBCs. Sick cell hemolytic transfusion reaction syndrome is a unique condition that occurs because of alloimmunization and may lead to acute or delayed transfusion reactions. Symptoms of hemolytic transfusion reaction syndrome mimic pain crises. Delayed reactions will occur 5–20 days post-transfusion. Severe anemia may occur after the transfusion because of a rapid decrease in hemoglobin and hematocrit with suppression of erythropoiesis. Additional transfusions may worsen the clinical picture because of the presence of autoimmune antibodies. Recovery will occur only after all transfusions are discontinued and will be evidenced by a gradual increase in hemoglobin and reticulocytes (References 12, 22, 31).

### *Iron Chelation*

Iron overload is a concern in any patient maintained on chronic transfusions for more than 1 year because humans do not have an effective means to excrete excess iron (Reference 32, 33). There is no consensus on the

best way to estimate iron overload in children with SCD maintained on chronic transfusion therapy. Most comprehensive sickle cell centers in the United States use a combination of serum ferritin concentrations, cumulative RBC transfusion volumes, and liver biopsy to determine the patient's iron status. Each milliliter of packed RBCs contains about 1 mg of elemental iron. Chelation therapy should be considered when the child or adolescent has received a cumulative total of 120 mL/kg of RBCs (around 20 units) and/or when the serum ferritin concentration is greater than 1,500–2,000 ng/mL (References 12, 33). If a liver biopsy is completed, chelation should start when the liver tissue iron content is greater than 7 mg per gram of dry tissue weight (Reference 34).

Two drugs are used in the United States for iron chelation in pediatric patients, deferoxamine and deferasirox (Table 2). Deferoxamine is a parenteral iron chelator that complexes with trivalent ferric ions to form ferrioxamine, which is then removed by the kidneys. Its poor oral bioavailability and short half-life necessitate an 8- to 12-hour subcutaneous infusion. Patients receiving deferoxamine should also receive supplemental ascorbic acid starting 1 month after deferoxamine initiation. Ascorbic acid increases the availability of iron for chelation. Children with preexisting cardiac conditions should not receive supplemental ascorbic acid. Contraindications include those with renal impairment. Complications of deferoxamine therapy may include ototoxicity, allergic reactions, growth failure, ocular disturbances, pulmonary hypersensitivity, and arthralgias. Adherence to deferoxamine can be an issue because of its route of administration. Children and adolescents receiving chelation with deferoxamine should have regular eye and auditory examinations. Deferasirox is an oral iron chelator that selectively binds iron, forming complexes that are excreted through the feces. It is available in an orally dispersible tablet that should be dissolved in water, orange juice, or apple juice, and it should be consumed 30 minutes before eating. Deferasirox is U.S. Food and Drug Administration (FDA) labeled for use in children 2 years and older. Serum ferritin concentrations should be monitored closely in patients receiving deferasirox. If serum ferritin decreases to less than 500 ng/mL, deferasirox should be discontinued and then reinitiated once the serum ferritin level increases to 500 ng/mL or higher (Reference 29). Adverse effects include headache, rash, abdominal pain, nausea, diarrhea, arthralgia, increased serum hepatic transaminases and creatinine, and visual and auditory disturbances. As with deferoxamine, regular annual eye and auditory examinations are recommended. Doses of deferasirox should be decreased if the patient's serum creatinine increases above the age-appropriate upper limit of normal on two consecutive measurements. If the patient's serum creatinine increases

**Table 2.** Iron Chelators Used in Children with SCD and Iron Overload

Drug	Route	Dosage Regimen	Toxicities	Notes

to more than 2 times the upper limit of normal for age, or the creatinine clearance is less than 40 mL/minute, deferasirox should be discontinued until measurements return to baseline (References 25, 26, 33).

Deferiprone was recently approved by the FDA for treatment of transfusional iron overload in adults with thalassemia syndromes who have inadequate responses to other chelation therapies. Deferiprone binds to ferric ions and forms a complex, which is excreted in the urine. It is an oral agent administered three times/day. Agranulocytosis has been reported in patients receiving deferiprone; therefore, careful monitoring is necessary. Studies of deferiprone use in children are limited.

## Acute Complication Management

### Infection and Fever

All children with SCD with a temperature of 101.3°F (38.5°C) or higher should seek immediate medical attention because the condition of these children may deteriorate rapidly. Because of splenic dysfunction, children with SCD are at high risk of complications from encapsulated bacteria such as *S. pneumoniae*. Hospital admission may be necessary, especially in infants younger than 1 year, patients with elevated white blood cell counts, patients with a history of sepsis or bacteremia, or any patient who appears acutely ill. Physical examination, blood cultures, complete blood cell counts including reticulocyte count, and chest radiographs if cough is present or if the child

has difficulty breathing should be completed. Patients should be immediately initiated on empiric broad-spectrum intravenous antibiotics such as cefotaxime, ceftriaxone, or cefuroxime. Patients who have a true allergy to cephalosporins may be treated with clindamycin. Vancomycin should be initiated if the patient has a history of a staphylococcal infection or is severely ill. If mycoplasma pneumonia is suspected, a macrolide such as azithromycin may be initiated. Pain and swelling in an extremity may indicate bone infarct, and osteomyelitis should be considered. *Salmonella* spp. are the most common cause of osteomyelitis in this population, followed by *Staphylococcus aureus* (Reference 12). Prophylactic penicillin regimens should be held while the patient is receiving broad-spectrum antibiotics. Intravenous fluids to prevent dehydration may also be indicated, as well as treatment of fever with appropriate doses of ibuprofen or acetaminophen (References 4, 10, 14).

### Acute Chest Syndrome

Patients with ACS will require hospitalization because they may rapidly deteriorate into respiratory failure and death. Acute chest syndrome may present during an acute illness or 2–3 days after a severe vaso-occlusive pain crisis. A patient receives a diagnosis of ACS when a new infiltrate is detected on chest radiograph, together with symptoms of a lower respiratory infection and possibly hypoxemia (Reference 12). Acute chest

syndrome may be caused by a viral or bacterial infection, pulmonary infarct, and pulmonary fat emboli. Gram-negative, gram-positive, and atypical bacteria should be suspected, and early use of appropriate empiric parenteral antibiotics such as a cephalosporin and a macrolide is important. Oxygen therapy may be indicated if the patient is hypoxic or in respiratory distress. Oxygen saturations measured with pulse oximetry should be maintained at 92% or above. Intravenous fluid use should be monitored closely to avoid fluid overload, which may lead to pulmonary edema and increase respiratory distress. Patients may require transfusion with RBCs, depending on their hemoglobin concentration, to improve oxygenation. Incentive spirometry is encouraged every 2 hours to help prevent atelectasis and to help with lung expansion. Appropriate management of pain is crucial, but care should be taken to prevent opioid-induced hypoventilation. Corticosteroid use is controversial because it has been associated with higher complication rates and readmission (References 12, 35–38).

### ***Cerebrovascular Accidents***

Initial assessment of stroke in a child with SCD should include a physical examination, a complete blood cell count including reticulocyte count, and noncontrast computer tomography or magnetic resonance imaging. Close monitoring every 2 hours with both physical and neurologic examinations is recommended. Treatment may include transfusion to maintain a hemoglobin concentration at 10 g/dL and an HbS concentration at less than 30%. Patients who seize may require anticonvulsants, and interventions may be needed to decrease intracranial pressure. Children with a history of stroke should be initiated on chronic transfusion therapy (Reference 12). The use of clopidogrel and other antiplatelet agents has not been studied in children with SCD and is not recommended.

Screening for early detection of ischemic events with transcranial Doppler ultrasonography is recommended for all children with SCD beginning at age 2 years, and screening should be performed on an annual basis. In the STOP (Stroke Prevention Trial in Sickle Cell Anemia) study, screening followed by chronic transfusion therapy significantly reduced the incidence of primary stroke (Reference 39). Children with positive findings may be candidates for chronic transfusion therapy for primary stroke prevention (References 40, 41).

### ***Priapism***

Two types of priapism are seen in children and adolescents with SCD. Stuttering episodes last from a few minutes to less than 2 hours, and they recur and resolve spontaneously. Severe episodes may last longer than 2–4 hours and will require medical attention to prevent

complications that may lead to impotence. Therapy goals for priapism are to provide pain relief, provide detumescence, and preserve fertility. Patients can self-treat initially by increasing oral fluid intake, urinating, taking warm baths, and using analgesics. If the episode continues for more than 2 hours, patients should be instructed to seek medical attention.

Initial treatment of severe prolonged episodes should include intravenous fluids and analgesics. Patients may require RBC transfusion if their hemoglobin concentration is below their baseline. Both vasodilators and vasoconstrictors have been used to treat severe episodes. Aspiration of penile blood, followed by intracavernous irrigation with epinephrine (1:1,000,000), has been used effectively with minimal complications (References 42, 43).

Several medications have been used to prevent or decrease episodes of priapism. First-line therapy is pseudoephedrine 30–60 mg orally at bedtime. Terbutaline 5 mg orally at bedtime has been used, but the evidence is not consistent. In severe cases, initiating the patient on hydroxyurea or chronic transfusion therapy may be beneficial (References 12, 42).

## **Crisis Management**

### ***Aplastic Crisis***

Treatment of aplastic crisis is generally supportive because most patients will spontaneously recover. Patients may require pain management and transfusion if the anemia is severe or if they are symptomatic. The most common cause of aplastic crisis is infection with human parvovirus B19. Patients should be isolated from immunocompromised individuals and pregnant women because parvovirus is highly contagious (References 4, 10, 12).

### ***Sequestration Crisis***

In young children, splenic sequestration of RBCs can lead to a rapid drop in the patient's hemoglobin concentration and an acutely enlarged spleen. This shift can result in hypovolemia, shock, and death. Treatment should include RBC transfusions to correct the hypovolemia and broad-spectrum antibiotics because infections can precipitate the sequestration crisis (References 4, 12). Management of recurrent episodes involves chronic RBC transfusions and splenectomy. Splenectomy is usually delayed in children until after age 2 years because of the risk of postsplenectomy septicemia (References 12, 14).

### ***Vaso-occlusive Pain Crisis***

Most cases of mild to moderate pain in children and adolescents with SCD can be managed at home. Patients should be instructed to increase their oral fluid intake, rest, apply warm compresses to the painful areas,

and take oral analgesics such as acetaminophen or ibuprofen with or without an opioid (codeine or hydrocodone). In moderate to severe cases, the patient should be hospitalized for treatment. Intravenous or oral fluids at 1.5 times maintenance should be initiated, with careful monitoring to prevent fluid overload (Reference 12). Transfusion may be required in patients who are anemic to bring their hemoglobin concentration back to their baseline level. Any patient presenting with fever should be initiated on broad-spectrum antibiotics empirically because infection may lead to a pain crisis. Aggressive pain management is required and should be individualized and titrated to achieve the best response in the patient (Table 3). Pain control should be assessed on a regular basis with a self-reported pain scale. Patients receiving intravenous opioids should be encouraged to use incentive spirometry to prevent atelectasis. Nausea and vomiting are common adverse effects of the opioid analgesics and can be managed with antiemetics such as promethazine or ondansetron. Promethazine is

contraindicated in children younger than 2 years, and it should be used with caution in young children because of the increased risk of respiratory depression. All patients receiving opioids should be assessed for stool frequency and initiated on prophylactic stool softeners and stimulant laxatives. Pruritus can be severe in patients taking higher doses of opioids, and use of an antihistamine such as diphenhydramine on a scheduled routine may be necessary. The use of low-dose continuous infusion of naloxone may be helpful when other agents do not adequately relieve pruritus (Reference 44).

## HEMATOPOIETIC STEM CELL TRANSPLANTATION

The only cure for SCD is a hematopoietic stem cell transplantation using marrow from a donor who does not have SCD, usually an HLA-matched sibling. More than 250 patients with SCD have received transplants

**Table 3. Drug Regimens for Vaso-occlusive Pain Crises in Children with SCD**

Mild to Moderate Pain	Acetaminophen with codeine: 1 mg/kg (based on codeine) PO every 6 hours
	Hydrocodone with acetaminophen: 0.2 mg/kg (based on hydrocodone) PO every 6 hours
	Ibuprofen: 10 mg/kg PO every 6–8 hours <sup>a</sup>
	Naproxen: 5 mg/kg PO every 12 hours <sup>a</sup>
Severe Pain	Morphine:
	Intermittent doses: 0.05–0.15 mg/kg IV every 3–4 hours
	CI: 0.02–0.05 mg/kg/hour; titrate to effect
	PCA: 0.02–0.03 mg/kg/hour basal + 0.02–0.06 mg/kg IV every 10 minutes
	Hydromorphone:
	Intermittent doses: 0.005–0.015 mg/kg IV every 3–4 hours
CI: 0.003–0.005 mg/kg/hour IV; titrate to effect	
PCA: 0.003–0.005 mg/kg/hour basal + 0.003–0.005 mg/kg IV every 10 minutes	
Adjunctive Treatment	Ketorolac: 0.5 mg/kg up to 30 mg per dose IV every 6 hours <sup>a,b,d</sup>
	Docusate: 5 mg/kg/day PO divided in one to four doses
	Diphenhydramine: 1 mg/kg/dose IV/PO every 6 hours
	Naloxone (for itching): 0.25–1 mcg/kg/hour IV infusion
	Promethazine: 0.25 mg/kg IV/PO every 6 hours (maximal dose: 25 mg) <sup>c</sup>
Ondansetron: 0.15 mg/kg/dose IV/PO every 8 hours	

<sup>a</sup>Use with caution in patients with kidney failure, dehydration, or bleeding.

<sup>b</sup>Use in children aged 1 year and older. Use with caution in children aged 6–12 months.

<sup>c</sup>Contraindicated in children younger than 2 years because of potential for severe and potentially fatal respiratory depression.

<sup>d</sup>Limit use to 5 days maximum.

CI = continuous infusion; IV = intravenously; PCA = patient-controlled analgesia; PO = orally (by mouth); SCD = sickle cell disease. Reprinted with permission from Hagemann T. Sickle cell disease. In: Richardson M, Chant C, Chessman KH, Finks SW, Hemstreet BA, Hume AL, et al., eds. *Pharmacotherapy Self-Assessment Program, 7th ed. Pediatrics*. Lenexa, KS: American College of Clinical Pharmacy, 2010:37.

from an HLA-identical sibling (Reference 45). Ideal SCD transplant recipients are younger than 16 years, with an HLA-identical donor and at least one of the following:

- Stroke,
- ACS,
- Recurrent severe pain episodes,
- Impaired neurologic function with an abnormal magnetic resonance imaging scan,
- Mild to moderate chronic sickle lung disease,
- Sickle nephropathy,
- Bilateral proliferative retinopathy,
- Osteonecrosis of several joints, or
- RBC alloimmunization secondary to long-term transfusion treatment (References 12, 45)

Less than 1% of children with SCD have an HLA-identical sibling who does not have SCD, which is the main barrier to the use of transplantation in SCD.

## CONCLUSIONS

Caring for children with SCD requires a comprehensive, multidisciplinary approach to prevent long-term complications and to improve or maintain the patient's quality of life. Children with SCD should have regularly scheduled assessments and treatment plans available for what to do if fever, pain, or symptoms of infection occur. The education of both the patient and the caregivers should be routinely updated.

# CHAPTER 51

## CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA

*Alix A. Dabb, Pharm.D.*

### LEARNING OBJECTIVES

1. Describe the impact of acute lymphoblastic leukemia (ALL) on the pediatric population.
2. Discuss the typical clinical presentation and diagnostic evaluation for a child with ALL.
3. Recognize major prognostic factors in pediatric patients with ALL.
4. Summarize the typical treatment approach for a patient with newly diagnosed ALL, including the phases of therapy and pharmacologic agents used in management.
5. Give an example of a subgroup of patients with ALL having different therapeutic considerations and approaches to management.
6. List acute and long-term toxicities from therapy for ALL.

### ABBREVIATIONS IN THIS CHAPTER

ALL	Acute lymphoblastic leukemia
EFS	Event-free survival
GCSF	Granulocyte colony-stimulating factor
HSCT	Hematopoietic stem cell transplantation
MRD	Minimal residual disease
Ph	Philadelphia chromosome
TLS	Tumor lysis syndrome
TPMT	Thiopurine methyltransferase

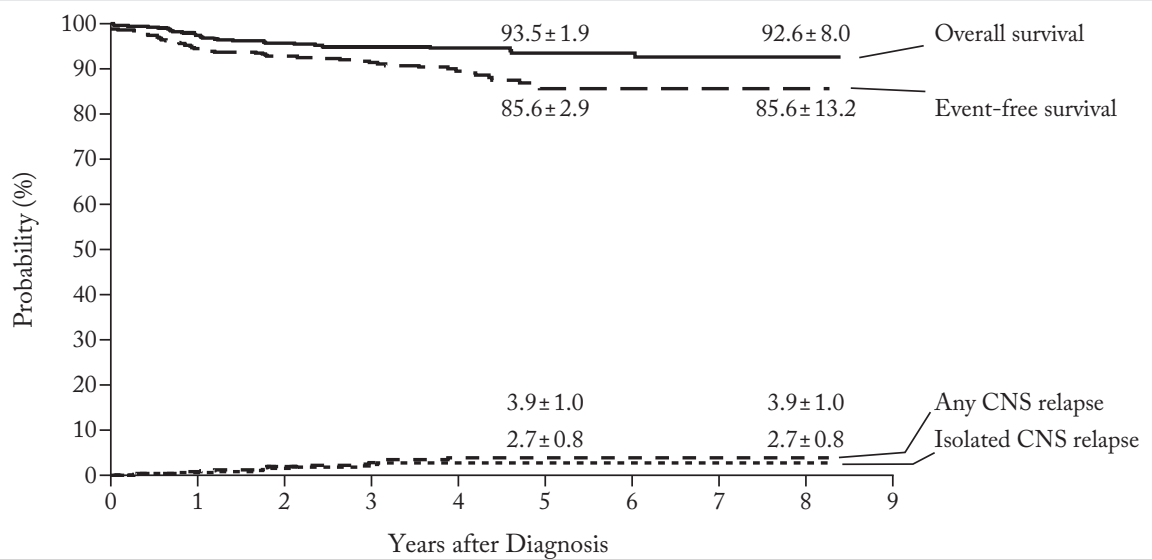

### INTRODUCTION

Acute lymphoblastic leukemia (ALL) is the most frequent malignancy occurring during childhood and is responsible for about 75% of all childhood leukemias, resulting in an annual incidence of 30–40 new cases per 1 million children in the United States (References 1, 2). Survival has drastically improved, partly because of a better understanding of the biology of the disease as well as by the therapeutic advances made through clinical trials, illustrated by improvements in 5-year survival rates from around 55% in the 1970s to 85% to 90% in the most recently reported period of 1999–2006. Figure 1 is an example of survival outcomes from a recently conducted clinical trial of patients with newly diagnosed ALL (References 2–5). Although ALL can occur

anytime during childhood development, presentation usually occurs between 2 and 5 years of age (Figure 2) (References 6, 7). In the United States, childhood ALL occurs with the highest incidence in Hispanic children, followed by whites and African Americans (References 8, 9). The incidence of ALL is higher in boys than in girls, and boys tend to present with more high-risk features than girls (References 8, 10).

Although the exact factors leading to the development of ALL remain unknown, much research has been done to investigate risk factors that may contribute to its development. However, the contribution of these risk factors remains controversial because many of the trials have produced conflicting results. From the environmental perspective, exposure to ionizing radiation has been linked with the development of ALL or acute myelogenous leukemia (Reference 11). Potential sources of ionizing radiation include nuclear accidents or atomic bombs and diagnostic x-rays, as well as living near a nuclear facility. Other environmental factors studied include exposure to electromagnetic fields, cigarette smoke, hydrocarbons, and pesticides (References 8, 11–13). Certain genetic factors can increase a child's likelihood of developing ALL. There is a high leukemia concordance rate in identical twins, and there are increased rates of leukemia in siblings of patients with childhood ALL (References 8, 11). In addition, children with other types of inherited diseases such as Fanconi anemia, ataxia telangiectasia, Down syndrome, and neurofibromatosis are at an increased risk of developing ALL (References 8, 11). Other factors that have been investigated as potentially contributing to the development of ALL include lack of exposure to infections, increased maternal and/or paternal age, increased birth weight, maternal alcohol exposure, household radon exposure, and chemical contamination of groundwater (References 8, 14, 15). These potential contributing factors must be interpreted with caution because reports are conflicting regarding their importance.

To better understand the pathogenesis of ALL, it is essential to understand the normal hematopoietic process. In brief, hematopoiesis begins with a pluripotent stem cell that is capable of differentiating into myeloid and lymphoid stem cells. The lymphoid progenitor cell then further differentiates into T and B lymphocytes. In the development of ALL, the lymphoid progenitor cell is defective in some way such that it does not undergo terminal differentiation, leading to uncontrolled

No. at Risk	0	1	2	3	4	5	6	7	8	9
Overall survival	498	498	481	408	319	241	151	105	60	9
Event-free survival	498	492	464	378	292	206	125	88	51	5
Any CNS relapse	492	492	464	378	292	205	125	88	51	5
Isolated CNS relapse	492	492	464	378	292	205	125	88	51	5

**Figure 1.** Kaplan–Meier and Kalbfleisch and Prentice Analyses of Outcomes in Children with Acute Lymphoblastic Leukemia. The overall survival, event-free survival, cumulative risk of any central nervous system (CNS) relapse (combined plus isolated), and cumulative risk of isolated CNS relapse are shown. The plus–minus values for 5-year and 8-year rates are means ± SE.

Pui CH, Campana D, Pei D, Bowman WP, Sandlund JT, Kaste SC, et al. Treating childhood acute lymphoblastic leukemia without cranial irradiation. *N Engl J Med* 2009;360:2730–41 (Reference 5). Copyright 2009, with permission from the Massachusetts Medical Society.

proliferation of immature lymphoblasts in the bone marrow (References 16, 17). This uncontrolled proliferation results in expanded populations of leukemia blast cells (lymphoblasts), which in turn can cause a decrease in normal hematopoiesis, leading to signs of bone marrow failure. The lymphoblasts can be either T or B lymphocytes, which is determined by analyzing the antigen expression on the surface of the lymphoblasts. Identification of the lineage involved is important for appropriate therapy decisions, risk stratification, and prognostic implications (Reference 18).

### CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

The clinical presentation of a child with ALL varies depending on the duration of symptoms and the degree of involvement of the bone marrow and other sites. Common symptoms that may be reported on presentation include bone pain, pallor, bruising, fatigue, weight loss, fever, and potentially an enlargement of the liver, lymph nodes, and spleen (Reference 6). These symptoms occur because of the effects of the leukemia on normal

hematopoietic function and because the leukemia blasts can infiltrate organs. A thorough physical examination should be completed to identify objective findings of ALL, including a testicular examination for males.

Once a patient has been identified with signs and symptoms suggestive of leukemia, it is imperative that a thorough laboratory analysis be conducted in a timely fashion. A complete blood cell count will often show decreased hemoglobin and hematocrit, decreased platelet counts, and a white blood cell (WBC) count that may be normal, elevated, or low. The differential on the WBC count will sometimes show the presence of blast cells, which corresponds to the absolute neutrophil count being low because normal hematopoietic function is compromised. The peripheral blood smear can be sent for morphologic analysis to identify the presence of leukemic blast cells. Care must be used in interpreting the presence of blasts on the peripheral blood smear because other causes may exist for the presence of these immature cells, such as a viral infection (Reference 19). In addition, a comprehensive metabolic panel and uric acid should be obtained to check the patient’s renal function and look for the presence of electrolyte abnormalities that may be suggestive of tumor lysis syndrome

(TLS). Tumor lysis syndrome will be discussed in more detail in the supportive care section of this chapter. Because the signs, symptoms, and clinical presentation of childhood leukemia are often nonspecific, it is important to include other disease states in the differential diagnosis. Nonmalignant diseases that might have similar presenting features include, but are not limited to, juvenile rheumatoid arthritis, infectious mononucleosis, osteomyelitis, aplastic anemia, and idiopathic thrombocytopenic purpura (Reference 19).

Next in the diagnostic evaluation is to obtain a bone marrow aspirate and/or biopsy to confirm the suspicion for ALL. At the same time, a diagnostic lumbar puncture is performed to evaluate central nervous system (CNS) involvement (Reference 6). Intrathecal chemotherapy may be given during the diagnostic lumbar puncture if the diagnosis of ALL has already been confirmed on the basis of peripheral blood analysis. The specimens obtained during these procedures are analyzed by various techniques including flow cytometry, immunophenotyping, and cytogenetic studies. These techniques are used to identify leukemic blasts, determine the extent of involvement, and learn more specific details about the leukemia such as antigen expression and cytogenetic abnormalities (Reference 6). These test results are important to determine the prognosis and to stratify the patient's therapy on the basis of risk of relapse.

## Classification

Childhood ALL can be classified on the basis of morphology, immunophenotype, and cytogenetic abnormalities. The French-American-British (FAB) system was used in the past to categorize ALL into three categories, L1, L2, and L3, based on cytologic features of the lymphoblast in the bone marrow biopsy specimen (Reference 8). The FAB system is no longer used to classify leukemia because it does not correlate well with risk stratification, and there are now more advanced and more accurate methods for classification (References 8, 20). Immunophenotyping is one such method that uses antigens and other markers expressed on the cell surface to categorize the subtype of ALL (Reference 8). Bone marrow samples are analyzed for cytogenetic abnormalities to better assess risk factors and prognosis, the details of which will be discussed further in the next section (Reference 8).

## Prognostic Factors

Throughout decades of clinical trials, a great deal of knowledge has been gained about different features that a patient may or may not have and the effect of these factors on outcomes. These factors affect treatment decisions such that more intensive therapy is provided to patients with poor prognostic features to maximize outcomes, whereas therapy is often minimized for patients with favorable features to eliminate excessive toxicity in the subset of patients likely to have good long-term survival (Reference 21). Table 1 provides an overview of some of the main prognostic factors, both favorable and unfavorable.

Age and WBC count at diagnosis are two strong prognostic factors that will help determine the initial therapy the patient will receive during induction. Infants (younger than 1 year at diagnosis) and children 10 years and older are at a higher risk of relapse and will receive more intensive therapy to overcome this high-risk factor (References 6, 21, 22). A presenting WBC count of 50,000/ $\mu\text{L}$  or more has been associated with a poor outcome, so these patients will also be considered high risk and receive more intensive therapy (References 6, 21, 22).

Chromosomal abnormalities in the leukemic blast cell have prognostic importance. Before discussing some of the specific abnormalities with prognostic significance, it is important to have a basic understanding of the terminology and nomenclature used. There are two main types of chromosomal abnormalities: changes in the number of chromosomes (gains and losses) and structural changes (translocations, insertions, inversions, and deletions) (Reference 23). A translocation occurs when genetic material is rearranged between chromosomes. An example of a translocation would be  $t(9;22)(q34;q11)$ , which identifies the presence of the Philadelphia

**Table 1.** Favorable and Unfavorable Prognostic Factors in Childhood ALL

Factor	Favorable Prognostic Factors and Their Approximate Incidence (%)	Unfavorable or Less Favorable Prognostic Factors and Their Approximate Incidence (%)
Age at diagnosis	≥1 and <10 years (77%)	<1 year (3%) or ≥10 years (20%)
Gender	Female (45%)	Male (55%)
White blood cell count at diagnosis	<50,000/ $\mu$ L (80%)	≥50,000/ $\mu$ L (20%)
Immunophenotype	CD10 <sup>+</sup> precursor B-cell ALL (83%)	CD10 <sup>-</sup> precursor B-cell ALL (4%), T-ALL (13%)
CNS disease <sup>a</sup>	CNS 1 (80%)	CNS 3 (3%), TLP+ (7%)
Genetic features <sup>b</sup>	Hyperdiploidy (20%), TEL/AML1 positivity (20%)	Hypodiploidy (1%), t(9;22) or BCR/ABL positivity (2%), t(4;11) or MLL/AF4 positivity (2%)
Prednisone response <sup>c</sup>	<1000/ $\mu$ L blood blasts (90%)	≥1000/ $\mu$ L blood blasts (10%)
Early bone marrow response	<5% blasts (M1) on day 15 of induction treatment (60%)	25% blasts (M3) on day 15 of induction treatment (15%)
Remission status after induction therapy in the bone marrow (morphologically assessed)	<5% blasts (M1) after 4 to 5 weeks of induction treatment (98%)	5% blasts (M2 or M3) after 4 to 5 weeks of induction therapy (2%)
Minimal residual disease <sup>d</sup> in the bone marrow (molecularly assessed)	<10 <sup>-4</sup> blasts after 5 weeks of induction treatment (40%)	10 <sup>-3</sup> blasts after 12 weeks of treatment (induction and consolidation) (10%)

NOTE. Prognostic factors are treatment-dependent and, therefore, the selection presented in the table cannot be entirely comprehensive; it reflects the current recommendations of the German BFM Study Group.

<sup>a</sup>CNS1 = puncture nontraumatic, no leukemic blasts in the cerebrospinal fluid (CSF) after cytocentrifugation; CNS3 = puncture nontraumatic, >5 leukocytes/ $\mu$ L CSF with identifiable blasts; TLP+ = traumatic lumbar puncture with identifiable leukemic blasts; a TLP with no identifiable blasts is not an adverse factor; the prognostic impact of CNS2 status (puncture nontraumatic, ≤5 leukocytes/ $\mu$ L CSF with identifiable blasts) is debated. For cytomorphological examination, CSF samples should be analyzed after cytopspin preparation, a method through which cellular components within the CSF are concentrated by centrifugation.

<sup>b</sup>Hyperdiploidy defined as the presence of more than 50 chromosomes or a DNA index (the ratio of DNA content in leukemic G0/G1 cells to that of normal diploid lymphocytes) ≥1.16; hypodiploidy defined by <45 chromosomes; the prognostic value of MLL gene rearrangements other than MLL/AF4 and presence of the E2A/PBX1 fusion transcript are debated.

<sup>c</sup>After 7 days induction with daily prednisone and a single intrathecal dose of methotrexate on treatment day 1.

<sup>d</sup>Assessed by molecular genetic techniques or flow cytometry; markers required to have a sensitivity of at least 10<sup>-4</sup>.

ALL = acute lymphoblastic leukemia; CNS = central nervous system.

Reprinted from Stanulla M, Schrappe M. Treatment of childhood acute lymphoblastic leukemia. *Semin Hematol* 2009;46:52–63 (Reference 6). Copyright 2009, with permission from Elsevier.

chromosome (Ph). In this case the “t” identifies that it is a translocation, (9;22) identifies that chromosomes 9 and 22 are involved, and (q34;q11) identifies the specific sections of each chromosome that are involved. The “q” refers to the long arm of the chromosome, whereas the use of “p” would identify the short arm of the chromosome. Thus, in this example of the Philadelphia chromosome, genetic material on the long arm of chromosome 9 at segment 3, band 4 has changed places with the genetic material on the long arm of chromosome 22, segment 1, band 1 (Reference 23). Additions occur when genetic material is gained. The most common example of this is trisomy 21, in which there are three copies of chromosome 21 rather than the normal two copies. Finally, a deletion occurs when there is a loss of genetic material. Deletions can affect a section of a chromosome or an entire chromosome. For example, monosomy 7 refers to the fact that there is only one copy of chromosome 7.

Table 1 reviews some of the main chromosomal abnormalities with prognostic importance. The implications of some of these abnormalities will be described in more detail later in the chapter when discussing the medical management of select subgroups of patients.

It is also important to consider the number of chromosomes in the blast cell compared with normal cells. This is referred to as the DNA index (Reference 23). A DNA index of 1.0 identifies that there is the same number of chromosomes in blast cells as in normal cells. A DNA index of more than 1, also referred to as hyperdiploidy, means that the blast cells have more chromosomes than normal cells (Reference 24). Hyperdiploidy has been associated with a favorable prognosis, partly because of the increased sensitivity to chemotherapy agents, and is generally found in patients with other favorable prognostic factors such as age and WBC count (References 24–26). Pseudodiploidy (DNA index = 1.0)

is used to describe blast cells with a normal number of chromosomes but with abnormalities such as translocations. Finally, a DNA index of less than 1, also referred to as hypodiploidy, shows that the blast cell contains fewer chromosomes than normal cells, which has been associated with a poorer prognosis (Reference 27).

Although childhood ALL is more common in boys, the male sex has been associated with a poorer prognosis than the female sex (References 10, 21). Through clinical trials and risk-adapted therapy, the impact of male sex has largely disappeared as a prognostic factor. Male patients are, however, at risk of testicular relapse as an additional site of disease. Historically, race has been identified as a factor affecting outcomes, with African American patients having a poorer outcome from therapy compared with white children (Reference 21). Results from a retrospective study showed that, although these patients were more likely to have unfavorable prognostic factors, their outcomes were similar to those of white children when treated with appropriate therapy (Reference 28).

Response to therapy is the most significant prognostic factor in childhood ALL (Reference 29). This has traditionally been measured by examining the bone marrow for the morphologic presence of leukemic blasts (greater than 5% has been correlated with a poorer response to therapy) at various times during induction and throughout therapy (References 30–33). In addition, the clearance of blasts from the peripheral blood helps predict a favorable outcome (Reference 34). Most recently, measuring minimal residual disease (MRD) has become standard practice to better assess response to therapy (Reference 35). Minimal residual disease, detected by flow cytometry or polymerase chain reaction, enables the identification of leukemic disease in the bone marrow or peripheral blood that would not have been detected morphologically. Thus, patients can now be identified as having a poor or suboptimal response when they would have otherwise been considered to have a complete response morphologically (Reference 29). The presence of MRD (MRD of 0.01% or greater) is predictive of relapse or poor response to therapy, especially in patients with high levels of MRD (MRD of 1% or greater) at the end of induction (References 29, 35, 36). The same has been true for the use of pretransplant MRD to predict the risk of relapse after transplantation (Reference 37). The ability to use MRD to risk stratify patients is being investigated in clinical trials (Reference 29).

## TREATMENT

Therapy for childhood ALL, lasting between 2 and 3 years, has become increasingly complex as clinical trial results are incorporated into front-line treatment protocols (see Table 2 for information on the chemotherapeutic agents used in therapy) (Reference 40). Traditionally,

therapy has been divided into three phases—induction, consolidation/intensification, and maintenance/continuation—with CNS-directed therapy provided throughout all phases. Current trials and therapeutic regimens have many more phases added in to intensify and add different treatment approaches, but the three general phases still exist in principle. Therapy is stratified on the basis of a patient's risk of relapse, with patients at high risk of relapse receiving more intense therapy compared with patients at low or standard risk of relapse. For this discussion on treatment approaches, we will focus on therapy for patients with precursor B-cell leukemia. The management of other patient subsets will be discussed later.

## Dosing Chemotherapeutic Agents

Chemotherapy doses are most commonly calculated using a patient's body surface area, except in the infant population where doses are usually calculated based on patient weight. There are several formulas available to calculate body surface area, all of which utilize height and weight in the calculation. See the Introduction to Pediatrics chapter for an example of a body surface area equation.

## Induction

The goal of induction is to induce a complete remission, which occurs successfully in around 98% of patients (Reference 40). Induction therapy usually lasts 4–6 weeks, during which time a regimen with either three or four drugs is administered (Reference 40). A three-drug induction with a glucocorticoid, asparaginase, and vincristine is used for patients with standard-risk ALL (WBC count less than 50,000; 1–9 years of age at presentation), whereas an anthracycline is added as the fourth drug in induction for high-risk patients (Reference 40). In addition to the systemic agents, intrathecal chemotherapy is given to all patients as prophylaxis against CNS relapse, regardless of CNS involvement (References 40–44). The typical 4-week induction regimen can be extended an additional 2 weeks for patients who do not achieve a complete remission at the end of induction. As discussed, response to therapy at various times during, at the end of induction, and after induction is the most important prognostic factor.

Glucocorticoids are used throughout most phases of therapy for ALL (Reference 45). The choice of glucocorticoid varies between prednisone, prednisolone, methylprednisolone, and dexamethasone, depending on the protocol. Clinical trials have shown that dexamethasone has an advantage over prednisone by improving event-free survival (EFS) and decreasing the rate of CNS relapses (References 46–48). In vitro, dexamethasone has a higher antileukemic potency than prednisone (References 45, 46, 49, 50). In addition, dexamethasone has a longer half-life and is better able to cross

**Table 2.** Chemotherapy Commonly Used in the Management of ALL (Reference 38)<sup>a</sup>

Drug Name	Class	Major Adverse Effects	Other Notes
Cyclophosphamide	Alkylating agent	Nausea, vomiting, myelosuppression, hemorrhagic cystitis, SIADH, sterility, secondary malignancy	
Cytarabine	Antimetabolite (pyrimidine analog)	Nausea, vomiting, myelosuppression, flu-like symptoms, rash, CNS changes	
Daunorubicin/ Doxorubicin	Anthracycline	Red discoloration of urine, myelosuppression, mucositis, cardiomyopathy, secondary malignancy	<ul style="list-style-type: none"> <li>Used mainly for high-risk patients</li> </ul>
Etoposide	Topoisomerase inhibitor	Myelosuppression, transient hypotension, secondary malignancy	
Imatinib	Tyrosine kinase inhibitor	Fluid retention, peripheral edema, myelosuppression, peripheral neuropathies, cardiotoxicity	<ul style="list-style-type: none"> <li>Used for Ph+ ALL only</li> </ul>
Mercaptopurine	Antimetabolite (purine analog)	Myelosuppression, nausea, vomiting, liver function abnormalities	<ul style="list-style-type: none"> <li>Administer in the evening.</li> <li>Take without food or milk for maximal absorption.</li> </ul>
Methotrexate	Antimetabolite	Transaminase elevations, nausea, vomiting, mucositis, photosensitivity, osteonecrosis, nephrotoxicity	<ul style="list-style-type: none"> <li>Oral: administer 1 hour before or 2 hours after food or milk</li> <li>High-dose IV methotrexate: ensure hyperhydration, urinary alkalinization, and leucovorin administration</li> </ul>
Nelarabine	Antimetabolite (purine analog)	Myelosuppression, nausea, peripheral neuropathies, somnolence, confusion	<ul style="list-style-type: none"> <li>Used in T-cell ALL only</li> </ul>
Pegaspargase	Miscellaneous	Hypersensitivity, pancreatitis, rash, coagulation abnormalities, hyperglycemia, liver function test abnormalities, hypertriglyceridemia	<ul style="list-style-type: none"> <li><i>Erwinia</i> asparaginase is an alternative product for patients with hypersensitivity to pegaspargase</li> </ul>
Prednisone or dexamethasone	Glucocorticoid	Hyperglycemia, hypertension, Cushing syndrome, immune suppression, gastritis, infections, osteopenia, avascular necrosis	
Vincristine	Vinca alkaloid	Peripheral neuropathies, constipation, jaw pain, SIADH, foot drop, hyperbilirubinemia	<ul style="list-style-type: none"> <li>Fatal if administered intrathecally</li> </ul>

<sup>a</sup>This table is intended to summarize adverse effects that occur commonly or are of major significance. It is not meant to be inclusive of all adverse effects or other pertinent information.

ALL = acute lymphoblastic leukemia; CNS = central nervous system; IV = intravenous; Ph+ = Philadelphia chromosome positive; SIADH = syndrome of inappropriate secretion of antidiuretic hormone.

the blood-brain barrier (References 46–48). However, the use of dexamethasone is also associated with an increased risk of infectious complications and avascular necrosis compared with prednisone (References 45, 46, 51, 52). The risk of developing avascular necrosis increases with age, with patients between 10 and 20 years of age at highest risk of developing this toxicity. Moreover, it was recently reported that the development of avascular necrosis may be related to specific

genetic polymorphisms (References 52–54). Although the best way to use these glucocorticoids is not known, several approaches are being investigated in clinical trials to maximize outcome and minimize toxicity.

Asparaginase is an essential component of ALL therapy that improves outcomes when it is included in the treatment regimen (References 55, 56). Asparaginase is very effective because leukemia blast cells rely on exogenous asparagine for protein synthesis, so when

asparaginase is administered, it reduces the asparagine available for use by these cells (Reference 57). There are currently two asparaginase products that may be used during ALL therapy. Asparaginase can be derived from either *Escherichia coli* or *Erwinia chrysanthemi* (References 57, 58). *E. coli* asparaginase, also referred to as “native” asparaginase, has a half-life of about 1.4 days. Its use in therapy is limited by the inconvenience of dosing (intramuscular administration given usually three times/week, repeated for 2–3 weeks) and the incidence of hypersensitivity reactions, which have been reported to occur in as many as 60% of patients in clinical trials (References 57, 59–62). *E. coli* asparaginase has recently been removed from the U.S. market. Pegaspargase (PEGylated asparaginase), derived from *E. coli* with a half-life of about 6 days, was introduced as an option for patients with a hypersensitivity reaction to native asparaginase (References 57, 63, 64). Initial data showed that the incidence of hypersensitivity reactions with pegaspargase was lower than that with *E. coli* asparaginase; however, clinical experience has seemed to favor a more pronounced incidence of these reactions with pegaspargase than is reported in the literature. The development of these reactions may be delayed and the duration prolonged, given the half-life of the preparation (References 57, 63). However, the use of pegaspargase has replaced the use of *E. coli* asparaginase in up-front clinical trials because it is more convenient to administer, data support administering pegaspargase intravenously rather than intramuscularly, and *E. coli* asparaginase has recently been removed from the U.S. market (Reference 65). If a patient cannot receive pegaspargase, the use of *Erwinia* asparaginase can be considered, which received FDA (U.S. Food and Drug Administration) approval in late 2011. Because the source of asparaginase is different, patients are more likely to tolerate *Erwinia* asparaginase after hypersensitivity reactions to native asparaginase or pegaspargase, with overall rates of hypersensitivity reactions reported as 5% to 33% (Reference 57). *Erwinia* asparaginase has a short half-life of about 0.6 day, requiring the administration of six intramuscular doses to replace one pegaspargase dose (Reference 58). Some data show inferior outcomes from therapy when *Erwinia* is used in place of an *E. coli* asparaginase product, but other trials have not confirmed this finding (References 59, 60). The pharmacokinetics, pharmacodynamics, and dosing schemas differ between these products, so care must be taken when a different product is used to ensure the appropriate dose, route, and administration schedule (References 57, 58, 62, 63). In addition, it is important to monitor for other common toxicities that may occur with the use of asparaginase, including pancreatitis, thromboembolism, hypertriglyceridemia, hyperglycemia, and liver dysfunction (References 57, 66).

## CNS Preventive Therapy

The CNS is a sanctuary site for leukemia involvement (Reference 67). The blood-brain barrier acts as an effective obstacle over which many of the systemically administered chemotherapy agents do not adequately cross; therefore, the leukemia can reside in the CNS virtually free from exposure to therapy (Reference 68). Relapse of disease in the CNS is a primary cause of treatment failure when adequate therapy is not provided to this site (References 41, 68). All patients are screened at diagnosis for CNS involvement by a lumbar puncture, with the cerebrospinal fluid (CSF) analyzed for the presence of WBCs and leukemic blasts. Because the results of the diagnostic lumbar puncture will affect the CNS-directed therapy the patient receives, the procedure should be completed by an experienced practitioner with good technique to avoid potential contamination with leukemia cells from the peripheral blood (References 69, 70). Patients are further classified as having CNS-1, CNS-2, or CNS-3 disease given the findings from the lumbar puncture. The CNS-1 disease classification identifies patients with no leukemic blasts in the CSF; CNS-2 shows the presence of blasts in the CSF with less than 5 WBCs/ $\mu$ L; however, patients with CNS-3 have leukemic blasts in the CSF with 5 or more WBCs/ $\mu$ L (Reference 8). This CNS classification is important in determining the risk of CNS relapse and the amount and intensity of CNS-directed therapy a patient will require.

All patients with childhood ALL are at risk of CNS involvement and CNS relapse, but certain features increase that risk, including patients with T-cell ALL, a high presenting WBC count, certain cytogenetic abnormalities, and CNS involvement at diagnosis (Reference 41). Intrathecal therapy, most often with methotrexate, is given to all patients concurrently with systemic chemotherapy administration as a prophylactic approach to preventing CNS relapse. In a patient who presents with CNS disease, therapy may be intensified to include additional agents (hydrocortisone and cytarabine) and/or given at a greater frequency. In addition, the choice of systemic glucocorticoid used in therapy can play a role in preventing CNS relapses because dexamethasone has fewer CNS relapses than prednisone (see previous discussion). Of note, the dosing for intrathecal therapy is based on age, not on body surface area as for most other chemotherapy agents. Age-based dosing of intrathecal allows more accurate dosing because the CSF volume changes with age, so age is a much better predictor for exposure than weight, height, or body surface area (Figure 3) (Reference 71).

In the past, cranial irradiation was effectively used as prophylaxis and treatment of ALL in the CNS. However, cranial irradiation, especially in children, is associated with many short- and long-term toxicities, including

secondary malignancies, neurocognitive dysfunction and learning disabilities, effects on growth and development, and neurotoxicity (Table 3) (Reference 41). Data now support that intrathecal therapy, used in conjunction with intensive systemic therapy, can either replace the use of cranial irradiation in most patients or allow the dose of cranial irradiation to be markedly reduced (References 5, 41–44, 72, 73). Cranial irradiation should be reserved for patients at extremely high risk of CNS relapse or in the setting of CNS relapse (Reference 41).

### Post-remission Therapy

Post-remission therapy begins after the completion of induction and the successful achievement of a complete remission. Post-remission therapy generally consists of two main phases, consolidation and maintenance/continuation. As more knowledge has been gained about prognostic factors and risk stratification, additional treatment phases have been added throughout continuation/maintenance to further intensify therapy and improve outcomes. Consolidation begins after the completion of induction therapy and usually lasts between 2 and 6 months. The purpose of consolidation therapy is to introduce medications with mechanisms of action different from those used during induction to treat any remaining undetectable disease. If post-remission therapy is not administered and completed, the patient will experience a relapse of his or her leukemia, despite achieving a complete remission after induction. Typical agents used during the consolidation phase include cytarabine, methotrexate, anthracyclines, etoposide, cyclophosphamide, and intrathecal chemotherapy. The drug dosing and administration schedules are variable, depending on the protocol or treatment plan (References 3, 4, 74, 75).

**Figure 3.** Relation between body surface area and central nervous system volume as a function of age.

Some of the important information learned about the optimal method for administering methotrexate for ALL is noteworthy. Methotrexate has antileukemic activity and is available to be administered orally, intramuscularly, or intravenously. The use of high-dose intravenous methotrexate (at least 1 g/m<sup>2</sup>) during consolidation improves outcomes (References 75–77). Obtaining a methotrexate serum concentration within a specific range after an infusion of high-dose methotrexate is also correlated with positive outcomes (Reference 78). A recent study showed that the duration of the methotrexate infusion can affect efficacy (Reference 79). In this study, patients were randomized to receive 1 g/m<sup>2</sup> of methotrexate intravenously over either 4 hours or 24 hours. The intracellular concentration of active drug, methotrexate polyglutamates, was higher in the patients receiving the 24-hour infusion, which correlated with a lower risk of relapse. In addition, another study showed that a high-dose infusion of methotrexate (5 g/m<sup>2</sup> per dose) had superior survival outcomes in a population of high-risk patients with ALL compared with low-dose, escalating methotrexate (Capizzi style) plus asparaginase (Reference 80). Event-free survival was improved, and the incidence of other toxicities did not increase in the patients receiving high-dose methotrexate. These are two recent examples of using information gleaned from clinical trials to support seemingly minor modifications to drug therapy to maximize outcomes with currently available agents.

Intensification of consolidation therapy has been shown in clinical trials to improve outcomes from therapy (References 81–86). This has been accomplished by adding in short phases of more intensive therapy, often called either re-induction or delayed intensification. The agents used are consistent with those used during induction and other phases of consolidation. Because of the success of these intensification regimens during consolidation and continuation, most protocols and standard treatment regimens now routinely include these additional phases of therapy.

Maintenance therapy, also referred to as continuation therapy, begins after the completion of consolidation and continues to complete a 2- to 3-year overall treatment course from the time of initial diagnosis. The purpose of this longest phase of therapy is to maintain a complete remission and prevent relapse. This therapy is less intense than what was previously prescribed and is delivered mainly in the outpatient and home settings. Maintenance therapy relies primarily on antimetabolite administration consisting of daily oral mercaptopurine and weekly low-dose oral/parenteral methotrexate (Reference 40). The doses of these agents will be modified or held, depending on the patient's response, as reflected in the WBC count, absolute neutrophil count, and platelet count (Reference 40). In addition, patients will receive

**Table 3. Long-term Toxicities from Childhood ALL Therapy**

Adverse Outcome	Treatment Associated with an Increased Risk	Factors Associated with Highest Risk
Neurocognitive deficits	Cranial radiation, intrathecal methotrexate, cytarabine	Females, younger age at treatment, increasing dose
Hypothyroidism	Craniospinal radiation	Increasing dose, females, age at treatment
Osteopenia/Osteoporosis	Corticosteroids, craniospinal radiation, gonadal radiation, total body irradiation	Associated hypothyroidism, hypogonadism, growth hormone deficiency
Hypogonadism	Alkylating agents, craniospinal radiation, abdominopelvic radiation, gonadal radiation	Males, treatment during peripubertal or postpubertal period in girls, higher cumulative doses of alkylators
Precocious puberty	Cranial radiation	Females, younger age at treatment, radiation dose >18 Gy
Avascular necrosis	Corticosteroids, high-dose radiation to any bone	Dexamethasone, adolescence
Growth hormone deficiency	Cranial radiation	Younger age at treatment, radiation dose >18 Gy
Obesity	Cranial radiation	Younger age at treatment (<5 years), females, higher cranial radiation dose
Secondary CNS tumor	Cranial radiation	Increasing dose, younger age at treatment
Therapy-related myelodysplasia	Topoisomerase II inhibitors	Schedule (weekly or twice weekly administration)
Skin cancer (basal cell, squamous cell, melanoma)	Radiation therapy	Orthovoltage radiation (prior to 1970)—delivery of greater dose to skin, additional excessive exposure to sun, tanning booths
Dental abnormalities	Cranial radiation	Younger age at treatment
Cataracts	Cranial radiation, steroids	Higher radiation dose, combination of steroids and radiation, single daily fraction
Chronic hepatitis C and HCV related sequelae (cirrhosis, hepatic failure, hepatocellular carcinoma)	Transfusions before 1993	Living in hyperendemic area
Cardiomyopathy/congestive heart failure	Anthracyclines	High cumulative doses (>550 mg/m <sup>2</sup> in patients >18 years of age; >300 mg/m <sup>2</sup> for patients <18 years of age), females, younger than 5 years at treatment, African-American race

ALL = acute lymphoblastic leukemia; CNS = central nervous system; HCV = hepatitis C virus.

intrathecal therapy at various times throughout this phase to prevent CNS relapse. Adding short pulses of more intense therapy during maintenance with vincristine and a glucocorticoid improves outcomes and is included in most treatment regimens (References 87–89).

### Management of Select Patient Subgroups

#### *T-cell ALL*

T-cell ALL represents about 10% to 15% of all cases of childhood ALL and has historically been associated with worse outcomes than cases with precursor B-cell ALL (Reference 90). Reports from the late 1970s

showed 3-year survival rates of around 56%, which increased to almost 80% in the early 1990s because of the intensification of therapy (References 90, 91). These patients are at an increased risk of induction failure, death during induction, early relapse, and isolated CNS relapses (Reference 91). Patients with a diagnosis of T-cell ALL are more likely to present with high-risk features including older age, an elevated WBC count greater than 50,000/ $\mu$ L, hepatosplenomegaly, the presence of a mediastinal mass, and CNS involvement (References 90, 92). Because of the high rates of CNS involvement at diagnosis and the increased risk of CNS

relapse, prophylactic and therapeutic cranial irradiation has routinely been administered to these patients (Reference 90). However, recent trials have shown that the dose of radiation delivered to the CNS can be minimized or even omitted without affecting overall EFS (References 90, 93–95).

Current therapy regimens for patients with T-cell ALL include the use of intensive, multiagent, systemic chemotherapy similar to that for patients with precursor B-cell ALL, in addition to CNS-directed therapy in the form of intrathecal chemotherapy and/or cranial irradiation (References 93, 95). Patients with T-cell ALL require an increased dose of systemic methotrexate (generally 5 g/m<sup>2</sup> rather than the 1 g/m<sup>2</sup> used for patients with precursor B-cell ALL) to achieve the same amount of methotrexate polyglutamates within the blast cell (Reference 5). Nelarabine, a nucleoside analog and prodrug of ara-G, is a relatively new drug that is indicated for the treatment of relapsed or refractory T-cell ALL (References 96, 97). Ara-G accumulates to a higher degree in T lymphoblasts, making this agent specifically active in the T-cell ALL population (References 96, 97). The potential role of nelarabine in combination with standard chemotherapy in the up-front management of T-cell ALL is under investigation in clinical trials (Reference 97). The most troublesome adverse effect of this drug is neurotoxicity, manifested mainly as somnolence and peripheral neuropathies (Reference 97). Treatment options for relapsed or refractory T-cell ALL include the use of a hematopoietic stem cell transplantation (HSCT).

### **Infant ALL**

Infant ALL, defined as ALL arising in children younger than 1 year at diagnosis, accounts for about 5% of childhood ALL and is associated with a worse prognosis than ALL in older children (References 98–107). Clinical trials in this population have shown a 5-year EFS reaching only about 50%. Although this survival rate has improved through the years, it continues to be substantially lower than the survival rate in children older than 1 year at diagnosis. A potential explanation for this difference in outcome is that infant ALL is biologically different from the ALL that occurs in other pediatric age groups (Reference 108). First, there is a very high rate of chromosomal translocations with the mixed-lineage gene (*MLL*), which has been implicated as a poor prognostic indicator (Reference 109). Moreover, blast cells in infant ALL are often resistant to steroid and asparaginase therapy, which are two of the mainstays of therapy for childhood ALL, but they appear to be more sensitive to cytarabine (Reference 109).

Mutations that lead to the development of infant ALL may occur completely or partly in utero. Leukemic clones have been identified in blood obtained from neonatal heel sticks (Guthrie cards) in patients who later developed ALL, showing that some or all of these genetic events occur in utero (Reference 110). Epidemiologic studies have implicated many factors that may be associated with the development of infant ALL; however, the literature remains conflicting on most of these factors. There is a documented increased risk of developing infant ALL in patients with certain genetic syndromes (References 108, 109).

The clinical presentation of infant ALL is similar to that in other children. However, these patients are more likely to present with an elevated WBC count, hepatosplenomegaly, and CNS involvement (References 108, 109). One-half of the patients receiving a diagnosis in the first month of life will present with a condition known as leukemia cutis, which is the presence of leukemic infiltrates in the skin, resulting in a bluish purple cutaneous lesion (Reference 109).

Given the rarity of this disease in infants, it is highly recommended that all patients with infant ALL be enrolled and treated in a clinical trial available through a cooperative group. Treatment of infant ALL has been modeled after therapy for older children with the addition of high-dose cytarabine, although with poorer outcomes because of early treatment failure, namely bone marrow relapse (References 108, 109). Because of the early treatment failure, attempts have been made to intensify therapy using more aggressive chemotherapy dosing and/or an HSCT. A recent report investigating the role of HSCT in infants with *MLL* gene rearrangements did not find a survival advantage associated with HSCT compared with intensified chemotherapy (Reference 111). The use of targeted therapy in infant ALL is currently being investigated (Reference 112). FLT3, a receptor tyrosine kinase, is expressed in leukemias but is of particular interest in infant ALL because this mutation has been correlated with poor outcomes (Reference 113). Lestaurtinib, an oral FLT3 inhibitor, has potential synergy with chemotherapy and is being investigated in clinical trials (Reference 114).

### **Down Syndrome**

Patients with Down syndrome, a genetic disorder characterized by a trisomy of chromosome 21, are at a markedly increased risk of developing acute leukemias in childhood (References 115–118). The reason behind this increased risk has not yet been identified (Reference 116). Although the clinical presentation of patients with Down syndrome is similar to that of patients without Down syndrome, there are some important differences. Patients younger than 1 year with Down syndrome do not develop ALL (Reference 116), making

the age distribution of ALL different in patients with Down syndrome. In addition, patients with Down syndrome and ALL have a lower incidence of high-risk features such as T-cell ALL, CNS involvement, hyperdiploidy, and other cytogenetic abnormalities (Reference 116). Historically, EFS rates in patients with Down syndrome were inferior to the results in patients without Down syndrome (References 116, 117). With the use of risk-adapted therapy, patients with ALL and Down syndrome can now be expected to have outcomes from therapy similar to those of patients without Down syndrome but with ALL (References 118, 119).

Patients with Down syndrome and ALL are also at an increased risk of developing toxicity from therapy, especially mucositis and infections (References 116, 120). Although the therapy for patients with Down syndrome and ALL is similar to that for patients without Down syndrome, the Down syndrome cohort is exquisitely sensitive to the effects of methotrexate (References 116, 117). The exact reason for this excess toxicity is unknown; however, potential reasons include delayed methotrexate clearance (Reference 121) and other alterations in drug handling secondary to involvement of chromosome 21 (References 116, 117). In some instances, this sensitivity to methotrexate may require dose reductions and/or more intensive rescue therapy by adding or optimizing leucovorin therapy. Other supportive care approaches to optimize care in the Down syndrome population include the use of enteral or parenteral nutrition and the use of opioids for pain management during periods of mucositis. Because these patients are at an increased risk of infections and infection-related complications, including death, prophylaxis with antibiotics, supplementation with immune globulins, close monitoring, and early initiation of empiric broad-spectrum antibiotics should be considered (References 115, 116, 118).

### ***Philadelphia Chromosome***

Caused by the translocation between chromosomes 9 and 22, the Philadelphia (Ph) chromosome is present in 3% to 5% of children with a diagnosis of ALL (References 122, 123). This genetic translocation arises when the breakpoint cluster region (BCR) gene on chromosome 22 is fused with the *ABL* gene on chromosome 9 (Reference 21). The presence of t(9;22) has been deemed a high-risk feature because it correlates with poor outcomes from traditional chemotherapy compared with patients with ALL lacking the Philadelphia (References 124–129).

Early studies that treated Ph-positive patients with intensive chemotherapy regimens, similar to the therapy described previously, showed an EFS rate ranging from 0% to 38% (References 124, 126–129). Attempts to identify high-risk features within the subset

of Ph-positive patients have revealed that increased age, elevated WBC count at diagnosis, and poor response to initial therapy are associated with a poorer outcome (References 126–129). The use of imatinib, a tyrosine kinase inhibitor that competes for binding at the *BCR-ABL* site, has improved the dismal outcome of patients with Ph-positive ALL. A recent clinical trial showed the benefit of using imatinib in combination with standard chemotherapy, as evidenced by the 3-year EFS rate of the patients receiving imatinib increasing to 80% (Reference 130). This trial also raised the question of the role of HSCT in this patient population in first complete remission. Outcomes of patients who received imatinib plus chemotherapy were similar to those of patients who received stem cell transplants (Reference 130). Additional research should be completed involving more patients to truly discern the role of transplantation versus continuing traditional chemotherapy plus imatinib.

Although adding imatinib to therapy for Ph-positive patients has dramatically changed outcomes, resistance to imatinib has developed, rendering patients refractory to this therapy (Reference 131). To address this resistance issue, a second generation of tyrosine kinase inhibitors has been developed and is being investigated in pediatric Ph-positive ALL (References 131, 132). Dasatinib appears to be more potent than imatinib and has expanded activity against other tyrosine kinases (References 131, 133). Nilotinib is another second-generation tyrosine kinase inhibitor that may have benefit in pediatric patients with Ph-positive ALL (References 131, 133). It is not yet known which of these tyrosine kinase inhibitors will provide the most benefit to patients while causing the least amount of toxicity, most commonly reported as fluid retention, peripheral edema, myelosuppression, peripheral neuropathies, and potential cardiotoxicity (Reference 38).

### ***Adolescents and Young Adults***

Adolescent and young adult patients with ALL, generally defined as being between 15 and 21 years of age at diagnosis, have been identified as a population with lower survival outcomes (Reference 134). Although the exact reason for the survival differences is unknown, studies have shown that these patients have a higher incidence of T-cell ALL, have a higher presenting WBC count, are more likely to have chromosomal abnormalities associated with a poor outcome, and have a lower remission rate in induction (References 135, 136). Other potential reasons for the differences in outcome include a decreased adherence to medications, the presence of comorbidities, and an increased toxicity from therapy (References 135, 137, 138).

The young adult population, 15–21 years of age, may be managed by either a pediatric or adult oncologist, which means these patients may receive therapy designed either for pediatric ALL or adult ALL. Pediatric regimens rely on the use of long-term continuous therapy, which is heavily based on asparaginase, vincristine, and corticosteroids, whereas adult therapy uses higher doses of myelosuppressive agents such as cyclophosphamide and cytarabine, which are given intermittently for a shorter period (References 137, 139). Several studies conducted in the United States and Europe have shown superior outcomes in the young adult population when they are treated with pediatric ALL regimens rather than adult-based regimens (References 140–143). Young adult patients treated with intensive, response-based therapy had an improved outcome with chemotherapy alone and did not require stem cell transplantation (Reference 138). Thus, it is currently advised that adolescent and young adult patients be treated at a pediatric center on a pediatric clinical trial or receive pediatric-based therapy.

The adolescent and young adult population also has increased toxicity from therapy compared with younger children (References 51, 138, 144, 145). Death during induction (References 138, 144), avascular necrosis (References 51, 138), and hyperglycemia (Reference 138) occur at higher frequencies in this patient subset, potentially because of the decreased clearance rate of steroids (Reference 146). These toxicities often necessitate that therapy be modified or delayed.

## Relapse

Even with major improvements in outcome over time for childhood ALL, disease relapse remains a serious problem, with survival rates in the relapsed setting reaching only 50% (Reference 147). Around 20% of patients will have a relapse of their disease at some point, with the main sites of relapse being the bone marrow, CNS, and testes (References 147, 148). It is important to consider the sites involved in the relapse and the time at which the relapse occurs because the prognosis and therapeutic approach will change on the basis of these factors (References 147, 148). An early relapse, defined as a relapse that occurs less than 36 months from initial diagnosis, has been associated with poor outcomes and often requires intensive chemotherapy to induce a second remission to proceed to stem cell transplantation (References 148–153). Late relapses, defined as those that occur 36 months or more from the initial diagnosis, will most often respond well to conventional multiagent chemotherapy, making the use of a stem cell transplantation potentially unnecessary (References 148, 152, 154). Emerging treatment regimens for relapsed ALL include the use of newer, novel agents such as

bortezomib (Reference 155), epratuzumab (Reference 156), and clofarabine (References 157, 158) in combination with a standard intensive chemotherapy regimen (Reference 159).

Isolated extramedullary relapses are those that occur outside the bone marrow. An isolated extramedullary relapse is generally associated with better outcomes than an isolated marrow relapse or a relapse involving the marrow combined with other sites (References 148, 152). Around 5% to 10% of patients with a diagnosis of childhood ALL will have an isolated CNS relapse. Patients at an increased risk of CNS relapse include those with T-cell ALL, CNS involvement at diagnosis, and certain cytogenetic abnormalities, as well as those considered high risk by age and WBC count at diagnosis (Reference 152). Historically, patients with an isolated CNS relapse have been managed with intensive intrathecal and systemic chemotherapy in conjunction with CNS radiation (References 160–162). New literature supports delaying the implementation of cranial irradiation so that adequate systemic and intrathecal therapy can be delivered up front (References 160–162). Systemic, intensive, multiagent chemotherapy regimens with agents that cross the blood-brain barrier are also necessary to prevent bone marrow relapses, which were the main cause of treatment failure in the past when only CNS-based therapy was provided (References 161, 162). With this approach, about 70% of patients will be expected to achieve and maintain a complete response (References 160–162). Isolated testicular relapses occur in about 2% of patients with childhood ALL, and these relapses tend to occur late (Reference 152). Testicular relapses are managed with testicular radiation and systemic chemotherapy (Reference 152).

## Supportive Care

The pediatric patient with ALL will be treated with, on average, 3 years of therapy. During this time, it is extremely important that each patient receive appropriate supportive care so that outcomes can be maximized. It is important for the pharmacist to screen for drug interactions (Reference 163), counsel the patient and his or her family on the prescribed medication regimen, and provide supportive care recommendations to the medical team.

At initial diagnosis, patients with a high tumor burden are at risk of developing TLS. In ALL, a high tumor burden is usually characterized by an increased WBC count. Tumor lysis syndrome occurs because of the lysis of WBCs, which causes the intracellular components of the cell to be released into the vasculature. This can occur spontaneously because of rapid cell turnover or upon starting therapy with chemotherapy, radiation, or even targeted therapy. Electrolyte abnormalities that can occur during TLS include hyperuricemia,

hyperkalemia, hyperphosphatemia, and hypocalcemia. The consequences of inadequate prophylaxis and treatment of TLS include acute renal failure, arrhythmias, and death. It is important to review the published guidelines and review articles for a more thorough discussion on determining a patient's risk of TLS and the literature supporting the current prevention and treatment strategies (References 164–166).

Patients with ALL may experience hematologic toxicity from therapy, resulting in the need for platelet and red blood cell transfusion. Blood counts should be followed to ensure the patient receives the appropriate blood product support. Because neutropenia occurs during therapy for ALL, the prophylactic use of granulocyte colony-stimulating factor (GCSF) has been investigated in several clinical trials for pediatric ALL. Prolonged neutropenia can put the patient at risk of infections and compromise the ability to deliver dose-intensive therapy; therefore, GCSF would be implemented in therapy to decrease these risks. Granulocyte colony-stimulating factor shortens the duration of neutropenia from chemotherapy, but this shortened duration has generally not been associated with clinically meaningful results (References 167, 168). Most clinical trials have shown that adding prophylactic GCSF does not decrease the incidence of neutropenic fever episodes, the incidence of documented culture-proven infections, or the cost associated with therapy (References 167–171). Therefore, the routine prophylactic use of GCSF is not indicated. The use of GCSF may be considered in patients with a documented, severe infection in which the timely recovery of neutrophils is critical for outcomes.

Patients with ALL are at risk of infections because of the effects of the therapy they receive. A fever that develops during periods of neutropenia should be managed as a medical emergency. It is critical that appropriate, broad-spectrum antibiotic therapy be initiated rapidly. Patients and their caregivers need to be appropriately educated about monitoring for fevers and getting the patient to the hospital as soon as possible. Clinicians should review the Infectious Diseases Society of America guidelines for neutropenic fever in the patient with cancer for additional information (Reference 172). *Pneumocystis jirovecii*, or PJP (formerly *Pneumocystis carinii* or PCP), is one of the specific infections these patients are at increased risk of developing during therapy. Patients should receive prophylaxis against PJP beginning by the end of induction and continuing for 6 months after the completion of therapy. Successful prophylaxis has been shown with sulfamethoxazole/trimethoprim (gold standard) (Reference 173), atovaquone (Reference 174), dapsone (Reference 175), and pentamidine (References 176, 177).

Malnutrition has been identified by some studies as a risk factor for poor outcomes. However, most of these clinical trials have been reported in developing countries (References 178, 179), whereas the same results have not been replicated in developed countries (Reference 180). Nutritional status plays an important role in the ability of the body to fight infections and tolerate intensive chemotherapy (Reference 181). Nutritional status should be monitored at baseline and throughout therapy, with the implementation of nutritional supplements, appetite stimulants, and/or enteral or parenteral nutrition as appropriate when a problem has been identified. To this extent, it is essential to have a dietitian as a member of the multidisciplinary health care team. On the other side of the spectrum is the emerging problem of treating overweight or obese patients (Reference 182). The obesity pandemic has brought with it a new set of challenges as it pertains to appropriate dosing of chemotherapy. It is currently unknown whether chemotherapy in the pediatric population should be dosed on body surface area calculated from actual body weight, ideal body weight, adjusted ideal body weight, or some other metric. Pharmacokinetic and pharmacodynamic studies are lacking in this area, especially for the pediatric population. To elucidate this dosing dilemma, it is important that studies be conducted and then correlated with clinical outcomes.

## MONITORING OF THERAPY

At various times during therapy and in long-term follow-up, patients will be monitored for disease response by obtaining a bone marrow aspirate and/or biopsy and CSF from a lumbar puncture. These specimens will be analyzed using sophisticated laboratory tests to detect the presence or absence of disease. The prognostic significance of an early response to therapy, the absence of MRD, and the duration of first complete remission has been discussed earlier. At any time during or after the completion of therapy, a patient may undergo a workup to look for disease if there is a clinical suspicion that the patient has relapsed. Detecting relapses early is important to maximize the success of salvage therapy.

Late effects from childhood cancer therapy are defined as toxicities that become apparent over time after the completion of therapy, as a result of the body's inability to compensate for the increased demands that occur as a person ages (Reference 183). The development of late effects is a serious problem in childhood ALL because more than 80% of patients can be expected to become long-term survivors (Reference 184). However, because the use of cranial irradiation has been minimized as a standard therapy in ALL, the incidence of many of these late effects has significantly decreased (Reference 39). Cranial irradiation has been associated

with the development of neurocognitive deficits/learning disabilities, hypothyroidism, precocious puberty, hypogonadism, growth deficiency, obesity, secondary malignancies, and cataracts (Reference 39). Patients who receive anthracyclines as part of their therapy are at an increased risk of developing cardiac dysfunction in the form of increased left ventricular afterload and decreased contractility (References 185, 186). Most patients who receive anthracyclines for the management of ALL do not exceed lifetime cumulative doses of greater than 300 mg/m<sup>2</sup>, above which has been associated with a markedly increased incidence of cardiotoxicity (Reference 184). The development of secondary malignancies in childhood ALL survivors, namely acute myeloid leukemia, myelodysplastic syndrome, or solid tumors, occurs at a low incidence of 1.4% to 4.2% (References 184, 187). Patients at highest risk of developing a secondary malignancy include females, patients with relapsed disease, and patients treated with radiation, anthracyclines, cyclophosphamide, and etoposide (References 184, 187–189). Infertility is not a major problem in survivors of childhood ALL (Reference 184). Patients at high risk of developing infertility include those who received testicular irradiation or who received total body irradiation or high-dose alkylating agents in the HSCT setting (References 184, 190). A good review of the risks and recommended monitoring for the late effects associated with various treatment modalities from the Children's Oncology Group Survivorship Guidelines is available at [www.survivorship-guidelines.org](http://www.survivorship-guidelines.org) (Reference 190). Survivors of childhood ALL require lifelong monitoring and medical care to screen for, prevent, identify early, and treat these late complications.

## FUTURE CONSIDERATIONS

The future of ALL therapy will involve the development of new targeted agents to maximize outcomes and minimize toxicity, particularly in certain patient subsets with suboptimal outcomes (References 112, 131). Several of these agents that are currently under investigation are bortezomib, mTOR (mammalian target of rapamycin) inhibitors, JAK (Janus kinase) inhibitors, FLT3 (FMS-like tyrosine kinase 3) inhibitors in infant ALL, NOTCH1 inhibitors in T-cell ALL, and newer tyrosine kinase inhibitors in Ph-positive ALL (References 112, 131). In addition, the use of pharmacogenomics to tailor therapy will likely become more common as research in this field advances. Pharmacogenomics or pharmacogenetics refers to the knowledge and use of genetic polymorphisms in drug-metabolizing enzymes to better understand and characterize the differences between individual responses to specific drugs and therapy (References 8, 192). The

most well-established example of pharmacogenomics in childhood ALL is the knowledge of thiopurine methyltransferase (TPMT) polymorphisms to predict response to mercaptopurine therapy (References 192–195). Mercaptopurine undergoes a complex metabolic pathway to be converted from a prodrug to its active moieties, thioguanine nucleotides, and inactive nontoxic compounds (Reference 194). The metabolism of mercaptopurine occurs through activity of the enzyme TPMT. It has been identified that 90% of the population had high TPMT activity (homozygous wild type), 10% had intermediate TPMT activity (heterozygous), and 0.3% had low or no measurable enzyme activity (homozygous TPMT-deficient) (Reference 194). An increased TPMT activity level was correlated with lower levels of thioguanine nucleotide accumulation (Reference 194). Conversely, lower TPMT activity was associated with very high concentrations of thioguanine nucleotides, which led to increased bone marrow suppression and better outcomes (References 196, 197). Therefore, the *TPMT* genotype can be used to identify patients at increased risk of toxicity from mercaptopurine therapy. Rather than using the surrogate markers of absolute neutrophil count and platelet count to determine the mercaptopurine dose adjustments mentioned previously, the prospective approach of using the *TPMT* genotype to initially dose mercaptopurine is currently employed at St. Jude Children's Research Hospital (Reference 198). Current practice in most institutions is to analyze for *TPMT* polymorphisms either initially at diagnosis or when a patient does not have the expected absolute neutrophil count and platelet count response to the standard, empiric dosing of mercaptopurine. New guidelines, including dosing recommendations based on genotype, were recently published (Reference 199).

## CONCLUSIONS

The role of the pharmacist on a multidisciplinary pediatric oncology team is variable, depending on the institution, but common responsibilities include verifying the accuracy of drug dosing while considering organ function and developmental concerns; confirming the point in therapy; ensuring that appropriate supportive care measures are addressed and maximized; providing education to the medical team; providing patient and caregiver counseling about drug therapy; and monitoring for expected responses and unexpected toxicities. Pharmacists are capable of contributing to the medical team, given the unique education and training they have received. In addition, pharmacists can play a vital role in contributing to clinical trial design as it pertains to drug therapy and in aiding in the conduct of these clinical trials at an institution. Pharmacists who practice in the pediatric oncology setting should become familiar

with the trials being conducted and the chemotherapeutic agents being used so that they can aid in the safe and effective delivery of therapy to these patients.

The outcomes for childhood ALL have improved drastically through the years because of a better understanding of the biology of the disease, the significance of prognostic factors, and the development of risk-adapted therapy to maximize outcomes while minimizing toxicity. Although the overall survival rates for childhood ALL are close to 90%, certain subgroups of patients still have a less favorable prognosis and outcome. Clinical trials should continue to be conducted, especially for these subgroups, to advance the knowledge and to design increasingly effective therapeutic regimens that will allow more patients to be long-term survivors. As the long-term survivor population continues to grow, it is important that these patients receive adequate long-term follow-up by experienced medical teams. These survivors need to be equipped with a thorough and complete medical history and therapeutic summary so that they can be appropriately monitored and screened for the late effects that may arise over time after the completion of therapy. With all the advances in therapy made through the years and the potential role for targeted therapy, pharmacogenomics, and response-based therapy stratification, the outlook for childhood ALL remains promising.

# CHAPTER 52

## ACUTE MYELOGENOUS LEUKEMIA

M. Brooke Bernhardt, Pharm.D., BCOP

### LEARNING OBJECTIVES

1. Understand the epidemiology and etiology of childhood acute myelogenous leukemia (AML).
2. Describe the standard approach to treating children with AML.
3. Discuss the potential role of targeted therapy in the treatment of pediatric AML.
4. Identify critical supportive care issues when treating children with AML.

### ABBREVIATIONS IN THIS CHAPTER

ALL	Acute lymphoblastic leukemia
AML	Acute myelogenous leukemia
APL	Acute promyelocytic leukemia
CINV	Chemotherapy-induced nausea and vomiting
CNS	Central nervous system
FLT3/ITD	FMS-like tyrosine kinase 3 internal tandem duplications
GATA1	GATA-binding protein 1 (or <i>GATA1</i> gene; globin transcription factor 1)
MLL	Mixed lineage leukemia
TMD	Transient myeloproliferative disorder

### INTRODUCTION

*Acute myelogenous leukemia* (AML) is a term used to describe a diverse group of disorders that arise from the proliferation of abnormal myeloid, erythroid, monocytic, and megakaryocytic cell precursors (Reference 1). Although the disease-free survival of patients with AML has improved during the past 3 decades, about one-half of patients with a diagnosis of AML will succumb to this disease (References 2–15). The focus of this chapter is to review the epidemiology, etiology, prognosis, diagnosis, and treatment of childhood AML.

### EPIDEMIOLOGY

About 12,060 children in the United States younger than 15 years receive a diagnosis of cancer each year (Reference 16). About one-third of these children are given a diagnosis of some form of leukemia, making leukemia the most common type of cancer in children (Reference

16). Of those children given a diagnosis of leukemia each year, around 18% are also given a diagnosis of AML. This reflects an incidence of about 7 in 1 million individuals younger than 19 years (Reference 17).

No known differences in incidence have been found between male and female patients. The incidence of AML appears to be highest in children of Hispanic ethnicity compared with African American or white children. Children of Hispanic descent also appear to have the highest incidence of the subtype known as acute promyelocytic leukemia (APL) (References 18–21).

### ETIOLOGY

Several inherited conditions and environmental exposures have been associated with the development of de novo and secondary AML. In many cases of childhood AML, a potential cause is unknown; however, at least one known genomic alteration can be found in more than 90% of cases (Reference 22). Inherited conditions associated with the development of de novo childhood AML are identified in Box 1 (References 19, 23–37).

Down syndrome is the most common inherited condition associated with AML in children younger than 19 years in the United States. These children have a 10- to 20-fold increased risk of developing some type of leukemia compared with children without Down syndrome

#### Box 1. Inherited conditions associated with childhood AML (References 19, 23–37).

- Bloom syndrome

- Noonan syndrome
- Shwachman-Diamond syndrome

AML = acute myelogenous leukemia; FPD/AML = familial platelet disorder with a predisposition to AML.

(Reference 28). About 10% of newborn children with Down syndrome or mosaicism may develop transient myeloproliferative disorder (TMD). This incidence may be underestimated because the screening of blood counts at birth is not routine. In most patients, abnormal blasts will spontaneously disappear, and the remaining components of the blood count will normalize (Reference 38). However, almost 20% of children with TMD will develop leukemia by a median of 20 months of age; of those, most will develop the M7 subtype of AML, or acute megakaryocytic leukemia (Reference 28). One study documented that 16% of patients with TMD developed AML or myelodysplastic syndrome at a median time of 441 days (range, 118–1085 days) (Reference 38). As a result, children with Down syndrome have a 500-fold higher risk of developing acute megakaryocytic leukemia than do children without Down syndrome within the first few years of life (Reference 28). Although not fully understood, it is thought that mutation in the GATA-binding protein 1 (globin transcription factor 1, or *GATA1* gene) on the X chromosome may be an initiating factor in the development of leukemia in patients with Down syndrome. This gene is responsible in part for normal erythroid and megakaryocytic differentiation. Alterations in this gene may lead to the greater trend toward development of this leukemia in boys with Down syndrome than in girls with the same disease. Mutations in this gene have been identified exclusively in Down syndrome–associated TMD and acute megakaryocytic leukemia (References 26–28).

Environmental exposures generally associated with the development of AML include benzene, organic solvents, herbicides, pesticides, petroleum products, maternal use of marijuana during pregnancy, and previous use or exposure to chemotherapy or ionizing radiation; however, except for ionizing radiation, a definitive association of these factors with childhood AML is difficult to establish (References 19, 39–41). Maternal consumption of fresh fruits and vegetables that contribute to DNA topoisomerase II inhibition (e.g., apples, berries, canned or dried legumes, onions, soy products) may increase the risk of infant AML with rearrangements of the mixed lineage leukemia (*MLL*) gene (Reference 42). Chemotherapeutic agents most notably associated with the development of secondary AML include etoposide, topoisomerase II inhibitors (e.g., doxorubicin), and alkylating agents (e.g., mechlorethamine, cyclophosphamide) (References 43–47). Finally, AML may also develop after an acquired predisposing condition, such as aplastic anemia or myelodysplastic syndrome (References 48–50).

## BIOLOGY AND PATHOPHYSIOLOGY

Genetic mutations or chromosomal rearrangements may result in abnormal hematopoietic precursors. Clonal transformation, replication, and proliferation of abnormal myeloid, erythroid, monocytic, or megakaryocytic

precursors can result in the development of AML. Differentiation and apoptosis of these precursors is impaired, resulting in dysregulation of normal hematopoiesis. Acute myeloid leukemia develops when at least one class I and one class II mutation in a host's hematopoietic precursor cells occur. Class I mutations do not affect cellular differentiation, but they do confer a proliferative or survival advantage to hematopoietic precursor cells. Examples of clinically relevant class I alterations include FMS-like tyrosine kinase 3 internal tandem duplications (*FLT3/ITD*) and oncogenic *ras* mutations. Class II mutations impair the normal precursor cell differentiation and apoptosis; treatment-related examples include the *PML/RARA* fusion gene (i.e., translocation of chromosomes 15 and 17, or *t(15;17)*) and *MLL* gene rearrangements (e.g., *t(4;22)*, *t(11;19)*, *t(9;11)*) (References 1, 22). The prognostic significance of these alterations will be discussed later in this chapter.

## CLASSIFICATION OF AML

The FAB (French-American-British) classification system has been used historically to describe seven subtypes of AML (M1–M7) on the basis of morphologic, histochemical, immunophenotypic, and cytogenetic features of the abnormal clone (Reference 51). The M0 subtype has been used to describe undifferentiated AML. The goal of this classification system was to create uniformity in diagnosing and categorizing AML in patients. The specific criteria for each subtype will not be discussed. Subtypes of clinical importance (M0, M4, and M7) with respect to differences in therapy will be discussed throughout this chapter.

The concept of classification based on cytogenetic subtypes is still relatively new. In 2008, the World Health Organization (WHO), the European Association for Haematopathology, and the Society for Hematopathology released a revised fourth edition of their classification system of hematopoietic and lymphoid tissues. The classification of AML and related neoplasms is included in this system, the subcategories of which are described in Box 2 (Reference 52). In general, AML is defined as the presence of at least 20% myeloblasts in the peripheral blood or among all nucleated bone marrow cells. This can occur *de novo* or through evolution from a previously diagnosed myelodysplastic syndrome or neoplasm. However, the presence of certain translocations (e.g., *t(8;21)(q22;q22)*, *t(16;16)(p13.1;q22)*, or *t(15;17)(q22;q12)*) or the inversion of chromosome 16 (*inv(16)(p13.1;q22)*) is definitive for a diagnosis of AML, regardless of the blast count or percent (Reference 52). As additional information becomes available, it is possible that cytogenetics will play an even greater role in the treatment of various AML subtypes with chemotherapy and/or hematopoietic stem cell transplantation.

**Box 2.** WHO classification of AML and related neoplasms (Reference 52).

**AML with recurrent genetic abnormalities, including the following:**

- t(8;21)(q22;q22); *RUNX1-RUNX1T1*
- inv(16)(p13.1;q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
- t(9;11)(p22;q23); *MLLT3-MLL*
- t(6;9)(p23;q34); *DEK-NUP214*
- inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*
- Megakaryoblastic with t(1;22)(p13;q13); *RBM15-MKL1*
- APL with t(15;17)(q22;q12); *PML-RARA*
- Provisional entities:
  - AML with mutated *CEBPA*
  - AML with mutated *NPM1*

**AML with myelodysplasia-related changes**

**Therapy-related myeloid neoplasms**

**AML not otherwise specified**

- AML with minimal differentiation
- AML without maturation
- AML with maturation
- Acute myelomonocytic leukemia
- Acute monoblastic/monocytic leukemia
- Acute erythroid leukemia
  - Pure erythroid leukemia
  - Erythroleukemia, erythroid/myeloid
- Acute megakaryoblastic leukemia
- Acute basophilic leukemia
- Acute panmyelosis with myelofibrosis

**Myeloid sarcoma**

**Myeloid proliferations related to Down syndrome**

- Transient abnormal myelopoiesis
- Myeloid leukemia associated with Down syndrome

**Blastic plasmacytoid dendritic cell neoplasm**

AML = acute myelogenous leukemia; APL = acute promyelocytic leukemia; inv = inversion; MLL = mixed lineage leukemia; t = translocation; WHO = World Health Organization.

(Reference 52)

## PROGNOSIS

For the past several decades, intensified chemotherapy has led to complete remission rates of 68% to 93% (References 3–15). However, relapse is relatively common, occurring in 30% to 40% of patients. The 5-year event-free and overall survival rates vary on the basis of the treatment protocol used, with these rates ranging from 31% to 54% and from 36% to 66%, respectively, as represented in Table 1 for patients without Down syndrome across several international cooperative groups (References 3–15).

The prognosis for patients with AML is affected by a variety of clinical features as well as genetic factors. In children and adolescents, age older than 10 years at diagnosis has been associated with a poorer outcome, even when controlling for potential confounding features (Reference 53). Ethnicity may also play a role in predicting prognosis. African American children have worse outcomes than white children undergoing treatment for AML. This disparity is thought to be a product of potential pharmacogenetic differences among ethnic groups, not access to care, because of the nature and delivery of cooperative group care to children with cancer (References 54, 55). Body mass index may also play a role in predicting prognosis; children who are underweight or overweight have a significantly lower chance of survival than patients who are of normal weight. This difference in survival is largely because of the increased risk of treatment-related mortality in underweight and overweight patients (Reference 56).

A retrospective evaluation of children with AML by the Children's Oncology Group revealed an 11% incidence of central nervous system (CNS) disease at presentation; children with Down syndrome–associated AML, APL, myelodysplastic syndrome, secondary AML, and isolated extramedullary AML were excluded from the analysis. Factors associated with CNS disease at presentation included younger age, hepatosplenomegaly, elevated white blood cell count (WBC), M4 morphology, abnormalities in chromosome 16, and hyperdiploidy (Reference 57). This study also found that children with CNS disease at diagnosis were at an increased risk of relapse, shortened disease-free survival, isolated CNS relapse, and concurrent bone marrow plus CNS relapse. Despite these risks, these children had similar remission rates, event-free survival, isolated bone marrow relapse, and overall survival compared with those having no CNS disease at diagnosis (Reference 57).

Pathologic disease-related features may also play a role in predicting survival. Children with AML of the M0 or M7 subtype (without Down syndrome) may have worse outcomes than those with other subtypes of AML (References 58, 59). Children with Down syndrome typically have a greater event-free survival rate

Reproduced with permission of W.B. Saunders Co., from Rubnitz JE, Gibson B, Smith FO. Acute myeloid leukemia [a review of References 3–15]. *Hematol Oncol Clin North Am* 2010;24:35–63; permission conveyed through Copyright Clearance Center, Inc. (Reference 1)

and a lower relapse rate than children without Down syndrome, especially with respect to the M7 subtype of AML. This enhanced response seen in children with Down syndrome AML may be a result of the greater sensitivity to chemotherapy, specifically cytarabine (References 60, 61).

Children with APL who receive treatment with standard chemotherapy and tretinoin (all-*trans*-retinoic acid, ATRA) may have complete remission rates greater than 95%, 5-year event-free survival greater than 70%, and overall survival of about 90% (References 62–64). Within this subgroup, an elevated WBC at diagnosis (specifically, WBC greater than  $10 \times 10^9/L$ ) is considered a major, adverse prognostic factor with a reduced event-free survival of about 60% (References 22, 63). A small percentage of patients die during induction; about half of the deaths occur because of coagulopathy and hemorrhagic complications. Other factors associated with a poor prognosis in childhood APL include the presence of FLT3/ITD, a *bcrl3 PML* breakpoint, or the microgranular variant (M3v) of the disease (References 22, 62).

Several additional cytogenetic abnormalities have been evaluated for prognostic and treatment-related purposes. In some patients, one or more of these cytogenetic abnormalities or a variety of other abnormalities may be present, making prognostic prediction and treatment decisions difficult. Some of the more notable karyotypes of blast cells that typically confer a more positive outcome include t(8;21) and inv(16). These two alterations are typically referred to as the CBF (core-binding factor) leukemias. Although they are generally grouped together in risk schema, they may differ with respect to actual outcome. Specifically speaking, patients with t(8;21) may have a lower overall survival compared with those with inv(16) because of a lower salvage rate after relapse. In patients with t(8;21), race may also play an important prognostic role (References 1, 65–67). Up to 20% of patients have *MLL* gene rearrangements at chromosome band 11q23; these patients are typically classified as having intermediate-risk disease (References 62, 68–70). Other karyotypes have been associated with a less favorable outcome, such as monosomy 5, del(5q), monosomy 7, and 3q abnormalities (Reference 62).

Other mutations that may confer prognostic significance include *c-kit*, *ras*, and FLT3/ITDs. The prognostic significance of *c-kit* and *ras* mutations in childhood AML is still unclear, and they may be of no prognostic significance (References 71–73). In adults, these have been associated with increased relapse rates and lower survival (References 74–76). FMS-like tyrosine kinase 3 internal tandem duplications in children are associated with unfavorable outcomes and are a strong predictor of relapse. Event-free survival rates for children with FLT3/ITDs may be as low as 7% to 29% (References 77, 78).

Finally, the response to initial therapy is of great prognostic significance. Children with detectable disease after the first course of induction therapy are 4.8 times more likely to relapse and 3.1 times more likely to succumb to their disease than those who achieve remission at the end of induction (Reference 79).

It is unclear how combinations of the various prognostic factors affect outcome. Much of the information available in this field is new and constantly changing. The reader is encouraged to seek additional resources for further information.

## CLINICAL PRESENTATION AND DIAGNOSIS

### Signs and Symptoms

Leukemic infiltration of the bone marrow and extramedullary sites is responsible for most of the commonly seen signs and symptoms of AML. Children may present with anemia, neutropenia, and thrombocytopenia as the normal hematopoietic cells within the bone marrow are replaced by the abnormal clone. As a result, pancytopenia, fever, fatigue, pallor, bleeding, bone pain, and infectious complications may occur. In some cases, patients may present with hyperleukocytosis at diagnosis instead of neutropenia or leukopenia. Lymphadenopathy, hepatosplenomegaly, chloromas, leukemia cutis, gum swelling and/or bleeding, and orbital swelling can result from extramedullary involvement of the leukemic clone (Reference 1).

Patients with Down syndrome may initially present with TMD weeks to months before AML develops. Transient myeloproliferative disorder, which has also been referred to as transient abnormal myelopoiesis or transient leukemia, may present on a spectrum from an incidental finding of blasts in the blood in a well-appearing child to a variety of severe complications including effusions, hydrops fetalis, and multiorgan system failure (Reference 28).

Patients with APL may present with signs and symptoms similar to those of children with AML. In addition, they often present with a specific coagulopathy that is a combination of fibrinolysis and disseminated intravascular coagulation (Reference 80). Emergency management of the presenting coagulopathy and underlying disease state is critical.

### Diagnostic Criteria

A diagnosis of AML is based on a combination of tests that are typically performed on a sample obtained during a bone marrow aspirate and biopsy. Diagnostic tests include morphologic evaluation, cytogenetic and cytochemical analysis, fluorescence in situ hybridization,

immunophenotyping by flow cytometry, and molecular testing (Reference 1). Lumbar puncture should be performed to determine the presence and extent of any abnormal myeloblasts in the CNS.

## TREATMENT

### Chemotherapy Overview

Improvement in the survival of children with AML is partly because of refinement in the use of conventional chemotherapeutic agents. Each of the international cooperative groups previously mentioned in Table 1 stratified therapy on the basis of various risk classifications and features. Therapy for each group involved intensive induction chemotherapy, followed by aggressive post-remission chemotherapy. Similar agents were used throughout each phase of therapy, including cytarabine, etoposide, and an anthracycline (i.e., daunorubicin, idarubicin, or mitoxantrone). Doses of each of the agents varied widely across groups. Among the 14 cooperative groups, cumulative doses of cytarabine ranged from 3.8 to 55.7 grams/m<sup>2</sup>, with about one-third of the groups giving cumulative cytarabine doses exceeding 30 grams/m<sup>2</sup>. Cumulative doses of etoposide varied as well, from 400 to 2250 mg/m<sup>2</sup>. Cumulative doses of anthracyclines varied from 180 to 610 mg/m<sup>2</sup> (expressed in daunorubicin dosing equivalents); almost all groups used doses exceeding 300 mg/m<sup>2</sup>, with some using cumulative doses as high as 610 mg/m<sup>2</sup>. In some patients, myeloablative hematopoietic stem cell transplantation was employed as a component of post-remission therapy (References 1–15).

The optimal anthracycline and its corresponding dose recommended for use in pediatric AML have yet to be determined. The use of idarubicin is at times recommended as the anthracycline of choice because it has shown faster cellular uptake, increased retention, and reduced susceptibility to resistance in preclinical and in vitro studies (References 81, 82). In a clinical trial using cytarabine and etoposide, the addition of idarubicin showed statistically greater blast clearance at induction day 15 compared with daunorubicin, yet it did not result in a greater event-free or overall survival at 5 years. In this study, patients who received idarubicin also had more bone marrow toxicity and exhibited a longer time to bone marrow recovery than patients who received daunorubicin (Reference 83). A later trial indicated that daunorubicin and idarubicin were similarly effective when a daunorubicin dose of 50 mg/m<sup>2</sup> was compared with an idarubicin dose of 10 or 12 mg/m<sup>2</sup>. This trial also showed that at these comparable doses, the use of idarubicin resulted in more renal, gastrointestinal, and pulmonary toxicities (Reference 84). Daunorubicin and mitoxantrone have shown similar efficacy, yet slightly different toxicity profiles, with mitoxantrone being more myelosuppressive (Reference 15). Pediatric patients may be at a greater risk

of developing cardiotoxicity from anthracyclines; therefore, some investigators have sought to determine whether the cumulative dose of anthracycline used can be reduced (Reference 1). To date, this dose has yet to be defined.

Chemotherapy for the treatment of AML is typically divided into two phases: induction and post-remission, or consolidation, therapy. Maintenance therapy, although typically used in acute lymphoblastic leukemia (ALL), is not used routinely but will be discussed briefly. A general schematic of the treatment of AML is provided in Table 2. Selected common and distinguishing toxicities of chemotherapy used in the treatment of AML are provided in Table 3.

### Induction Therapy

The goal of the induction phase of therapy is to eliminate the disease to the point of remission. Although the cumulative dose of cytarabine given for the duration of therapy appears to be important, the specific dose and

frequency of cytarabine during induction do not appear to significantly affect outcomes. Various doses of cytarabine have resulted in similar complete response rates (References 1–15, 87). On the contrary, the dose of the anthracycline used during induction may be of critical importance (References 1–15, 83). In previously untreated adults with AML, a higher dose of daunorubicin (90 mg/m<sup>2</sup>) given as three daily doses during the induction phase of therapy provided a statistically higher complete remission rate and overall survival compared with a lower dose of 45 mg/m<sup>2</sup> (Reference 88). The optimal dose of anthracycline for children with AML is unclear; it is possible that doses of 375–550 mg/m<sup>2</sup> are necessary because protocols using anthracycline doses (in daunorubicin equivalents) of less than 375 mg/m<sup>2</sup> report lower event-free survival (Reference 1). These higher doses are assumed to increase the risk of developing cardiotoxicity, but this has not been characterized (Reference 1).

**Table 2.** Overview of the Treatment of AML

Patient Subgroup	Phase of Therapy	Agents Employed <sup>a</sup>
Non-Down syndrome	Induction (two cycles)	Standard- or high-dose cytarabine + etoposide + anthracycline
	Post-remission/Consolidation (two or three cycles <sup>b</sup> )	High-dose cytarabine + one of the following (per cycle): <ul style="list-style-type: none"> <li>• Etoposide</li> <li>• Mitoxantrone OR idarubicin</li> <li>• L-Asparaginase</li> </ul>
Down syndrome	Induction (two to four cycles)	Standard-dose cytarabine + daunorubicin (or mitoxantrone) + thioguanine High-dose cytarabine + L-asparaginase <sup>c</sup>
	Consolidation/Intensification (two or three cycles <sup>a</sup> )	Standard-dose cytarabine + one of the following (per cycle): <ul style="list-style-type: none"> <li>• Etoposide</li> <li>• Mitoxantrone</li> <li>• L-Asparaginase</li> </ul>
Acute promyelocytic leukemia	Induction	ATRA + idarubicin
	Consolidation	ATRA + one of the following (per cycle): <ul style="list-style-type: none"> <li>• High-dose cytarabine + mitoxantrone</li> <li>• Mitoxantrone + etoposide</li> <li>• High-dose cytarabine + idarubicin ± thioguanine</li> <li>• Arsenic trioxide (investigational)</li> </ul>
	Maintenance	ATRA + mercaptopurine + methotrexate

<sup>a</sup>Agents employed will vary on the basis of institutional practice and clinical protocol or trial. These agents are representative of some of the types of combinations used in the respective disease state.

<sup>b</sup>Patients at a high risk of relapse with a matched donor may proceed to hematopoietic stem cell transplantation on the basis of institutional practice or protocol-directed therapy.

<sup>c</sup>May be used in some centers for one cycle.

AML = acute myelogenous leukemia; ATRA = all-*trans*-retinoic acid.

References 1-15, 60, 62-64, 85, 91.

### Post-remission/Consolidation Therapy

Post-remission, or consolidation, therapy is given with the intent of eliminating any residual disease. For many patients, chemotherapy given in the post-remission phase will include two or three additional courses of high-dose cytarabine with other active agents, such as etoposide, mitoxantrone, idarubicin, or L-asparaginase. In this setting, the use of high-dose cytarabine appears to be of greater benefit than standard or low-dose cytarabine in some patients with AML. Specifically, adult patients with t(8;21) who were given three or more courses of chemotherapy with high-dose cytarabine in the post-remission period had improved failure-free and overall survival compared with those who received only one course of post-remission chemotherapy that included high-dose cytarabine (Reference 89). Similarly, adult patients with

inv(16) and t(16;16) had a significantly lower cumulative incidence of relapse and a trend toward a reduction in relapse-free survival with three or four courses of high-dose cytarabine-containing chemotherapy compared with one course in the postinduction period (Reference 90). A clinical trial involving both children and adults with previously untreated AML found no difference in relapse rate, relapse-free survival, death in complete remission, or overall survival when patients were administered four versus five courses of chemotherapy (i.e., two vs. three courses of chemotherapy in the post-remission or consolidation phase) (Reference 91).

Considerable controversy still exists regarding the appropriate type and use of stem cell transplantation in children with AML in first remission. Complicating matters, international cooperative groups use various risk criteria

**Table 3.** Common and Unique Toxicities of Chemotherapy for AML<sup>a</sup>

Agent	Toxicities
Arsenic trioxide	Tachycardia, prolongation of the QT interval, edema, hypotension, insomnia, anxiety, dizziness, depression, dermatitis, bruising, hypokalemia, hyperglycemia, hypomagnesemia, nausea, vomiting, sore throat, constipation, anorexia, leukocytosis, APL syndrome, anemia, transaminitis, pain, rigors, paresthesias, cough, dyspnea, hypoxia, pleural effusion, epistaxis, sinusitis, diarrhea, fatigue, fever, headache, pruritus
L-Asparaginase	Anaphylaxis, fever, chills, nausea, vomiting, abdominal cramping, seizures, coma, azotemia, coagulopathy, hypofibrinogenemia, decreased clotting factors, decreased antithrombin III, hepatotoxicity, pancreatitis, hyperglycemia
ATRA	Arrhythmias, chest discomfort, dyspnea, respiratory insufficiency, pleural effusion, edema, weight gain, shivering, dizziness, pain, pruritus, nausea, vomiting, diarrhea, earache/ear fullness, fever, malaise, flushing, rash, headache, hypercholesterolemia, hypertriglyceridemia, leukocytosis, mucositis, hemorrhage, disseminated intravascular coagulation, retinoic acid syndrome, skin/mucous membrane dryness, increased liver function tests, infection
Cytarabine	Conjunctivitis (w/high-dose use steroid eye drops), rash, alopecia, anorexia, diarrhea, fever, malaise, nausea, vomiting, mucositis, myelosuppression, neurotoxicity (cerebellar toxicity, confusion, seizures, tremor), hepatotoxicity, thrombophlebitis
Daunorubicin and idarubicin	Cardiomyopathy (may be delayed), transient ECG changes, mucositis, myelosuppression, radiosensitizer, vesicant if extravasated, nausea, vomiting, red discoloration of urine
Etoposide	Anaphylaxis, hypotension, irritant if extravasated, mucositis (with higher doses), myelosuppression, alopecia, nausea, vomiting
Mercaptopurine (6-MP) and thioguanine (6-TG)	Hepatotoxicity, myelosuppression, pancreatitis (6-MP), sinusoidal obstruction syndrome (6-TG), drug fever, alopecia, hyperpigmentation, rash, diarrhea, hyperuricemia, anorexia
Methotrexate	Nausea, vomiting, diarrhea, anorexia, mucositis, myelosuppression, neurotoxicity, rash or reddening of skin, renal failure, nephropathy, transient transaminitis
Mitoxantrone	Cardiomyopathy (may be delayed), arrhythmia, edema, fever, pain, fatigue, alopecia, nausea, vomiting, diarrhea, anorexia, mucositis, amenorrhea, myelosuppression, hyperglycemia, transaminitis, increased BUN, bluish discoloration of sclera, fingernails, and urine

<sup>a</sup>This list is not meant to be inclusive, but rather, representative of the more common or distinguishing toxicities of each agent. AML = acute myelogenous leukemia; APL = acute promyelocytic leukemia; ATRA = all-*trans*-retinoic acid; BUN = blood urea nitrogen; ECG = electrocardiogram. Reference 86.

and stratification to determine which patients should receive a transplant in first remission as part of post-remission or consolidation therapy. It is generally accepted that children with APL, Down syndrome, inv(16), or t(8;21) have considerably better outcomes than other patients with AML and that stem cell transplants in first remission could result in excess toxicity without a survival advantage (Reference 1). Retrospective data suggest that an allogeneic stem cell transplantation from a matched sibling donor provides a survival benefit over additional chemotherapy for patients with intermediate-risk AML. On the basis of these data, it is assumed that the same would be true for patients with high-risk disease (e.g., patients with deletions of 5q, monosomy 5 or 7, or more than 15% blasts remaining after the first course of chemotherapy) (References 92–94). It is possible that patients who receive a matched sibling transplant have a reduced risk of relapse without a corresponding improvement in overall survival (Reference 15). The risk of secondary malignancy and the potentially severe toxicities incurred because of stem cell transplantation should be balanced with a significant survival advantage; to date, this transplant advantage is unclear in any subgroups of children with AML (References 92–94).

### Maintenance Therapy

Although critically important in pediatric ALL, maintenance therapy does not play a role in the treatment of most types of pediatric AML. Overall survival for patients who did not receive maintenance therapy was significantly higher than for patients who received maintenance therapy for up to 18 months (Reference 95). The reduction in overall survival may have been caused by the development of drug resistance and subsequent treatment failure (Reference 95). Acute promyelocytic leukemia appears to be the only type of AML for which maintenance therapy is important in maintaining remission. Patients with APL who receive tretinoin together with chemotherapy during induction and maintenance have improved response and survival (Reference 62).

### CNS Therapy

Unlike its role in the treatment of pediatric ALL, the role of CNS-directed therapy in pediatric AML is unclear. The use of systemic high-dose cytarabine and idarubicin is thought to contribute to the treatment or prophylaxis of CNS disease in pediatric AML (Reference 96). Up-front cranial irradiation is not widely used by various international cooperative groups and is not used for the treatment of pediatric AML in the United States (References 1, 97). It is used in some patients who do not clear leukemic blasts from the CNS after systemic and intrathecal chemotherapy (References 5, 12, 14). The use of cytarabine alone or triple-agent (cytarabine,

hydrocortisone, and methotrexate) intrathecal chemotherapy may be used for CNS prophylaxis in children with AML or treatment of those with abnormal myeloid precursors in the CNS at diagnosis (Reference 1).

### Special Exceptions

#### *Children with Down Syndrome*

Children with Down syndrome are uniquely sensitive to chemotherapeutic agents active in the treatment of AML. Myeloblasts in children with Down syndrome and AML exhibit enhanced activation and reduced metabolism of cytarabine. This is likely the result of the mutant *GATA1* gene seen in these patients, which results in the increased expression of deoxycytidine kinase and cystathionine  $\beta$ -synthase together with decreased expression of cytidine deaminase (References 60, 98, 99). This enhanced sensitivity is likely related to the greater treatment-related toxicity and mortality seen in children with Down syndrome. A reduction in the dosing of conventional chemotherapy may result in improved survival because of a reduction in treatment-related mortality (Reference 85).

#### *Acute Promyelocytic Leukemia*

Historically, APL has been treated with standard chemotherapy (cytarabine plus anthracyclines) in induction and consolidation/post-remission therapy, like other types of AML. Some studies have used daunorubicin as the anthracyclines of choice, whereas others have used idarubicin or mitoxantrone. Tretinoin was recently added to standard chemotherapy with success (References 62–64). As previously mentioned, the t(15;17) translocation fuses the *PML* gene on chromosome 15 to the retinoic acid receptor (*RAR*) gene on chromosome 17 (Reference 80). Tretinoin is recognized as the first molecularly targeted pharmacologic agent in the treatment of acute leukemias because of its ability to destabilize the *PML-RAR* complex, permitting the expression of genes that allow differentiation of the abnormal clone (Reference 22).

Patients with APL treated with tretinoin may experience a unique collection of adverse events in the first few days to weeks after beginning therapy. This condition, retinoic acid syndrome, may occur in 6% to 27% of patients and be more pronounced in children than in adults. Retinoic acid syndrome has been associated with increasing WBCs, fever, weight gain, dyspnea, pleural effusion, pulmonary infiltrates, and pseudotumor cerebri (Reference 80). Pseudotumor cerebri, which is characterized by increased intracranial pressure, visual abnormalities, and papilledema, may occur without other complications of retinoic acid syndrome and may be more common in children (References 62, 63, 100). The management of pseudotumor cerebri may require the dose reduction or discontinuation

of tretinoin and the administration of corticosteroids, analgesics, and mannitol (Reference 100). In some patients, renal failure, hypotension, and pericardial effusion may also occur. The mechanism of this syndrome is not well understood, but it is speculated to involve the release of cytokines from the APL cells undergoing differentiation (Reference 80). Medical management of the patient in the critical care unit is often required.

Improved outcomes through the years have been associated with intensive treatment with anthracyclines, including cumulative doses as high as 400–750 mg/m<sup>2</sup> (Reference 101). These higher doses of anthracyclines increase the risk of late cardiotoxicity in children and have led investigators to examine ways to reduce total anthracycline exposure (Reference 22). Of particular interest is the utility of arsenic trioxide in the management of relapsed/refractory and children with newly diagnosed APL (References 102–107). A recent cooperative group clinical trial evaluated the effect of arsenic in the consolidation phase in lieu of an anthracycline-containing course with the aim of reducing anthracycline exposure while maintaining a high survival rate (Reference 108). Preliminary data from this study of children with APL suggest that the substitution of arsenic in the consolidation phase has similar efficacy with respect to event-free and overall survival; in adult patients, the addition of arsenic significantly improved event-free and overall survival (Reference 109). This trial also used high-dose cytarabine on the basis of data showing a higher event-free and overall survival together with a reduced relapse rate in patients receiving cytarabine plus daunorubicin (Reference 108). Tretinoin is used in the maintenance phase along with chemotherapy (References 22, 62).

### Therapy for Relapsed Disease

Survival after relapse is low. Only 21% to 33% of patients who receive chemotherapy for the treatment of relapse survive (References 110–115). Agents that have been used in the treatment of relapsed disease include fludarabine, clofarabine, and cladribine as well as the agents used during the initial treatment of the disease (e.g., cytarabine, etoposide, daunorubicin, idarubicin, and mitoxantrone). Various combinations have been studied, including fludarabine plus cytarabine, fludarabine plus cytarabine and idarubicin, clofarabine monotherapy, clofarabine plus cytarabine, and clofarabine plus cytarabine and etoposide (References 116–120).

The length of first remission is an important predictor of long-term survival (References 111–113). An evaluation of prognostic factors for survival in children with relapsed AML found that the only independent variable associated with outcome was the time to relapse. Specifically, children who relapsed after a disease-free period of at least 18 months (1.5 years) had a statistically higher long-term survival, regardless of

whether they received chemotherapy alone or chemotherapy plus stem cell transplantation (Reference 111). Children with a late relapse had a 5-year survival estimate of 40% (standard error [SE] 10%), whereas those relapsing earlier (i.e., within 1.5 years from the end of previous therapy) had a 5-year survival estimate of 10% (SE 5%) (Reference 111). Patients who receive a stem cell transplant after an early relapse can be expected to have a 56% chance of survival at 5 years compared with 65% at 5 years for late relapse (Reference 115).

### Future Approaches and Targeted Agents

Future approaches to improving outcomes in childhood AML may include earlier incorporation of newer agents such as clofarabine into front-line treatment protocols, enhanced supportive care techniques to support intensive chemotherapy, and further refinement of the role and timing of stem cell transplantation. Additional approaches should focus on a greater understanding of the biologic features of the disease and the development of targeted therapies that improve survival without increasing treatment-related mortality. Agents under consideration include proteasome inhibitors (e.g., bortezomib) and tyrosine kinase inhibitors (e.g., sorafenib) (Reference 122).

The tyrosine kinase inhibitors targeting FLT3 are of particular interest in the treatment of childhood AML because about one-fourth of younger adults with AML possess internal tandem duplications of the *FLT3* gene (Reference 121). Sorafenib is a tyrosine kinase inhibitor which has expressed activity in treating patients with FLT3/ITDs. Sorafenib, which among other targets is also known to inhibit the Raf-1 kinase and subsequently the Raf/MEK/ERK pathway, is approved by the U.S. Food and Drug Administration for the treatment of hepatocellular carcinoma and renal cell carcinoma (Reference 121). A phase I/II clinical trial of sorafenib, idarubicin, and cytarabine in adults with AML showed a clear response to sorafenib; however, the risk of relapse was not eliminated, even in patients with FLT3/ITDs (Reference 121). A phase III clinical trial by the Children's Oncology Group is evaluating the efficacy of sorafenib or bortezomib in addition to conventional chemotherapy for children with newly diagnosed, previously untreated AML (Reference 122).

### Supportive Care

Supportive care is critical to minimize toxicities and treatment delays. As with patients having other hematologic malignancies, patients with newly diagnosed AML must receive close monitoring and treatment for tumor lysis syndrome, infection, and various hematologic complications. Clinical tumor lysis syndrome, defined as laboratory findings of tumor lysis syndrome plus at

least one clinical complication (i.e., cardiac arrhythmias/sudden death, renal insufficiency, seizures), has been reported to occur in 3.4% to 5% of children with AML; this is slightly less than the incidence of tumor lysis syndrome in children with ALL (5.2%) and non-Hodgkin lymphoma (6.1%) (Reference 123). Children with newly diagnosed AML and a total WBC greater than 50,000 have been characterized as being at high risk of developing tumor lysis syndrome (Reference 123). Tumor lysis syndrome can be prevented or managed through the aggressive use of oral or intravenous hydration, electrolyte monitoring and prompt correction. Either rasburicase or allopurinol is used in the treatment of tumor lysis syndrome on the basis of an institution's preference. Given an evidence-based review of tumor lysis syndrome, rasburicase may be a better option in AML, as clinically appropriate (Reference 123). Hematologic parameters may require correction through packed red blood cell or platelet transfusions and, in some cases, exchange transfusions or leukapheresis.

Patients with AML are at an increased risk of a variety of infectious complications because of prolonged periods of neutropenia. Patients with AML who develop febrile neutropenia should receive treatment with broad-spectrum antibiotics in a closely monitored inpatient setting. Empiric antibiotics administered to the febrile, neutropenic patient with AML should at minimum include appropriate coverage for gram-negative enteric bacteria and viridans streptococci. Of note, patients who have recently received high-dose cytarabine are at increased risk of developing sepsis from viridans streptococci (Reference 124). A retrospective analysis of the use of prophylactic antibiotics revealed that the use of cefepime and vancomycin can significantly reduce the risk of general bacterial sepsis as well as streptococcal sepsis (Reference 125).

Because of the high risk of invasive fungal infection in patients with AML, many treatment protocols now recommend or require the use of an antifungal agent as prophylaxis. For patients who develop febrile neutropenia, broad-spectrum antifungal agents (e.g., amphotericin products, echinocandins, or voriconazole) should be considered. For severe cases of sepsis or prolonged neutropenia, the addition of granulocyte colony-stimulating factors should be considered (Reference 1). In some cases, granulocyte transfusions may also be considered.

One of the greatest concerns for patients with cancer is the development of chemotherapy-induced nausea and vomiting (CINV). The introduction of 5-HT<sub>3</sub> (serotonin-5 receptor) antagonists (e.g., dolasetron, granisetron, ondansetron) has improved the prevention and treatment of CINV (Reference 126). These agents are now routinely used as front-line agents to manage this complication in children with cancer. Adjunctive agents such as promethazine, prochlorperazine,

metoclopramide, diphenhydramine, and lorazepam are also used. Although dexamethasone is an effective antiemetic, many centers avoid its use in patients with hematologic malignancies for various reasons; in patients with AML, the routine addition of dexamethasone or other corticosteroids holds the potential of increasing the already high risk of developing invasive fungal disease. In adult patients with CINV, the neurokinin 1 receptor antagonist, aprepitant, has significantly improved CINV management (Reference 127). In children and adolescents, it has shown less promise (References 128–130). Moreover, the concern for potential drug-drug interactions cannot be ignored because of the effect of aprepitant as an inhibitor of the cytochrome P450 3A4 isoenzyme (Reference 131).

### Late Effects

All children who receive chemotherapy for the treatment of a malignancy should receive long-term monitoring. Long-term follow-up should include plans to monitor for treatment-related toxicities as well as disease recurrence. Children with AML who are in remission after treatment with chemotherapy are at an increased risk of developing several late effects, depending on the agents included in the treatment regimen. For any child who receives an anthracycline, long-term follow-up must include monitoring for cardiac toxicities, specifically left ventricular hypertrophy. Most children will require a vaccination “catch-up” schedule based on the time of diagnosis and the number of vaccines missed during the treatment period. Children who receive a stem cell transplant will require additional interventions, such as revaccination with any vaccines received before transplantation. The reader is encouraged to refer to the Children's Oncology Group *Long-Term Follow-Up Guidelines for Survivors of Childhood, Adolescent, and Young Adult Cancers* for additional information on the appropriate timing and selection of evaluation criteria and markers for survivors of childhood cancer (Reference 132).

### CONCLUSIONS

Childhood AML continues to be a difficult malignancy to treat. Merely half of patients with newly diagnosed AML can be expected to have a long-term survival. Significant progress in recent years has occurred in the treatment of APL, a subtype of AML. Survival in these patients exceeds that of other subtypes because of the development of targeted therapy for the specific genetic alteration seen in the disease. Although genetic associations have been seen in other patients with AML, a successful targeted therapy has yet to be discovered. Further refinement and understanding of the genetic alterations responsible for disease development and progression are necessary for targeted drug development. Future

clinical trials will focus on the treatment of childhood AML with various targeted therapies and other investigational agents, techniques to minimize the late effects of chemotherapy, and the role and timing of hematopoietic stem cell transplantation.

# CHAPTER 53

## PAIN MANAGEMENT

Peter N. Johnson, Pharm.D., BCPS

### LEARNING OBJECTIVES

1. Describe the impact of neurobiologic changes on the development of pain in pediatric patients.
2. Recognize two differences in pain management in children compared with adults.
3. Differentiate between five different pain scales used for pain assessment in children.
4. Identify the pharmacokinetic and pharmacodynamic effects of non-opioids and opioids in children.
5. Select an appropriate agent for acute and chronic pain on the basis of severity and location of pain.
6. Compare and contrast agents used for procedural sedation in neonates and children.

### ABBREVIATIONS IN THIS CHAPTER

AAP	American Academy of Pediatrics
ADME	Absorption, distribution, metabolism, excretion
FLACC	Face Legs Activity Cry Consolability Scale
LET	Lidocaine, epinephrine, and tetracaine
NCA	Nurse-controlled analgesia
NCCPC-PV	Non-communicating Child's Pain Checklist-Postoperative Version
NRS	Numerical rating scale
NSAIDs	Nonsteroidal anti-inflammatory drugs
PCA	Patient-controlled analgesia

### INTRODUCTION

Pain management in children is a unique challenge for pharmacists and other health care professionals. Children admitted to the hospital or seen at an emergency department or outpatient clinic may experience several different etiologies of pain including acute pain (e.g., diagnostic and therapeutic procedures, oral/nasal/tracheal suctioning), established pain (e.g., thermal/chemical burns, postsurgical pain), prolonged

pain (e.g., meningitis, necrotizing enterocolitis), and chronic pain (e.g., sickle cell disease) (Reference 1). Pain pharmacotherapy is associated with many challenges for clinicians, not limited to assessment and treatment. The heterogeneity of the pediatric population makes it difficult for a one-size-fits-all approach. Inadequate pharmacotherapy can be associated with adverse physiologic changes, especially in the neonatal population. In children, analgesics are among the highest class for medication errors, and there are several medication safety concerns that pharmacists should consider when developing pain care plans.

Historically, there have been many misconceptions regarding the definition, recognition, and management of pain in infants and children compared with that of adults. In the 1970s, the International Association for the Study of Pain Subcommittee on Taxonomy defined pain as “an unpleasant sensory emotional experience associated with actual or potential tissue damage” (Reference 2). Inherent in this definition was the idea that pain is a learned response. Another common misconception was that neonates could not feel pain, and even if they did, they would not remember the experience (Reference 3).

Because of these misconceptions, evidence suggests that children have suboptimal pain treatment compared with adults. In the 1980s a retrospective study comparing analgesic usage patterns in 90 children and 90 adults matched for sex and diagnosis was conducted (Reference 4). The investigators found that children received fewer opioid doses compared with adults but concluded that it is was challenging to know whether these findings were related to discrepancies in pain assessment or other factors. More recent studies have identified that untreated pain is associated with significant behavioral and biochemical consequences (References 5–7). Clinically, these consequences may result in delayed healing, complicated recovery time, and significant stress not only for the patient but also for the patient's caregivers. Because of the emerging research in this population, researchers have proposed a new definition of pain that states “pain perception is an inherent quality of life that appears early in development to serve as a signaling system for tissue damage” (Reference 8). The system is composed of both physiological and behavioral indicators that can adequately depict pain and others can interpret (Reference 8).

## Physiology of Pain Transmission

Studies during the past 20 years have explored pain perception among young infants and adults. Research has confirmed that although pain perception is similar among adults and neonates, the differences between the two have been primarily attributed to neurophysiologic and cognitive immaturity (Reference 9). To understand these differences in more detail, it is important to review the physiology of pain stimulation, transmission, perception, and modulation. The first step in the development of pain involves the sensation of painful or noxious stimuli leading to the excitation of nerve endings called nociceptors in the periphery. Several different mediators including bradykinin, prostaglandin, histamine, substance P, and serotonin have been associated with the sensitization and activation of nerve transmission in concert with the noxious stimuli. These mediators may be a source for targeted intervention (Reference 10). Activation of nociceptors results in transmission of nerve impulses along the ascending pain pathway from the periphery along A-delta and C-afferent nerve fibers to the dorsal horn of the spinal cord. The A-delta nerve fibers are myelinated, large-diameter fibers that allow sharp, localized pain response. The C-afferent fibers are unmyelinated fibers, representing the most common path for nociception in both neonates and adults, and result in dull, aching, poorly localized pain. The nerve impulse is then transmitted along various spinal tracts, including the spinothalamic tract to the thalamus. Once the signal reaches the thalamus, the patient is able to become consciously aware of the source of pain and is able to localize the origin of the pain (Reference 11). Modulation of the pain response occurs through the descending pain pathway when a series of supraspinal structures, including the locus coeruleus and rostral ventromedial medulla, directly or indirectly alter the pain transmission from the brainstem to the spinal dorsal horn (Reference 10). The net result of modulation is that nociception of the painful stimuli is either inhibited, leading to pain inhibition, or facilitated, leading to exacerbation of the pain response.

## Differences in Pain Management in Children vs. Adults

Even though the pathways for pain perception through modulation are essentially the same in all populations, several neurophysiologic factors in neonates make pain management unique in the neonatal population. The elements of the peripheral and central nervous system necessary for pain transmission and perception develop in the fetus at the end of the first trimester (Reference 12). Evidence suggests the fetus has the ability to perceive pain even before birth; however, the structures necessary for pain modulation through the descending pain pathway are not complete until 30–32 weeks' gestation

(Reference 1). The final stage of neural development is complete at 37 weeks' gestation with the integration of a myelin sheath around the spinothalamic tract (Reference 12). In addition to the environmental and disease state factors that may be a source of pain in neonates, the developmental maturity (i.e., gestational age and postnatal age) of the neonate can contribute to differences in pain perception and modulation between neonates and adults. Because premature neonates younger than 32 weeks' gestational age do not have a fully developed descending pain pathway, they have been shown to experience a lower pain threshold and even a hypersensitivity that develops as a result of repeated painful procedures (References 1, 13). In addition, infants have less-precise pain transmission than older infants and children. The touch and pain transmission pathways are close to each other on the spinothalamic tract (Reference 12). Because of the infant's decreased accuracy in pain perception, he or she may lose the ability to differentiate a painful response from a non-painful response. Research has shown that neonates experience pain and that the early pain responses they experience are associated with long-term changes in pain perception (Reference 12).

In addition to the neurophysiologic factors, other differences in pain management between adults and children must be recognized. There are cognitive and developmental differences in young children that make it difficult to assess and treat pain. Clinicians should also note specific factors in children that may affect the dose of an analgesic medication or even the selection of particular analgesics. Small children may have high oxygen consumption and smaller lung volumes, so they may be more prone to periods of apnea when they are administered opioids or sedative medications to relieve pain and anxiety (Reference 14). In such cases, a dosage adjustment may be required to avoid adverse events. The absorption, metabolism, and excretion of selected pain medications may also be altered in pediatric patients requiring a dosing adjustment compared with adults.

An abundant amount of data suggests the significance of pain in children. As a result, several different organizations have emphasized the need for pain assessment in children (References 15, 16). In 2001, the Joint Commission implemented pain management standards that mandated health care facilities to execute uniform pain assessment and standardized approaches to pain treatment in children (Reference 17). Pain has often been termed "the fifth vital sign," emphasizing the need for continuous reassessment of hospitalized pediatric patients. Despite these recommendations, pediatric pain management continues to be a challenging field with many barriers because of the developmental changes and pharmacokinetic alterations associated with this heterogeneous population.

## CLINICAL PRESENTATION AND DIAGNOSIS

### General Assessment Principles

Uniform pain assessment can be very difficult in the pediatric population. Infants may experience nonspecific symptoms of pain with changes in facial expressions and crying; they may also present with autonomic symptoms (e.g., tachycardia, tachypnea), but these symptoms may be associated with their underlying disease state rather than pain by itself (Reference 18). Just like in adults, clinicians should inquire about the character, location, intensity, and duration of painful stimuli in children. Of note, children may not be forthcoming with this information. They may experience a certain level of anxiety with physicians and other health care professionals related to needlesticks, medication injections, and other interventions that they may receive in the clinic, emergency department, or hospital setting. In non-verbal

children, it may also be difficult to ascertain whether crying and other behavioral manifestations are associated with pain or other factors such as hunger or fear.

The ability of a child to describe his or her pain varies with age, experience, and cognitive developmental states (Reference 19). In general, clinicians may use self-report, physiologic, and/or behavioral assessments to differentiate between pain and other factors. Because pain is a subjective experience, self-report is generally preferred to make inferences about a patient's pain episodes (Reference 20). However, for non-verbal children or children with cognitive impairment, this may be difficult. Current recommendations call for clinicians to use a child's self-reported pain in conjunction with standardized assessment tools (Reference 20).

Table 1 provides a summary of the most common types of assessment tools. Specific vital sign changes including elevation in heart rate and blood pressure may be used in all ages as an indirect measurement of pain.

**Table 1.** Summary of Pain Measurement Tools in Children (Adapted from References 18, 19, 25)

Name	Recommended Age Range or Groups	Advantages	Disadvantages
Physiologic measures (e.g., heart rate, blood pressure)	All ages	Useful for nonverbal children	Vital sign changes occur unrelated to pain
Neonatal behavioral/physiologic scales (e.g., NIPS, NFCS, PIPP)	Premature to full-term infants	Evaluate age-appropriate behavioral and physiologic factors; useful for nonverbal children	Nonspecific in some cases; some are time-consuming; questionable validity in selected patients
Other behavioral/physiologic scales (e.g., FLACC)	2 months to 7 years	Evaluate age-appropriate behavioral and physiologic factors; useful for nonverbal children	Nonspecific in some cases; some are time-consuming; questionable validity in selected patients
Graphic scale (e.g., color analog scale)	4 years and older	Used for preschool children	Limited utility in children with cognitive impairment or who are color-blind
FACES scale (e.g., Wong-Baker)	3 years and older	Simple scoring tool used for pain discrimination; used for very young preschool children	Children may confuse their emotional states with pain ratings.
Visual Analogue Scale	8 years and older	Straightforward, one-dimensional scoring tool for older children	Limited applicability in children with cognitive impairment
Numerical Rating Scale	7 years and older	Simple scoring tool that can be given verbally or as a written instrument	Application of scores to treatment decisions is inappropriate.
NCCPC-PV	Cognitively impaired children	Validated tool for pain assessment in children with cognitive impairment	Assessment may take substantial time at the bedside to complete (e.g., 10 minutes).

FLACC = Face Legs Arms Cry Consolability Scale; NCCPV-PV = Non-communicating Children's Pain Checklist-Postoperative Version; NFCS = Neonatal Facial Coding System; NIPS = Neonatal Infant Pain Scale; PIPP = Premature Infant Pain Profile.

However, the utility of these markers alone is questionable because of the effects of the child's underlying disease state or other underlying emotional factors (e.g., anxiety, depression). Other more specific pain assessment tools have been developed, but it is important to understand the role of these tools in relation to the child's age and cognitive developmental stages.

### Assessment Methods in Pediatric Subgroups

The most common tools used in this population other than physiologic changes are behavioral/physiologic scales. These scales involve the assessment of a variety of behavioral features including crying, facial expressions, body posture/movements, and, in some cases, vital sign changes (e.g., blood pressure, heart rate) (Reference 19). When clinicians evaluate one of the behavioral features alone, they may be unable to assess pain accurately. For example, premature infants and sick full-term infants may be unable to produce an adequate cry when in distress (Reference 19). Many of these scales are available, including the Neonatal Facial Coding System (NFCS), Neonatal Infant Pain Scale (NIPS), and Premature Infant Pain Profile (PIPP). Each scale has been validated in the neonatal population, and each has unique parameters that are evaluated. These scales can be time-consuming, and their utility in intubated neonates is questionable (Reference 19).

Toddlers have a decreased cognitive ability compared with older children and may not have the ability to differentiate between types of pain. As a result, nonverbal behaviors such as facial expressions, limb movements, and crying may be more accurate than their own self-reports (Reference 19). Children older than 3 years will be able to give a good description of the intensity, location, and severity of their pain, whereas verbal toddlers younger than 3 years will often have a decreased ability to do so (References 18, 19). Toddlers may have a limited knowledge of numbers and colors, making it difficult to use certain types of pain assessment tools. Thus, age-appropriate behavioral scales such as the Faces Legs

Figure 1. Color Analog Scale (Obtained with permission from Reference 22).

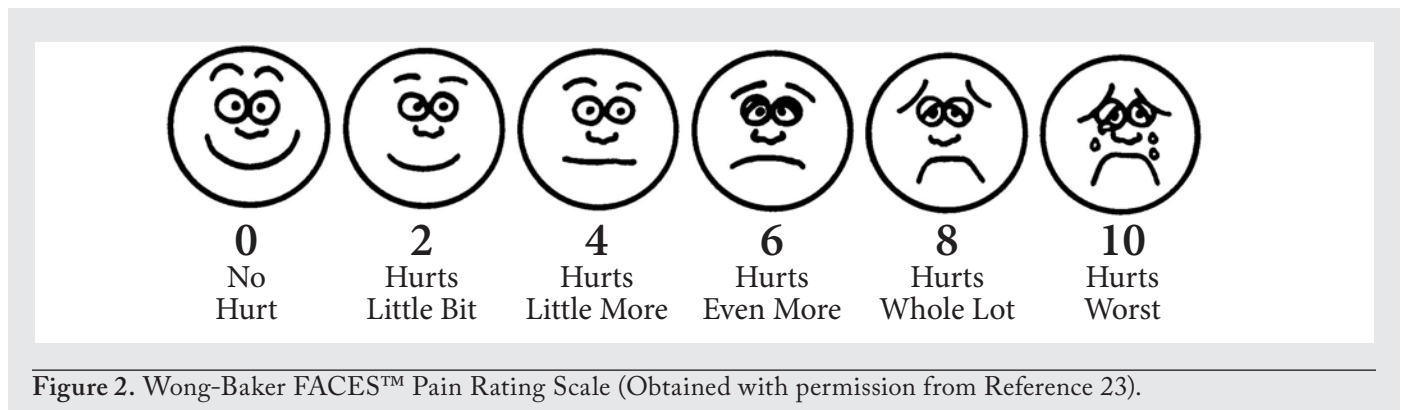

Figure 2. Wong-Baker FACES™ Pain Rating Scale (Obtained with permission from Reference 23).

Activity Cry Consolability Scale (FLACC) have been developed for children as young as 2 months up to 7 years. The FLACC involves a 0- to 10-point scale that evaluates five key indicators, including the face, legs, activity, cry, and consolability (Reference 19). Overall, this scale is relatively easy to use and has been validated in the literature (Reference 21).

Preschool children have an increased ability to articulate and discriminate their pain. By 5 years, most children will be able to rate the severity of their pain (Reference 19). Many different scales have been developed for this age group including the Child Facial Coding System (CFCS), Poker Chip Tool, Graphic Scale, and FACES Pain Scale. Examples of these scales can be found in Figure 1 and Figure 2 (Reference 22). These scales, which can be used in children as young as 4 years, involve the use of color and/or drawings. In general, the higher the number and intensity of color, the more intense the pain. One limitation of this type of tool is its utility for children who are color-blind and/or possess developmental disabilities (Reference 18).

The Wong-Baker FACES Pain Rating Scale is one of the most common tools used by several institutions (Figure 2) (Reference 23). This scale is recommended for children 3 years and older and requires health care professionals to point to each face and describe the corresponding intensity of pain with the corresponding face (Reference 19). Then, the child is asked to point to the face that most accurately describes his or her pain. Although the Wong-Baker scale is one of the most common scales used, one disadvantage of it is that the face associated with “no pain” is the “smiling face.” Other similar scales involve the use of a “neutral face” instead of a “smiling face.” Investigators compared the Wong-Baker scale versus other types of faces scales (Reference 24). They found that children who saw the smiling face were more likely to report higher pain scores than children who saw the neutral face and suggested that young children may confuse pain ratings with the faces describing different emotional states (Reference 24). For example, an anxious child without a true source of pain may select a face with a corresponding higher pain score because he or she is sad rather than experiencing pain.

School-aged children have an increased ability to describe their pain compared with younger children. In general, they are more concrete thinkers than are preschool children, and they tend to have a better understanding of measurements, quantitative expressions, and facial expressions (References 18, 19). Thus, analog scales such as the Visual Analogue Scale and numerical rating scale (NRS) either use faces or numbers to accurately assess their pain. The Visual Analogue Scale is a one-dimensional pain assessment tool that involves a 100-mm horizontal line with

corresponding descriptions of pain (Reference 19). The lower end of the spectrum highlights no pain, whereas the highest point score represents severe pain. Children are asked to mark along the continuum the line that best corresponds to the given pain descriptions. One of the main disadvantages of this tool is that it may have questionable utility in school-aged children with cognitive impairment (Reference 18).

The NRS is another commonly used scoring tool in older children and adults; one example of this scoring tool is its 0 (no pain) to 10 (severe pain) scale. Few studies have evaluated the validity of this scoring tool in children. Recently, the use of the NRS in 113 children ranging from 7 to 16 years old who required hospital admission after surgery for postoperative pain management was evaluated (Reference 25). It was noted that children with NRS scores greater than 4 had good sensitivity and specificity to predict what children needed additional pain medication. However, in children with an NRS score greater than 6, less than one-half of them were somewhat satisfied with their current pain regimen, and another one-fourth of them were very satisfied with their regimen. The investigators concluded that there was a discrepancy in the relationship of higher pain scores and patient satisfaction with their analgesic regimens. In addition, they concluded that the NRS could be used in this population to assess pain but that there might be a limited role in children with the correlation of the NRS for treatment decisions.

Adolescents tend to have the highest capacity to describe their pain, although in front of close family or friends, they may deny the presence of their pain (Reference 19). In fact, they may prefer that friends and family are not present when clinicians assess or discuss their pain. Overall, they generally want the choice to receive interventions for painful procedures, but under certain situations, adolescents may have regression of their developmental ability to cope with their pain (References 19, 20). Most, if not all, pain measurement tools would be acceptable in this population.

For children with cognitive impairment, pain assessment can be very difficult. Children with Down syndrome may not adequately describe the character of their pain (Reference 18). Because the sensory perception in children with autism is different from that in other children, it may be difficult to accurately assess painful stimuli versus other stimuli that may exacerbate their underlying disease (Reference 18). It is imperative that clinicians ascertain the patient's neurologic baseline from the parents/caregivers when a child's self-report is not possible. Recent work has focused on the development of standardized assessment tools in this population. One recent study

sought to validate the Non-communicating Child's Pain Checklist-Postoperative Version (NCCPC-PV), a standardized pain assessment scale in the postoperative period for patients younger than 18 years with cognitive impairment (Reference 26). This scale assesses six domains: vocal sounds, social interaction, facial expressions, general activity, body/limb movements, and physiologic signs. The investigators correlated the score on the NCCPC-PV with that of caregivers and the research team and found good correlation between their assessments. It is extremely important for clinicians to use a multi-professional approach to pain assessment that includes the physician, nursing staff, other allied health care professionals, and parents/caregivers. Recent evidence suggests that the NCCPC-PV is a useful clinical tool to augment clinical assessment in children with cognitive impairment.

### Key Point Summary for Pain Assessment

- Pain should be assessed by patient self-report, together with behavioral/physiologic assessments at regular intervals in hospitalized children.
- Several types of behavioral pain assessment tools are available, and each of them may have advantages and disadvantages over another.
- Pain assessment in children with cognitive impairment requires a multidisciplinary approach and can be augmented with validated assessment tools such as the NCCPC-PV.

## TREATMENT

### Nonpharmacologic Therapy

Many nonpharmacologic interventions can be used to prevent and treat pain in children. An increasing amount of evidence supports the use of these interventions because they have good safety profiles and very few downsides (References 16, 18). One of the proposed mechanisms of these interventions is that they interfere with pain transmission along the ascending pain pathway by introduction of other excitatory messages (Reference 14). Several different types of health care professionals may be needed to incorporate these therapies. One such health care professional that may be used is the child life specialist; these professionals are trained to employ such nonpharmacologic therapies and educate the parents/caregivers and health care professionals on strategies to reduce and eliminate painful stimuli in children (Reference 16). This education will be needed to ensure the success and

implementation of these therapies not only for the patient but also for the other members of the health care team (Reference 16). Everything from the "physical" medical environment to the use of child life specialists can be a useful therapeutic intervention to relieve pain and/or anxiety for children in the emergency department and hospital setting (Reference 16).

In recent years, many nonpharmacologic interventions have been suggested for the neonatal population. These nonpharmacologic interventions are useful to decrease pain and discomfort for neonates during procedures (e.g., heel lancing, adhesive removal, intramuscular/subcutaneous injection, venipuncture, lumbar puncture, suctioning) (References 12, 13). Several of these interventions such as swaddling, facilitated tucking, rocking, pacifier use, and positioning have been validated (Reference 12). Positioning is a useful intervention that allows the infant to adjust himself or herself after a painful procedure. Facilitated tucking is a process by which an infant is wrapped in a blanket and restrained in a tucked position. Practitioners have also focused on targeting environmental factors that may cause neonates pain and anxiety to create a quiet and restful environment. Some neonatal units have taken measures to reduce lighting, decrease the amount of time per day the baby is actually touched, and decrease the volume of alarms and telephones (Reference 12).

The nonpharmacologic therapies in older children can be classified into cognitive, behavioral, and physical interventions. Cognitive therapies include the use of music, guided imagery, distraction, and hypnosis to reduce or eliminate pain (Reference 14). Distraction techniques can include bubbles, therapeutic play, video games, and television. Behavioral techniques can range from breathing exercises to relaxation techniques and may require education for both the provider and patient to be totally effective (Reference 14). Physical nonpharmacologic interventions may also be used; these interventions may involve the use of acupuncture, massage therapy, and application of transcutaneous electrical nerve stimulation (Reference 14). These therapies may be particularly useful for pain in localized regions (Reference 18).

In summary, nonpharmacologic interventions can be very useful for preventing and treating pain in neonates and children. Some children may respond better to nonpharmacologic interventions than others. In addition, certain therapies may not be appropriate for some children and should not be used in place of analgesic agents. A detailed discussion of these interventions is beyond the scope of this chapter, but these interventions have been published elsewhere (References 18, 19).

## Pharmacologic Therapy

### *Pharmacokinetic and Pharmacodynamic Considerations in Children*

#### *Developmental Pharmacology Considerations*

Clinicians should consider the pharmacodynamic and pharmacokinetic changes that occur with age when selecting not only medication dosing but also the actual analgesic agent. In the first few years of life, significant changes occur in the absorption, distribution, metabolism, and excretion (ADME) of various medications. A complete review of the ADME principles in children appears in the Pediatric Pharmacokinetics chapter, but it is necessary to point out some of these considerations as they pertain to pain medications in infants and children. Neonates have a thinner stratum corneum and greater hydration to the epidermis compared with older children (References 27, 28). As a result, infants may have an excessive exposure of medications administered topically (Reference 29). The application of transdermal medications such as transdermal fentanyl should be avoided in children younger than 2 years because of unpredictability in dosing (Reference 30). Neonates and infants have a diminished capacity to metabolize medications through the hepatic system. Phase 1 and 2 enzymatic reactions including oxidation and glucuronidation, respectively, are significantly delayed in neonates compared with older children. As a result, medication regimens in neonates may need to be altered on the basis of decreased hepatic clearance. For example, several studies have noted inadequate efficacy with morphine in preterm infants (References 31–33). Morphine is metabolized to an active metabolite by glucuronidation. One study suggests these infants have diminished concentrations of morphine-6-glucuronide, the active metabolite of morphine, and elevated concentrations of morphine-3-glucuronide (Reference 31). Elevated concentrations of morphine-3-glucuronide may antagonize the effects of morphine and morphine-6-glucuronide. These enzyme pathways usually mature by about age 6 months (Reference 34). In fact, children who are 2–6 years old often show increased metabolic clearance and may require doses of medications more frequently for a given therapeutic effect.

In addition to knowledge of the developmental changes associated with skin absorption and metabolism, clinicians should be aware of the effects of renal excretion when prescribing certain medications. Specifically, neonates exhibit decreased glomerular filtration and tubular secretion (Reference 34). Morphine-3-glucuronide and morphine-6-glucuronide are both renally excreted, and neurotoxicities like

myoclonus could occur in patients with renal insufficiency (Reference 35). As a result, neonates may require an extension of dosing intervals to prevent the accumulation of a given medication and its metabolites.

#### *Pharmacokinetic Alterations in Obese Children*

In addition to the developmental changes related to ADME principles in the pediatric populations, other alterations may be noted in obese children. The prevalence of overweight and obese children has increased dramatically during the past 30 years. A study recently found that around 16.9% and 31.7% of children 2–19 years old in 2007–2008 were obese and overweight, respectively (Reference 36). In addition, another study found that one-third of all admissions of patients 5–12 years old during a 6-month period were overweight (Reference 37). A complete review of pediatric obesity may be found in the Pediatric Obesity chapter. Pharmacokinetic alterations have been noted in obese adults, including a higher volume of distribution for lipophilic medications and increased glomerular filtration rates (Reference 38).

There is a paucity of pharmacokinetic studies of obese pediatric patients. Studies of obese adults receiving continuous infusions of fentanyl highlight some possible concerns. Researchers found that optimal dosing of fentanyl continuous intravenous infusions had better correlation with the “pharmacokinetic mass” of the patient rather than an actual, ideal, or adjusted body weight (References 39, 40). The investigators determined the “pharmacokinetic mass” on the basis of observations of the analgesic effect, serum fentanyl concentrations, and fentanyl dose. Results show that as the actual body weight increased, the pharmacokinetic mass increased logarithmically, suggesting an upper limit to the weight by which fentanyl is dosed (Reference 40). There is a concern in obese patients that if fentanyl is dosed on the basis of actual body weight, there is a higher risk of overdosing and adverse events such as oversedation. Until more pharmacokinetic studies have been conducted, it seems reasonable to use the following recommendations for dosing of pain medications in obese children (References 38, 41).

- For children weighing less than 40 kg and younger than 18 years: Use weight-based dosing (i.e., milligram or microgram for single-dose medications and milligrams per kilograms per hour or micrograms per kilograms per hour for continuous intravenous medications).

- For children weighing 40 kg or more:
  - Single-dose medications: Use weight-based dosing unless the patient's dose or dose per day exceeds the recommended adult dose for the indication.
  - Continuous intravenous medications: Avoid weight-based dosing strategies and use adult dosing strategies (i.e., microgram per hour or milligram per hour).

### Acute Pain Management

Children who experience acute pain require prompt attention. The World Health Organization (WHO) has developed a useful algorithm, the analgesic ladder, for the management of cancer pain that involves three unique classifications: mild pain, moderate pain, and severe pain (Reference 42). Even though the analgesic ladder was developed to help clinicians treat patients with cancer pain, the principles of this algorithm can

be extrapolated to any painful episode, acute or chronic, in children. Non-opioid analgesics are the mainstay of the first stage and should be initiated on a maintenance schedule and titrated to maximum effect. Patients with mild to moderate pain should receive an opioid analgesic with or without a non-opioid analgesic. In general, patients with severe pain should be initiated on scheduled opioid agents. Intermittent doses of opioids can be useful for patients experiencing acute, breakthrough pain, though this strategy often results in a fluctuation of plasma concentrations. Because several opioid agents have relatively short half-lives, the therapeutic benefit may decrease toward the end of the dosing interval, and the patient may experience breakthrough pain. As a result, patients with severe postoperative pain or other painful episodes should receive continuous intravenous opioid infusions or patient-controlled analgesia (PCA) when appropriate. At any stage, clinicians are encouraged to consider the use of adjuvant agents (e.g., benzodiazepines, antidepressants).

**Table 2.** Non-opioid Analgesic Agents (Adapted from References 44–50)

Medication	Route	Pharmacokinetics	Dose
Acetaminophen	PO	Onset: 0.5 h (PO) t <sub>1/2</sub> : 3–7 h (children to neonates)	< 12 Y/O: 10–15 mg/kg/dose q4–6h (max dose NTE > 5 doses/day 75 mg/kg/day or 2.6 g/day) ≥ 12 Y/O: 325–5000 mg q4–6h or 1 g q8h (max dose 3 g/day)
Acetaminophen	RC	Onset: Unknown t <sub>1/2</sub> : Unknown	< 12 Y/O: 10–20 mg/kg/dose q4–6h ≥ 12 Y/O: 325–650 mg q4–6h or 1 g q6–8h (max dose 4 g/day)
Acetaminophen	IV	Onset: 0.25 h after a 15-minute infusion t <sub>1/2</sub> : 3–7 h (children to neonates)	2–12 Y/O or < 50 kg: 15 mg/kg/dose q6h or 12.5 mg/kg/dose q4h (max single dose NTE 750 mg and max dose per day NTE 75 mg/kg/day or 3.75 g) ≥ 50 kg: 1 g q6h or 650 mg q4h (max single dose NTE 1 g and max dose per day NTE 4 g).
Ibuprofen	PO	Onset: 1–2 h t <sub>1/2</sub> : 1–2 h (children)	< 12 Y/O: 4–10 mg/kg/dose q6–8h (max dose 40 mg/kg/day) ≥ 12 Y/O: 200–400 mg q4–6h (max dose 2.4 g/day)
Ketorolac	IV/IM	Onset: 0.5 h t <sub>1/2</sub> : 3–6 h (children)	2–16 Y/O or < 50 kg: IM: 1 mg/kg/dose (max dose 30 mg) IV: 0.5 mg/kg/dose (max dose 15 mg); 0.5 mg IV q6h NTE 5 days > 16 Y/O or > 50 kg: 30 mg IV q6h (120 mg/day) NTE 5 days
Naproxen	PO	Onset: 0.5–1 h t <sub>1/2</sub> : 8–17 h (children)	2–11 Y/O: 5–7 mg/kg/dose q8–12h > 12 Y/O: 250–500 mg q12h (max dose 1250 mg/day initially; then 1000 mg/day thereafter).
Choline magnesium trisalicylate	PO	Onset: NA t <sub>1/2</sub> : 2–3 h (adults)	Based on total salicylate content: Children: 30–60 mg/kg/day divided 3 or 4 times/day Adults: 500 mg–1.5 g 1–3 times/day

h = hour(s); IM = intramuscular; IV = intravenous; max = maximum; NA = not available; NTE = not to exceed; PO = oral; q = every; RC = rectal; t<sub>1/2</sub> = half-life; Y/O = years old.

### *Non-opioid Analgesics*

Non-opioid analgesics represent an attractive option for patients who may be experiencing mild to moderate pain. They have been used in patients with acute and chronic pain in a variety of settings, including children with cancer pain and postoperative pain, and show opioid-sparing effects. In contrast to opioid analgesics, non-opioid analgesics are not associated with respiratory depression, constipation, or urinary retention but may have other risks specific to the individual agents. These agents show a ceiling effect, making their use in patients with moderate to severe pain limited at best. Hence, there is limited efficacy with doses approaching the maximum recommended range but significant risk of toxicity.

This group of agents includes both the nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen. The NSAIDs inhibit the cyclooxygenase enzymes' ability to convert arachidonic acid to prostaglandin precursors. Prostaglandins are associated with a wealth of pharmacologic activity including the potentiation of inflammation, protection of the gastrointestinal mucosa, and sensitization of nerves to painful stimuli (Reference 22). Acetaminophen inhibits cyclooxygenase-3, and most experts believe that its main analgesic effects come from inhibiting prostaglandin synthesis in the central nervous system (Reference 43). Unlike NSAIDs, acetaminophen does not inhibit peripheral prostaglandin production, so it is thought not to have any anti-inflammatory activity.

Table 2 includes the most common agents used in an emergency department or inpatient setting. There are no studies comparing the efficacy of these agents in children. In addition, a great degree of patient inter-variability exists between these agents. Therefore, the rationale for choosing one agent over another would include the dosage form, cost, and adverse effect profile.

#### ACETAMINOPHEN

Acetaminophen represents the most widely used non-opioid analgesic. This agent is available in a variety of formulations including tablets, oral liquid dosage forms (i.e., elixirs, solutions, and suspensions), suppositories, and an intravenous formulation approved in the fall of 2010. For children younger than 12 years, the usual oral dose of acetaminophen is 10–15 mg/kg with a maximum of 75 mg/kg/day or 2.6 g/day (Table 2) (Reference 44). New dosing recommendations for obese children or children older than 12 years were made available in fall 2011 (Reference 50). In the fall of 2011, the maker of Extra Strength Tylenol voluntarily changed the labeling for its acetaminophen product from a maximum of 4 g to 3 g/day. The new dosing instructions were developed in an attempt to decrease the incidence of hepatotoxicity secondary to accidental overdoses.

Until late in the spring of 2011, acetaminophen was available in a concentrated solution for young infants (i.e., 100 mg/mL) and in another oral solution for older children (i.e., 32 mg/mL). However, the Consumer Healthcare Products Association released a notice of voluntary removal of the concentrated solution from the market beginning in mid-2011, citing concerns with medication safety of self-care use in the community (Reference 51). In the future, only a single-concentration solution (i.e., 32 mg/mL) will be available. Parents and caregivers of children who receive these products should be educated to use a standardized oral syringe when drawing up and preparing acetaminophen doses for their children because of inaccuracies in parent/caregiver measurement.

Rectal administration of acetaminophen has been used in many different situations for children who may be unable to tolerate oral doses. The recommended doses are found in Table 2. The peak serum concentration is about 2–4 hours (Reference 52). Many sources recommend a loading dose of 20–30 mg/kg/dose to achieve a quicker therapeutic response given that the rectal absorption of this agent is believed to be erratic and slow. Some studies of children in the postoperative period have shown that children may require doses of 25–45 mg/kg to achieve a therapeutic response, but the optimal dosing remains to be determined (Reference 52).

An intravenous formulation of acetaminophen (Ofirmev) has been released. This agent has a U.S. Food and Drug Administration (FDA)-labeled indication for moderate pain and fever in children 2 years and older (Reference 45). Of note, this agent has a quicker onset and higher peak concentration than the oral formulation; however, the total area under the curve is similar to oral administration (Reference 52). Table 2 lists the FDA-labeled dosing. Current studies are investigating the use of this product in children younger than 2 years. In general, the area under the curve of intravenous acetaminophen is higher in this population than in older children and adults. The package insert lists preliminary recommendations for this population, suggesting that a 33% reduction in dose is required for infants to children younger than 2 years, and a 50% reduction in dose is recommended for neonates (Reference 45). Some additional considerations must be noted. A 1000-mg vial of intravenous acetaminophen costs about 10 times as much as oral acetaminophen (Reference 53). Moreover, these vials are intended for single use and short stability after opening (i.e., 6 hours) (Reference 45). Because of these factors, pediatric institutions could experience a significant amount of wastage. Ongoing studies are investigating extended stability with this product. It seems prudent to restrict the use of this product to children who are unable to take anything by mouth for an extended period, patients in the postoperative care setting,

or patients with a contraindication to the rectal administration of medications (i.e., immunocompromised children). In addition, this agent may be considered an alternative to children who have an inadequate response to rectal acetaminophen.

The maximum dosages of acetaminophen products for adults and children are noted in Table 2. The recommendations should especially be noted for children receiving combination opioid analgesic agents because of the propensity for increased hepatic failure with excessive acetaminophen doses. In addition, chronic administration of acetaminophen with doses at or less than the recommended maximum daily doses has been noted to cause hepatotoxicity in healthy adult volunteers (Reference 54).

#### NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The most common NSAIDs used in the emergency department or hospital setting include ibuprofen, naproxen, choline magnesium trisalicylate, and ketorolac. These agents are attractive because they show analgesic and anti-inflammatory activity. Aspirin is classified as an NSAID; however, this agent should generally be avoided for pain in children younger than 12 years because of concerns about the development of Reye syndrome. The common and maximum doses for these agents are shown in Table 2.

Ibuprofen (Caldolor) and ketorolac are the only intravenous NSAIDs with an FDA-labeled indication for pain in the United States. This agent should not be confused with the other salt form, ibuprofen lysine (NeoProfen, Lundbeck, Deerfield, IL), which is indicated for closure of the patent ductus arteriosus. However, there are currently no studies supporting the use of ibuprofen lysine (NeoProfen) for pain in pediatric patients, and this agent does not have an FDA-labeled indication (Reference 55). Ketorolac is approved for children younger than 2 years for single-dose treatment of 0.5 mg/kg/dose intravenously and 1 mg/kg/dose intramuscularly. Few studies have evaluated the efficacy of several doses of intravenous ketorolac. An observational study reports on 112 children ranging in age from 6 months to 19 years who received usual intravenous doses of 0.5-mg/kg/dose (range 0.17–1.0), most often every 6 hours (Reference 56). Another report describes the use of ketorolac in 53 neonates and infants receiving a multiple dosing regimen (Reference 57). The average dosage regimen included a  $0.93 \pm 0.14$  mg/kg loading dose followed by a maintenance regimen of  $0.44 \pm 0.09$  mg/kg/dose every 6–8 hours. Although the authors did not specifically evaluate efficacy given the retrospective nature of the study, they proposed that the agent provided beneficial analgesic effects in these children after cardiac surgery. Of note, this agent has a black box warning and

should not be used for adults or children for more than 5 days because of an increased incidence of adverse events (i.e., gastrointestinal bleeding) (Reference 47).

The NSAIDs are associated with several adverse events that may limit their use in pediatric patients and are associated with an increased incidence of bleeding secondary to their inhibition of platelet aggregation. If a clinician desires to use an NSAID in a patient with thrombocytopenia or increased bleeding, he or she should consider choline magnesium trisalicylate because it has no appreciable effects on platelet aggregation. However, this agent is only available in a liquid preparation, which may not be an acceptable alternative for some patients (Reference 49). Other adverse effects of NSAIDs include nephropathy and gastrointestinal bleeding caused by the inhibition of protective prostaglandins in the kidney and stomach, respectively. Ketorolac has been associated with a significant increase in gastrointestinal bleeding, ulceration, and perforation that appears to be related to duration of therapy and dosing (Reference 47). These agents have been associated with fluid retention and edema, especially in patients with congestive heart failure and cardiac decompensation. However, a recent report suggests this is a safe option in children after cardiac surgery (Reference 57).

Clinicians should consider two other disease states that may preclude the use of NSAIDs. Because NSAIDs inhibit prostaglandin production, children with asthma could experience an increase in leukotriene production, leading to the development of an asthma exacerbation. It is estimated that 2% of children with asthma are intolerant of aspirin, and another 5% of these patients may have a cross-intolerance with other NSAIDs (Reference 58). A diagnosis of asthma alone should not rule out NSAID use in pediatric patients, but this issue does imply that a complete medication history, including a review of allergies, should be taken before an NSAID is prescribed. Another relative precaution of NSAIDs may be for patients with orthopedic injuries. Some animal research suggests that these agents impair bone healing, but there have been conflicting reports in this population (Reference 58). One author recommends that the benefits of these agents outweigh the risk of adverse events, except in patient populations where bone healing may be a significant issue (e.g., patients recovering from posterior or anterior spinal fusions) (Reference 58).

#### *Opioid Analgesics*

##### OVERVIEW

Opioid analgesics represent the mainstay of treatment for moderate to severe pain in children. These agents are available in several different dosage forms. With oral opioids, the onset of activity may be 45 minutes, with peak activity in 1–2 hours (Reference 59). The intravenous

route of administration is favored for patients with an acute onset of severe pain until their pain is under control and for patients unable to take oral medications. Some opioids are available for other routes of administration (e.g., transdermal, oral lozenges); however, these products are generally reserved for chronic pain rather than acute pain.

Overall, the mechanism of opioid analgesia is related to the agonism of  $\mu$ - and  $\kappa$ -receptors. These receptors, which are coupled with guanine-nucleotide-binding protein (G-protein), modulate nerve activity through these G-proteins. Opioids inhibit the transmission of nerve impulses through the ascending pain pathway in the spinal cord and higher levels in the central nervous system. However, opioids have no effect on pain transmission through the peripheral nervous system. Unlike acetaminophen and NSAIDs, opioids are not associated with a ceiling effect. These agents can be titrated on the basis of clinical effect until significant adverse events, including respiratory depression, occur.

Table 3 lists the equianalgesic doses for the opioid agents together with suggested equianalgesic potencies (References 35, 60–67). Of note, there are significant differences between the potency of the opioid agents. Many different sources provide recommendations for various types of equianalgesic conversions. These conversions are based on potency and on pharmacokinetic parameters of acute versus chronic administration. Clinicians should choose one set of opioid equianalgesic conversions that they are familiar with and use it consistently in their practice setting.

#### SPECIFIC AGENTS

Intravenous opioids can be delivered by intermittent bolus, continuous infusion, or PCA. Bolus doses may be effective for patients needing immediate relief of pain, but the bolus dose can also be associated with an increase in adverse events. Intermittent dosing has been associated with inadequate pain control as plasma concentrations decrease between doses (References 68, 69). Continuous infusions are often used in patients requiring more steady-state opioid concentrations. This method of delivery has been found extremely effective in the postoperative setting (References 69, 70). Of note about continuous infusions is that patients may become tolerant of the effects of opioids and may require intermittent bolus doses of opioids over time or before painful procedures. Table 3 lists common doses for opioids delivered as continuous intravenous infusions including morphine, fentanyl, and hydromorphone.

Morphine is one of the most frequently prescribed opioid agents in children. It is available in several dosage forms including oral elixirs, tablets, and sustained-release products. Intravenous morphine is the most common opioid administered for intermittent bolus

dosing. One important consideration about morphine is related to its metabolism. As mentioned previously, morphine is metabolized by glucuronidation to morphine-6-glucuronide (active metabolite) and morphine-3-glucuronide (inactive metabolite). Several studies have shown that morphine continuous infusions are less efficacious in neonates because of a reduced ability to produce the morphine-6-glucuronide metabolite (References 31–33). Thus, some experts recommend against using this agent for continuous intravenous infusions (Reference 32). Morphine is renally eliminated with a half-life from 1 to 3 hours in older infants and children and from 10 to 20 hours in preterm neonates (Reference 35). With these considerations in mind, see the usual dosage recommendations in Table 3.

Morphine produces a significant degree of hypotension that may limit its use. Many different mechanisms for hypotension have been proposed including histamine-mediated vasodilation, negative chronotropic and inotropic effects on the heart, and a decrease in baroreceptor reflex response (Reference 22). This adverse effect has mainly been implicated in patients who are hemodynamically unstable, but it can also occur with all opioids. In addition, the morphine-mediated histamine release may exacerbate episodes of bronchospasm in patients in status asthmaticus (Reference 71). In these cases, it may be prudent to use alternative opioid agents including hydromorphone and fentanyl.

Hydromorphone is a potent opioid available in both oral and intravenous dosage forms. This agent is generally 5 times more potent than morphine. It may be preferred over morphine for intermittent dosing for patients in renal failure because of its decreased amount of metabolites (Reference 22). Hydromorphone has pharmacologic properties similar to morphine. Table 3 lists the common oral, intermittent bolus, and continuous intravenous infusion doses in children.

Fentanyl is a synthetic opioid that is structurally similar to meperidine. In general, it is thought to be 70–100 times more potent for single-dose administration than intravenous morphine. It is more lipophilic than intravenous morphine and has a quicker onset of action, 30 seconds versus 10 minutes (Reference 61). In addition, fentanyl has a short half-life of about 2 hours in children. With the quick onset and short half-life, this agent is very useful for intubation and other procedures including dressing changes and lumbar puncture.

As a continuous infusion, fentanyl has been found to have a “context-sensitive” half-life of 21 hours secondary to its accumulation in peripheral tissue sites (Reference 72). For patients receiving continuous infusions of fentanyl with acute onset of pain, it would be advisable to administer a bolus dose of fentanyl before increasing the rate of the continuous infusion secondary

**Table 3. Opioid Analgesic Agents (Adapted from References 18, 34, 35, 60–67)**

Medication	Equianalgesic Dose		Initial IV Dosages		IV/PO Ratio		Initial PO Dosages	
	IM/IV (mg)	PO (mg)	< 40 kg	≥ 40 kg			< 40 kg	≥ 40 kg
Morphine	10	Acute: 60 Chronic 10	Bolus: 0.05–0.2 mg/kg/dose q2–4h (max 15 mg/dose) CI: 0.01–0.03 mg/kg/h	Bolus: 5–10 mg q2–4h CI: 0.8–1.5 mg/h	Chronic: 1:2.5 Acute: 1:6	0.2–0.5 mg/kg/dose q4–6h IR	10–30 mg q4h IR	
	Hydromorphone	1.5	7.5 Bolus: 0.015 mg/kg/dose q3–6h CI: 0.003–0.005 mg/kg/h	Bolus: 1–2 mg q2–4h CI: 0.3–0.5 mg/h	1:3	0.03–0.08 mg/kg/dose q3–4h (max 5 mg/dose)	2–4 mg q3–4h	
Fentanyl	0.1	—	Bolus: 1–2 mcg/kg/dose q1–2h CI: 1–2 mcg/kg/h	Bolus: 25–100 mcg q1–2h CI: 25–100 mcg/h	—	—	—	
Methadone	Acute: 10 Chronic: 2–4	Acute: 20 Chronic: 2–4	Bolus: NR CI: NR	Bolus: NR CI: NR	Chronic: 1:2.5 Acute: 1:6	0.1 mg/kg/dose q4 × two or three doses; then 0.1 mg/kg/dose q6–12h (max 10 mg/dose)	5–10 mg q4–12h	
	Meperidine	75–100	300 Bolus: 0.75–1 mg/kg/dose q3–4h CI: NR	Bolus: 50–100 mg q3–4h CI: NR	1:3	1–1.5 mg/kg/dose q3–4h	50–150 mg q3–4h	
Codeine <sup>a</sup>	NR	200	NR	NR	NR	0.5–1 mg/kg/dose q4–6h (max 60 mg/dose)	1 or 2 tablets (30 mg of codeine) q4–6h	
Oxycodone <sup>a</sup>	—	15–30	—	—	—	0.05–0.15 mg/kg/dose q4–6h (max of 5 mg/ dose of oxycodone)	1 or 2 tablets (5 mg of oxycodone) q4–6h	
Hydrocodone <sup>a</sup>	—	30–45	—	—	—	0.2 mg/kg/dose q4–6h	1 or 2 tablets (5 mg of hydrocodone) q4–6h	
Tramadol	—	100	—	—	—	—	Immediate-release formulations <sup>b</sup> : 50–100 mg q4–6h (max 400 mg/day) Extended-release formulations <sup>c</sup> : 100 mg/day (max 300 mg/day)	

<sup>a</sup>These opioids are available as an oral combination product with acetaminophen. Clinicians should ensure that patients do not exceed 4 g of acetaminophen per day.

<sup>b</sup>Tramadol is available as an immediate-release tablet (50 mg) as Ultram with an FDA-labeled indication for those 17 years and older for moderate to moderate-severe pain. It is also available as an immediate-release orally disintegrating tablet (50 mg) as Rybix with an FDA-labeled indication for age 16 years and older for postoperation, cancer, neuropathic, and low back pain. It is also available as an oral combination product with acetaminophen (Ultracet) for those 18 years and older for short-term (less than 5 days) acute pain management.

<sup>c</sup>Tramadol is available as an extended-release tablet (100, 200, 300 mg) as Ryzolt with an FDA-labeled indication for those 16 years and older and as Ultram ER for those 18 years and older for moderate to moderate-severe pain. It is also available as an extended-release capsule (100, 200, 300 mg) as Con Zip for those older than 18 years with moderate to moderate-severe pain. CI = continuous intravenous infusion; h = hour(s); IM = intramuscular; IR = immediate-release product; IV = intravenous; NR = not recommended; PO = oral.

to this increased half-life. One adverse event that may limit the use of intermittent doses of fentanyl is chest wall rigidity. A prospective study of 89 premature and term neonates found that the overall incidence was low at 4% (Reference 73). Previous reports have noted that this adverse event occurred with fentanyl doses of 25–50 mcg/kg for patients during anesthetic induction, but this study found that chest rigidity occurred with the rapid administration of doses of 3–5 mcg/kg and greater (Reference 73). Chest wall rigidity can be managed with a dose of intravenous naloxone of 10–40 mcg/kg, administration of a dose of an intravenous neuromuscular blocker before the fentanyl bolus, and/or adjustment of the mechanical ventilator for intubated patients (Reference 73).

Methadone is a long-acting opioid often used for chronic pain, detoxification programs for heroin substance abuse, and treatment of iatrogenic opioid withdrawal in critically ill children. Methadone is metabolized by *N*-demethylation and has an extended half-life of  $19 \pm 14$  hours (range 4–62 hours) in children (Reference 62). It has generally the same potency as morphine, but the peak onset of action for intravenous methadone is 1–2 hours versus 10 minutes for intravenous morphine (Reference 62). Methadone is structurally similar to verapamil and may exert calcium channel blockade (Reference 74). All methadone formulations have been associated with bradycardia, hypotension, and cardiac arrhythmias (Reference 62). One recent report highlighted significant bradycardia with a widened QRS complex in one patient after a methadone continuous intravenous infusion (Reference 74). The rapid administration of an intravenous methadone bolus dose in hemodynamically unstable patients could theoretically increase the likelihood of cardiovascular toxicities. Therefore, clinicians should consider avoiding intravenous methadone administration in children who can tolerate enteral administration of medications.

Meperidine is a synthetic opioid that is less potent, with a shorter duration of action than intravenous morphine. This agent is limited in the acute setting because of adverse events secondary to accumulation of its metabolite, normeperidine (Reference 63). This metabolite is associated with adverse events including seizures, agitation, and hyperreflexia. Risk factors for these adverse events include patients receiving higher doses of meperidine or patients in renal failure (Reference 75). This agent may be reserved for prevention of rigors after the administration of blood products or amphotericin and the treatment of postanesthetic shivering. However, its clinical usefulness for acute pain is limited at best.

Codeine is an opioid available in a combination product for patients with mild to moderate pain. The intravenous route of administration is not routinely recommended secondary to hypotension and vasodilation from histamine release. This agent is metabolized to morphine by cytochrome P450 (CYP) 2D6 and demethylation to morphine (Reference 64). Recent studies suggest that pharmacogenomic differences determine the efficacy of codeine in pain management. One concern is that some children may be “poor metabolizers” because of the decreased activity of the CYP2D6 isoenzyme, resulting in decreased conversion to the active metabolite and decreased analgesic effects (Reference 76). A study investigated the genotype, phenotype, and morphine production in 96 children receiving codeine and diclofenac versus morphine and diclofenac after adenotonsillectomy (Reference 76). The researchers found that 36% of children randomized to codeine and diclofenac had no evidence of conversion to morphine, suggesting these patients have deficiencies in 2D6 isoenzymes. An additional concern is that some patients may be “ultra-fast metabolizers” because of the additional activity of the CYP2D6 isoenzyme, which results in high concentrations of morphine and increased incidence of respiratory depression (Reference 77). Recently, several cases of death in children have been reported because of this pharmacogenomic variation (Reference 78). However, no widespread, clinically useful laboratory test is available to identify these pharmacogenomic variations with the CYP2D6 isoenzyme, and this agent should not be routinely recommended in patients with moderate to severe pain.

Hydrocodone and oxycodone are two other opioids available for oral administration. Structurally, these agents are similar to morphine and are considered more potent than codeine. Oxycodone is the most potent oral opioid agent and is used for moderate to severe pain. Table 3 shows the usual dosage. This agent is available in immediate-release tablets, an oral solution, and a controlled-release product (Reference 65). Hydrocodone is an opioid used for moderate pain control and is available solely in combination products. These combination opioid analgesics are available in oral elixir preparations or tablets (Reference 66). Of note, these agents are typically dosed on a “milligram per kilogram” basis according to the opioid analgesic agent. The FDA has requested that manufacturers of acetaminophen and opioid combination products reduce the acetaminophen content in their dosage forms (Reference 79). Specifically, they have requested that manufacturers reduce the acetaminophen content in these products to 325 mg per tablet, capsule, or other dosage unit to decrease the occurrence of toxicities that have been reported for the past several years.

Despite this change, clinicians should still counsel the parents and guardians of children receiving these medications to halt the use of other acetaminophen-containing products while taking these combination opioid agents.

Tramadol is a centrally acting opiate that binds to  $\mu$ -opiate receptors to inhibit the ascending pain pathway (Reference 67). This agent also has additional activity beyond its effects with the opioid receptor because it inhibits the reuptake of norepinephrine and serotonin. Tramadol may have a role for some types of pain in the adolescent population. It is available in an immediate-release tablet, an immediate-release orally disintegrating tablet, and an extended-release formulation with FDA-labeled indications for children 16 years and older with moderate-severe pain and other types of pain syndromes, including neuropathic and postoperative pain (Table 3). The use of this agent may be limited in children with underlying seizure disorders because of its ability to lower the seizure threshold. Prescribers should avoid using tramadol in children who are receiving concomitant selective serotonin reuptake inhibitors (SSRIs) because of the potential for serotonin syndrome (Reference 18).

Other dosage forms of opioids are currently on the market. Rectal dosage forms are available for morphine. Fentanyl is available in a transdermal patch, an oral transmucosal lozenge, and a buccal tablet. These agents are preferred for patients with chronic cancer pain (References 30, 80). The transmucosal lozenge is generally avoided in most children because there is a risk they could bite down on the lozenge and receive an unintentional bolus of fentanyl. In general, these medications are not used for the management of acute pain and should not be used in patients who are opioid naive or for patients in the postoperative period.

#### ADVERSE EVENTS

Several adverse events have been implicated with opioids, but a complete review of these events is beyond the scope of this chapter. Table 4 provides an overview to managing these adverse events (References 22, 81–83). In general, many of the adverse events can be managed by reducing the opioid dose, switching to another opioid agent, or adding another agent. Respiratory depression may be a specific concern in neonates and infants younger than 6 months because of their decreased renal elimination and hepatic immaturity, and they may be at higher risk of significant adverse events including respiratory depression, apnea, and hypoventilation (References 34, 84). As a result, all infants should receive routine pulse oximetry monitoring when administered opioids. Patients with obstructive sleep apnea or those who are opioid naive may also be at increased risk of respiratory depression

and should be considered for cardiorespiratory monitoring by end-tidal  $\text{CO}_2$  monitoring and/or pulse oximetry (Reference 22).

Other adverse events may be common including constipation, sedation, nausea/vomiting, and pruritus. Of importance, the rate of adverse events depends largely on the agent and dose used for pain control. All patients receiving long-term opioid agents should receive a scheduled bowel regimen to prevent or decrease the incidence of constipation. For patients who are refractory to the first-line agents in Table 4, other alternatives like the addition of low-dose opioid antagonists (e.g., naloxone) have been useful (Reference 22). In patients who experience pruritus, clinicians can consider the administration of oral or intravenous antihistamines to prevent severe itching. One recent review highlighted the potential benefit that opioid antagonists such as low-dose, continuous naloxone infusions may have in patients experiencing a decreased quality of life and comfort associated with profound pruritus (Reference 83). Sedation can be a significant adverse event noted in some patients, especially those with advanced cancer or HIV (human immunodeficiency virus) (Reference 22). In general, sedation can be managed by switching to another opioid agent, but this may not be possible in all patients. Some success has been reported with the use of psychostimulants such as methylphenidate or dextroamphetamine (Reference 22). Clinicians should initiate the lowest dose possible and titrate to effect. Nausea and vomiting can also be a significant complication noted with opioid agents. The addition of antiemetics can be a very helpful strategy to manage this adverse event. Promethazine should be avoided in children younger than 2 years because of the black box warning for respiratory depression in this population. Other alternatives such as 5-HT<sub>3</sub> serotonin receptor antagonists, metoclopramide, and low-dose opioid antagonists may also be useful (Reference 22).

Prolonged use of opioids can also be associated with additional complications that require careful consideration. Some children may experience tolerance; this refers to a decrease in analgesic effect despite a consistent serum plasma opioid concentration (Reference 81). This complication occurs because of cellular changes at the opioid receptor or another receptor distant to it and can be managed by increasing the opioid dose, switching to another agent within its class, or adding another agent to reduce tolerance from occurring (e.g., ketamine, low-dose naloxone) (References 81, 82). In general, patients receiving an extended duration of synthetic opioids like fentanyl are more likely to be at risk because of the higher degree of tolerance associated with these agents versus the tolerance of patients receiving natural opioids like

**Table 4.** Management of Opioid Adverse Events (Adapted from References 22, 81–83)

Adverse Event	First-line Intervention	Alternative Interventions
Respiratory depression	Reduce opioid dose if possible.	Add low-dose opioid antagonist (e.g., naloxone).
Nausea/vomiting	Reduce opioid dose if possible; add antiemetic agent (e.g., promethazine <sup>a</sup> and/or ondansetron).	Add motility agent (e.g., metoclopramide); alternatively, consider use of low-dose opioid antagonist (e.g., naloxone).
Sedation	Add non-opioid analgesic to limit use of opioids or switch to opioid agent.	Reduce opioid dose or add psychostimulant (e.g., methylphenidate).
Constipation	Add stool softener (e.g., docusate) for all patients, together with stimulant laxative (e.g., bisacodyl).	Add an osmotic laxative (e.g., polyethylene glycol) or consider enema; alternatively, consider use of low-dose opioid antagonist (e.g., naloxone).
Pruritus	Switch to a different opioid agent (e.g., fentanyl); add antihistamine (e.g., diphenhydramine, hydroxyzine).	Alternatively, consider use of low-dose opioid antagonist (e.g., naloxone, nalbuphine).
Tolerance	Increase the opioid dose or switch to a longer-acting agent.	Add a non-opioid analgesic or an agent that prevents or delays tolerance (e.g., $\alpha_2$ -agonist, low-dose naloxone).
Withdrawal	Taper opioid dose slowly or add long-acting opioid agonist (e.g., methadone, extended-release morphine).	Add a $\alpha_2$ -agonist (e.g., dexmedetomidine, clonidine) or gabapentin.

<sup>a</sup>Promethazine for children older than 2 years because of the black box warning for respiratory depression in younger children.

morphine (Reference 82). Extended use of opioids can also result in additional complications including psychological dependence, addiction, and physiologic dependence. Psychological dependence refers to the individual's need for a substance to obtain euphoric effects. Addiction refers to an individual's persistent need to obtain an opioid medication for its euphoric effects, which often involves criminal activity to obtain the agent (Reference 81). Addiction and psychological dependence are rare with acute pain and are topics beyond the scope of this chapter.

Physiologic dependence, more commonly known as opioid abstinence syndrome, can also occur in children who are iatrogenically receiving a prolonged duration of opioids. About 35% to 52% of critically ill infants and children develop withdrawal because of receiving long-term opioids in the intensive care unit setting (Reference 85). Opioid abstinence syndrome symptoms fall into three separate categories: central nervous system irritability (e.g., anxiety, agitation, grimacing, sleep disturbance), gastrointestinal dysfunction (e.g., vomiting, diarrhea), and autonomic dysfunction (e.g., tachypnea, diaphoresis, hypertension) (Reference 85). Several agents have been suggested to treat these symptoms, including  $\alpha_2$ -agonists and oral morphine and methadone tapers (Reference 85). It is important for clinicians to have a careful discussion with parents and caregivers to help them

understand that children who are experiencing withdrawal from the acute administration of opioids are unlikely to experience psychological dependence.

For children who are discharged on opioids regardless of the indication, clinicians should perform thorough patient education. Analgesics are considered in the top two classes for medication errors in the pediatric population (Reference 37). Because these agents have many serious adverse events, counseling should include not only a complete review of the agent and indication for use, but also proper instruction on the actual administration of the agent. When possible, all parents and caregivers should be given an oral syringe for children receiving liquid dosage forms of the opioid agents. For patients receiving complex taper schedules, parents/caregivers should be provided a schedule including the date of administration, the times of administration, and both the medication dose (in milligrams) and corresponding volume (in milliliters).

#### ***Patient- and Nurse-Controlled Analgesia***

For children with severe pain, the use of PCA or nurse-controlled analgesia (NCA) can be quite effective. Patients who are administered intravenous intermittent opioid doses can often experience low opioid trough concentrations before their next scheduled dose, leading to increased pain. In addition, the initial administration of a bolus dose can result in an

increased incidence of adverse events such as respiratory depression. With the PCA approach, studies have shown that patients can have similar or even lower pain scores but receive cumulatively fewer opioids than do other children (Reference 22). The PCAs and NCAs involve the use of five components administered through an intravenous delivery pump: initial dose, basal rate, PCA/NCA bolus dose, lockout time between doses (e.g., 5–20 minutes), and maximum opioid dose per hour or per every 4 hours (i.e., depending on the institution's policy) (Reference 86). The three most common agents initiated are morphine, hydromorphone, and fentanyl.

Studies have shown that PCAs can be an effective strategy in children as young as 6 years (Reference 22). Other studies have evaluated the use of PCAs in younger children but have not shown promising results. There have been some concerns that these children may lack the cognitive maturity to understand the relationship between pushing the button on the PCA delivery system and pain relief (Reference 22). Nurse-controlled analgesias can be an alternative for children younger than 6 years, for children with cognitive impairment, or for those who are physically unable to push the button on the delivery system.

In addition to these strategies, parent- or caregiver-controlled analgesia has been suggested for patients with cognitive impairment or for those unable to push the button on the delivery system. This approach is quite controversial and may not be an option at some institutions. Some advocates claim that the parents and caregivers of children know their child better and are thus better able to determine whether they are in pain. This method is thought to benefit children who may be unable to receive prompt attention from their nurse to push the bolus dose on their delivery system in hospitals with a higher patient-to-nurse ratio. The danger with this approach may be of especial concern for children with acute onset of pain who are opiate naive (e.g., postoperative surgery). In such cases, the addition of several bolus doses can result in significant adverse events. As a result, some have restricted the use of this strategy to children with cancer or palliative care and have suggested a thorough education program for parents/caregivers involving pain assessment and an overview of opioids (Reference 22).

### ***Chronic Pain Management***

#### *Overview*

In addition to the acute pain episodes children experience, there are chronic pain conditions in children that require alternative management, including cancer pain and burn pain. Many of these children may also experience concomitant psychiatric illnesses such as

depression, anxiety disorders, and posttraumatic stress disorder that may also affect their pain (Reference 18). Table 5 has some selected adjuvant agents used in the management of chronic pain (References 18, 87–97). Most of the medications do not have an FDA-labeled indication for chronic pain. Dosing information is either extrapolated from adult references, anecdotal case reports, or personal experience. Although these agents are used primarily in the management of chronic pain, the WHO guidelines for pain management clarify that these agents can be used at any stage (i.e., mild, moderate, or severe pain) (Reference 42).

#### *Specific Pain Disorders*

##### NEUROPATHIC PAIN

Neuropathic pain refers to a complex type of chronic pain caused by irregular peripheral and central nervous system activity after the resolution of an injury (e.g., posttraumatic or postsurgical nerve injuries) or inflammatory state (Reference 18). Specific sources of neuropathic pain include solid-organ tumor infiltration of the peripheral nervous system, metabolic disorders, pain after spinal cord injury, and phantom-limb pain (References 18, 22). Adults often present with symptoms including “burning,” “tingling,” and “stabbing” pain after a hypersensitive response to even the slightest of touch to their skin, called allodynia (Reference 22). Young children may have difficulty describing these symptoms. In these cases, additional tests such as quantitative sensory testing can be conducted to detect sensory abnormalities (Reference 22). Some children and adolescents may also experience a specific type of neuropathic pain called complex regional pain syndrome type I, formerly known as reflex sympathetic dystrophy. This condition is characterized by several different symptoms including allodynia, temperature instability, cyanosis, and swelling and is caused by hyperalgesia in a specific body part (e.g., stomach, esophagus) in patients who have not suffered from a specific nerve injury (References 18, 22).

Managing neuropathic pain in children can be very difficult. In general, patients with neuropathic pain will not respond to opioid analgesics. Table 5 lists some of the most common agents used to treat neuropathic pain. In adults, the most common agents used as first-line treatment include tricyclic antidepressants (TCAs) and antiepileptics. This practice has been expanded to the management of neuropathic pain in children. The two most common TCAs used in children are nortriptyline and amitriptyline. These agents may be especially useful for children who may have insomnia because of their sedative effects. In general, nortriptyline may be preferred over amitriptyline in young children because of the commercial availability

**Table 5.** Overview of Adjuvant Analgesic Agents (Adapted from References 87–97)

Medication	Indication	Dosing Formulations	Clinical Pearls
Amitriptyline	Neuropathic pain; adjuvant agent for burn pain	Tablets (10, 25, 50, 75, 100, 150 mg)	Obtain ECG before initiating therapy.
Nortriptyline	Neuropathic pain; adjuvant agent for burn pain	Capsule (10, 25, 50, 75 mg); oral solution (2 mg/mL)	Obtain ECG before initiating therapy; preferred TCA in young children
Gabapentin	Neuropathic pain; adjuvant agent for burn pain	Tablet (600, 800 mg); capsule (100, 300, 400 mg); oral solution (50 mg/mL); extemporaneous suspension (100 mg/mL)	Agent with most evidence in neuropathic pain; wide inter-patient variability in dosing
Topiramate	Neuropathic pain (e.g., trigeminal neuralgia)	Tablet (50 mg); extended-release tablets (100, 200, 300 mg); orally disintegrating tablets (50 mg); extemporaneous solution (5 mg/mL)	Cognitive impairment may limit its use in school-aged children.
Fluoxetine	Miscellaneous chronic pain; concomitant depression and anxiety	Capsule <sup>a</sup> (10, 20, 40 mg); oral solution (4 mg/mL); extemporaneous solution (1 mg/mL)	Monitor for drug interactions; avoid abrupt discontinuation.
Escitalopram	Miscellaneous chronic pain; concomitant depression and anxiety	Tablet (5, 10, 20 mg); oral solution (1 mg/mL)	Monitor for drug interactions; avoid abrupt discontinuation.
Diazepam	Decrease anxiety	Tablets (2, 5, 10 mg); oral solutions (1, 5 mg/mL)	Concentrated diazepam solution contains 19% ethanol; prolonged half-life; relies heavily on hepatic metabolism
Lorazepam	Decrease anxiety	Tablets (0.5, 1, 2 mg); oral solution (2 mg/mL)	Preferred benzodiazepine for acute pain management
Clonidine	Decrease the need for additional opioids; adjuvant agent for burn pain	Tablets (0.1, 0.2, 0.3 mg) <sup>b</sup> ; extended-release tablets (0.1 mg); extemporaneous suspension (0.1 mg/mL)	Must be tapered off before discontinuation to avoid withdrawal symptoms

ECG = electrocardiogram; TCA = tricyclic antidepressant.

<sup>a</sup>Also available in tablets (10, 20 mg) as Sarafem with an FDA-labeled indication for premenstrual dysphoric disorder.

<sup>b</sup>Also available in a 0.1-mg extended-release tablet (Kapvay) for children with ADHD and a 0.17-mg extended-release tablet (Nexiclon XR) and 0.09-mg/mL extended-release oral suspension (Nexiclon XR) with an FDA-labeled indication for hypertension in adults.

of an oral solution. Both of these agents have the potential to cause QT prolongation (References 89, 90). Clinicians should perform a thorough physical and family history for cardiac arrhythmias, heart disease, and syncope before these agents are initiated (Reference 18). A baseline electrocardiogram should be conducted on all children (Reference 22). Additional QT monitoring should be considered in patients who require additional increases in dosing for their pain. Children who develop a corrected QT interval greater than 445 milliseconds should be referred to a pediatric cardiologist (Reference 18). Because of the potential toxic effects of these medications, some experts have suggested that clinicians prescribe no greater than a 30-day supply of them to ensure that only limited

adverse events occur in children who may attempt suicide. When these agents are discontinued, clinicians should gradually taper the doses of the agents to prevent discontinuation syndrome (i.e., symptoms including agitation, sleep disturbances, and gastrointestinal complications) (Reference 18).

Several antiepileptics have been used to treat neuropathic pain. Table 5 lists two antiepileptics that have been used. The most available evidence is with gabapentin, but of note, no randomized controlled trials have compared the use of one antiepileptic over another (Reference 22). Gabapentin has a favorable safety profile with less somnolence than other antiepileptics and is available in different dosage formulations for the pediatric population (Reference 91). One

important consideration with this agent is that the dosing for neuropathic pain is very patient-specific, and it is difficult to make conclusive recommendations on the dosing range for this indication. Topiramate is another antiepileptic that has been used in selected patients with trigeminal neuralgia (Reference 18). One particular concern with this agent is the potential for cognitive impairment. Children with this adverse event may have speech problems, memory difficulties, and significant problems concentrating, rendering this agent not useful for school-aged children (Reference 92). One additional adverse event that should be monitored in patients receiving topiramate is weight loss. This adverse event may be especially difficult in children receiving palliative care who already may have difficulty in receiving adequate nutrition. Other antiepileptics have been used including valproic acid and carbamazepine, but the adverse effect profiles of these agents often limit the routine use for this indication in children (Reference 18).

Other antidepressants may be effective adjuvant agents in children experiencing neuropathic pain. The SSRIs have shown some effect in adults to decrease various types of pain episodes (Reference 18). These agents may be especially useful in children with concomitant anxiety and depression in addition to chronic pain. Table 5 lists two of the SSRIs with an FDA indication for depression in the pediatric population (References 93, 94). Alternatively, venlafaxine and duloxetine have also shown some promise in the management of chronic pain. These agents inhibit the release of norepinephrine and serotonin and may have some direct effect on antagonizing selected pain receptors (Reference 18). In children with chronic pain and concomitant depression, the SSRIs, venlafaxine, and duloxetine may be preferred over TCAs because of the difference in their adverse event profiles. There are special concerns to note, however. Venlafaxine is associated with hypertension and orthostatic hypotension, and for this reason, children receiving this agent should receive routine blood pressure monitoring (Reference 18). The SSRIs may be associated with serotonin syndrome in children receiving concomitant agents such as tramadol and trazodone (Reference 18).

#### CANCER PAIN

Children with cancer experience pain from many different sources. For example, children with a newly diagnosed solid-organ tumor may experience severe pain as a symptom on initial presentation. These tumors can cause significant pain because of infiltration of the viscera, bone, and nerves (Reference 22). Children with hematologic malignancies such as leukemia and lymphoma can also experience infiltration of malignant cells into the viscera and bone marrow and also can present with splenic and

hepatic distention (Reference 22). Other children may experience pain from many different etiologies including severe mucositis, distress from painful diagnostic or therapeutic procedures, or pain associated with metastasis to other organs (e.g., bone, lungs).

Mucositis can be a difficult source of acute but also chronic pain in children with cancer. This complication can occur as the result of high-dose chemotherapy or radiation. A complete review of this topic is beyond the scope of this chapter. In general, the mainstay of treatment is preventive care, with good oral hygiene performed to ensure removal of loose tissue and to keep the mucosa moist. This can be accomplished with saline, chlorhexidine, or hydrogen peroxide mouth rinses (Reference 98). For patients experiencing mild cases of mucositis, treatment involves topical therapies consisting of sucralfate, magnesium hydroxide, and viscous lidocaine (Reference 98). For patients with more profound pain, opioid agents should be considered. In patients undergoing bone marrow transplantation in which mucositis may be a profound problem, children may require the use of PCAs to control their pain (Reference 22).

The management of advanced cancer pain in children is very difficult and involves the use of pharmacologic and nonpharmacologic approaches. In such cases, the goal should be to keep the patient comfortable and optimize their quality of life. The NSAIDs should be initiated for children experiencing bone pain. Choline magnesium trisalicylate should be first-line therapy in children with profound thrombocytopenia. Scheduled opioids should be initiated for severe pain. In children able to take solid dosage forms, sustained-release or extended-release agents should be initiated, together with an immediate-release product for breakthrough pain. Methadone oral solution may be a suitable alternative in children who are unable to swallow tablets because of its long half-life. Transdermal fentanyl may also be an option in children older than 2 years. The doses of these agents should be escalated on the basis of the patient's response, keeping in mind that both tolerance and the disease itself will have a profound impact on a child's opioid requirement. In refractory cases, PCAs should be considered and titrated to effect until these agents can be switched to a more acceptable long-term alternative. Clinicians should keep in mind that the opioid adverse events might be the rate-limiting step in escalating a child's dose. As a result, they should use the strategies listed in Table 4 and consider using an adjuvant agent in Table 5 to reduce the incidence of these adverse events. It has been estimated that 90% of children with advanced cancer will respond to gradual escalation in their opioid therapy (Reference 18). However, another 5% of children may require more than a 100-fold increase in their opioid

dose and the use of alternative approaches to pain management including intrathecal administration of anesthetics and opioids, agents targeted at neuropathic pain (e.g., gabapentin), or sedative agents (Reference 22). Nonpharmacologic interventions such as spiritual care and massage therapy should also be considered for children receiving palliative care.

#### BURN PAIN

Children with burn injuries will also experience both acute and chronic pain. Thermal, electrical, and chemical burns are common in children younger than 10 years (Reference 87). All children with burn injuries will experience pain, no matter the type or severity of the injury. If this pain is untreated in children, they may experience nonadherence to their treatment therapies and have delayed wound healing (Reference 88). They may also develop concomitant psychiatric disease states such as posttraumatic stress disorder because of the untreated pain (Reference 88). Children with acute burn pain may experience background or continuous pain as well as pain associated with procedures (Reference 87). Although the continuous or background pain can be alleviated with scheduled analgesics, the management of procedural pain (e.g., associated with dressing changes) may be difficult to assess. Clinicians may have a difficult time identifying that the procedure itself is a source of a child's pain; thus, many children may have a source of untreated pain during these periods (Reference 88).

Once the burn injuries are healed, children with these injuries may experience chronic pain, often because of neuropathic pain (Reference 88). In such cases, opioid and non-opioid agents will not be entirely effective in diminishing pain. Antidepressants and antiepileptics are useful treatments in these situations. Evidence has suggested that gabapentin has several roles in the management of burn pain. This agent has been shown to decrease the hyperalgesia associated with acute injury and has shown some positive impact in children with neuropathic pain (Reference 87). In addition, gabapentin has been a useful agent to inhibit the management of refractory pruritus in children after burn injuries (Reference 87).

Anxiety can play a major role in the underlying pain that children face after a burn injury. They may especially be anxious before procedures, and treating their anxiety can decrease their anticipatory anxiety before the procedure. Anxiolytic agents have also been shown to reduce opioid requirements and may have a role in decreasing opioid tolerance (Reference 88). As a result, clinicians have often used benzodiazepines as an adjuvant therapy in burn victims. Table 5 lists two specific benzodiazepines used in maintenance therapy. Diazepam has a long and variable half-life in

children that ranges from 15 to 95 hours (Reference 95). It undergoes extensive hepatic metabolism to two active metabolites. Lorazepam has a shorter half-life and is primarily metabolized by glucuronidation to an inactive metabolite (Reference 96). Lorazepam may be preferred to diazepam in patients with burn injuries who may have hepatic or renal insufficiency to avoid the accumulation of active metabolites.

Central  $\alpha_2$ -agonists such as clonidine may also be a useful approach to alleviating acute and chronic pain associated with burn injuries. Children with acute burn injuries may require significant escalation in their opioid doses to achieve analgesic effect because of rapidly developing tolerance. In such cases, patients may develop an increased incidence of adverse events, limiting the utility of opioids for chronic pain (Reference 87). These agents work to augment the descending pain pathway and thus possess anxiolytic, sedative, and analgesic properties (Reference 88). Studies have noted that these agents can have an opioid-sparing effect in certain types of pain episodes (Reference 87). Clonidine is available as an enteral formulation and as a transdermal patch. Of note, this agent can also be compounded as an extemporaneous formulation that can be suitable for young children (Table 5) (Reference 97). The transdermal patch may be suitable in some patients. The lowest dosage form is 0.1 mg, and this dose may exceed the recommended initial dose per kilogram for young children. Some individuals have suggested that these patches be cut into smaller patches; however, this practice is not encouraged because of difficulty in obtaining consistent pharmacokinetic concentrations (Reference 85). Dexmedetomidine is another commercially available  $\alpha_2$ -agonist. This agent is 6–8 times as potent as clonidine; however, it is only available as an intravenous agent and would not be appropriate for long-term administration (Reference 85). Special care must be taken in children who discontinue these agents. Withdrawal symptoms are common and can include rebound hypertension, irritability, and agitation if they are tapered off too quickly (Reference 85).

#### *Procedural Pain Management*

Other non-opioid analgesics may be used for localized administration in children in the emergency department or hospital setting. These agents may be used for many different indications including suture of lacerations, needle procedures, placement of an intravenous line, and prevention of pain associated with laboratory draws (References 99, 100). The following are recommendations for medications for minor procedures and suture/laceration repair in the emergency department and inpatient settings.

### *Lidocaine-Based Agents*

Several lidocaine-based agents have been used for minor procedures for placement of intravenous lines and prevention of pain with blood draws including EMLA, LMX<sub>4</sub>, lidocaine iontophoresis, Synera, and the J-Tip needleless injection system. The drug EMLA (Abraxis Pharmaceutical Products, East Schaumburg, IL) is a eutectic mixture available in a cream formulation of local anesthetics including 2.5% lidocaine and 2.5% prilocaine. This drug is recommended to be applied to a clean, intact area of the skin about ½ inch past the area needed for anesthesia and covered with an occlusive dressing for about 1 hour before venipuncture (Reference 101). This formulation has an FDA-labeled indication with dosing based on age and weight (Reference 102). However, one source notes that the application of EMLA may be necessary for up to 2–3 hours before intramuscular injection for full anesthesia efficacy (Reference 102). Because of the risk of methemoglobinemia, EMLA should be avoided in neonates with a gestational age younger than 37 weeks (Reference 101).

The drug LMX<sub>4</sub> (Ferndale Laboratories, Ferndale, MI) is a 4% topical lidocaine formulation manufactured in an encapsulated lipid layer for greater dermal absorption. It is available over the counter in the United States and is recommended for children 2 years and older (References 102, 103). This product has significant advantages because it is available over the counter for patients with chronic illness who may require frequent trips to the emergency department and because it has a fast onset of activity (i.e., 15–30 minutes for LMX<sub>4</sub> vs. 1 hour for EMLA).

Another formulation that may be used for minor procedures is Numby Stuff (Iomed, Salt Lake City, UT). This product contains 2% lidocaine with 1:100,000 epinephrine, which is delivered through an electrical current called iontophoresis (Reference 104). A prospective randomized trial comparing the use of lidocaine iontophoresis with EMLA in 100 preoperative pediatric patients found a significant difference in the time to accomplish anesthesia, 13 minutes versus 60 minutes ( $p < 0.001$ ) (Reference 105). This product has a faster onset than EMLA and LMX<sub>4</sub> because it achieves anesthesia efficacy 10–20 minutes after administration. In addition, it provides a much broader area of action than EMLA and LMX<sub>4</sub>, with 8–9 mm in duration (Reference 22). Clinicians should note that the Numby Stuff delivery system might be limited in some patients because of discomfort on administration (Reference 106).

Another product, Synera, was recently approved for children 3 years and older for superficial venous access and dermatologic procedures (e.g., shave biopsy of skin and skin excision) (Reference 107). Synera (ZARS Pharma, Salt Lake City, UT) is a combination patch consisting of lidocaine 70 mg and tetracaine 70 mg

(Reference 107). This unique disposable patch is composed of an oxygen-activating system to enhance the absorption of the active ingredients through the stratum corneum. After it is removed from its package, its level of heating reaches a maximum skin temperature of 40°C or less (Reference 108). This agent has an onset time of 20 minutes, and ideally, it should be applied 20–30 minutes before procedures. Of importance, several patches should be applied simultaneously or in immediate succession, and the Synera patch should not be applied to broken or non-intact skin (Reference 107).

In 2001, a needle-free injection of lidocaine, the J-Tip needleless injection system (National Medical Products, Irvine, CA), was introduced to the market. This agent is a disposable, needle-free injection device that uses pressurized carbon dioxide to deliver either 0.25 mL or 0.5 mL of lidocaine into subcutaneous skin (Reference 109). This product, a delivery system, must be filled in the pharmacy with typically 1% to 2% buffered lidocaine powder (Reference 109). The product is operated by pressing the device firmly against the skin where the procedure is to take place. Then, subsequently pressing the lever on the device begins the delivery of the lidocaine within seconds and results in an onset of analgesia in 1–3 minutes (Reference 108).

The American Academy of Pediatrics (AAP) Committee on Pediatric Emergency Medicine and Section on Anesthesiology and Pain Medicine has provided recommendations on the role of selected topical agents for procedural pain (Reference 16). They recommend that EMLA and LMX<sub>4</sub> be used interchangeably in many different settings for painful procedures including lumbar puncture, joint aspiration, and abscess drainage (Reference 16). This committee did not specifically address Numby Stuff, Synera, or the J-Tip needle-free injection system. It is difficult to make evidence-based decisions between these agents because there are few clinical trials comparing them. All of these agents have a different onset of action, a variance in cost, and different delivery mechanisms. For pain prevention with procedures, the committee recommended that the lidocaine-based agents be administered as soon as possible to the affected area to ensure adequate anesthetic effect. One important consideration is that, regardless of the lidocaine-based agent used, it will not provide complete pain relief. Other agents like benzodiazepines and opioids may also have to be administered to complete these procedures. Relative contraindications to the products include allergies to amide anesthetics, non-intact skin, and recent administration of a sulfonamide antibiotic (i.e., EMLA only).

### *Miscellaneous Agents*

For patients requiring other minor procedures including suture and laceration repair, clinicians may use a combination of topical anesthetics/vasoconstrictor combinations

such as lidocaine, epinephrine, and tetracaine (LET). The exact formulation of LET may differ from institution to institution according to the recipe of the pharmacy department in the particular institution. This product has been noted to achieve anesthesia for wound suture repair in 20–30 minutes (Reference 110). The AAP recommends that a maximum dose of 3 mL of LET is indicated for lacerations of the head, neck, extremities, or trunk less than 5 mm in duration. The use of LET is contraindicated in patients who may have an allergy to one of the amide anesthetics, for wounds greater than 5 mm in duration, or for wounds in the ear and genitalia. Of note, the maximum dose of lidocaine administered without epinephrine is 4 mg/kg and, with epinephrine, is 7 mg/kg (Reference 22). Some experts also recommend that intravenous diphenhydramine could be used if a patient receives greater than the maximum dose of lidocaine or LET because of intravenous diphenhydramine's partly local anesthetic effects (Reference 22).

Another unique pharmacologic agent that has been used for minor procedures is vapocoolant spray. This product works by rapidly cooling the skin, with the goal of slowing the initiation and conduction of nerve impulses (Reference 108). Gebauer's Ethyl Chloride (Gebauer's Pain Ease, Cleveland, OH) is recommended for venipuncture and minor procedures (Reference 111). This agent works immediately, but its duration of action is 15 seconds. Gebauer's Pain Ease should be sprayed for 4–10 seconds continuously and at no greater than 7 inches away from the skin (Reference 111). Experts state that if this agent is used, it may take two providers to perform the procedure, with one professional to administer the agent and the other one to perform the procedure (Reference 108). Some children may not tolerate the cooling sensation and may have increased anxiety and perceived pain from the administration of this agent alone. With the availability of other agents for minor procedures, the use of the agents has diminished (Reference 108).

Oral sucrose solutions may be considered for infants for prevention of pain with minor procedures. Sucrose solutions have been associated with a decrease in the production of painful stimuli from heel sticks and venipunctures in neonates (Reference 112). Several institutions have adopted compounded formulations of sucrose. Two commercially available products are available on the market, Sweet-Ease (Children's Medical Ventures, Norwell, MA) and Toot Sweet (Natus Medical, San Carlos, CA). A study found significant analgesic activity with sucrose combined with the use of a pacifier in neonates (Reference 113). Therefore, the AAP recommends that sucrose solutions be administered to infants younger than 6 months and be used in combination with a pacifier and administered no more than 2 minutes before starting a procedure (Reference 16).

## CONCLUSIONS

Pediatric pain management remains a definite challenge for health care professionals. Many differences exist between the assessment and management of pain in children versus adults. Each institution should ensure that pain is assessed on a routine basis with a standardized approach. Several nonpharmacologic interventions are available that should be used in conjunction with pharmacologic treatment. Pharmacists definitely need to be involved in the multidisciplinary pain management in children. As pharmacists, we can play a role in the selection of the appropriate medication for the specific type of pain, monitoring of adverse events, and provision of recommendations for managing these adverse events. In addition, all pharmacists should be involved with the education of parents/caregivers and the patients themselves to ensure that they understand the indication for each pain medication and understand how to safely administer these medications.
